2. Name the default **Screen** control **Source**, add another **Screen** control, and name it **Target**.

3. In **Source**, add a Shape control (such as an arrow), and set its OnSelect property to this formula:

   ```
   Navigate(Target, ScreenTransition.Fade)
   ```

   Want more information about the Navigate function or other functions?

4. In **Target**, add a Shape control (such as an arrow), and set its OnSelect property to this formula:

   ```
   Navigate(Source, ScreenTransition.Fade)
   ```

5. Set the Fill property of **Target** to this formula:

   ```
   If("Red" in ScreenFills.Selected.Value, RGBA(255, 0, 0, 1), RGBA(54, 176, 75, 1))
   ```

6. Select the **Source** screen and then, while holding down the Alt key, select either option in the Radio control, and then select the Shape control.

   Target appears in the color that you selected.

7. In **Target**, select the Shape control to return to **Source**.

8. (optional) Select the other option in the Radio control, and then select the Shape control to confirm that **Target** appears in the other color.

9. (optional) Reorder the screens by hovering over **Target** in the left navigation bar, selecting the ellipsis that appears, and then selecting **Move up**.

   Target appears first when the user opens the app.

Accessibility guidelines

Color contrast

When the **Screen** is the effective background for text, there must be adequate color contrast between:

- Fill and text
- BackgroundImage and text (if applicable)

For example, if a **Screen** contains a Label and the label has transparent fill, then the screen's Fill effectively becomes the background color for the label.

In addition to text, consider checking color contrast with essential graphical objects like the star images in a Rating control.

Screen reader support

- There must be a meaningful name for each **Screen**. The screen name can be viewed and edited in the same way as other controls: in the tree view of the controls pane or in the header of the properties pane.

  > ⓘ Note

When a new **Screen** is loaded, screen readers will announce its name.

Shape and Icon controls in Power Apps

Article • 12/16/2022

Graphics for which you can configure appearance and behavior properties.

Description

These controls include arrows, geometric shapes, action icons, and symbols for which you can configure properties such as fill, size, and location. You can also configure their OnSelect property so that the app responds if the user selects the control.

Key properties (icons and shapes)

Fill – The background color of a control.

OnSelect – Actions to perform when the user selects a control.

Key properties (icons only)

Icon - The type of icon to display (for example, **ArrowDown** or **ShoppingCart**).

Rotation - The number of degrees to rotate the icon.

Color - The color of the icon by name or RGBA values.

Additional properties

AccessibleLabel – Label for screen readers.

DisplayMode – Whether the control allows user input (**Edit**), only displays data (**View**), or is disabled (**Disabled**).

FocusedBorderColor – The color of a control's border when the control is focused.

FocusedBorderThickness – The thickness of a control's border when the control is focused.

Height – The distance between a control's top and bottom edges.

HoverFill – The background color of a control when the user keeps the mouse pointer on it.

PressedBorderColor – The color of a control's border when the user selects that control.

PressedFill – The background color of a control when the user selects that control.

TabIndex – Keyboard-navigation order in relation to other controls.

Visible – Whether a control appears or is hidden.

Width – The distance between a control's left and right edges.

X – The distance between the left edge of a control and the left edge of its parent container (screen if no parent container).

Y – The distance between the top edge of a control and the top edge of the parent container (screen if no parent container).

Related functions

Navigate(*ScreenName*, *ScreenTransition*)

Example

1. Name the default **Screen** control **Target**, add a **Label** control, and set its **Text** property to show **Target**.

   Don't know how to add and configure a control?

2. Add a **Screen** control, and name it **Source**.

3. In **Source**, add a **Shape** control, and set its **OnSelect** property to this formula:

```
Navigate(Target, ScreenTransition.Fade)
```

1. Press F5, and then select the **Shape** control.

   The **Target** screen appears.

2. (optional) Press Esc to return to the default workspace, add a **Shape** control to **Target**, and set the **OnSelect** property of the **Shape** control to this formula:

```
Navigate(Source, ScreenTransition.Fade)
```

Accessibility guidelines

Color contrast

The following applies only to graphics that are used as buttons or are otherwise not just for decoration.

For icons:

- **Color** and **Fill**
- Other standard color contrast requirements apply (if used as a button)

For shapes with borders:

- **BorderColor** and the color outside the control
- **FocusedBorderColor** and the color outside the control (if used as a button)

For shapes without borders:

- **Fill** and the color outside the control
- **PressedFill** and the color outside the control (if used as a button)
- **HoverFill** and the color outside the control (if used as a button)

Screen-reader support

- **AccessibleLabel** must be set for important graphics.
- If the graphic is for decoration or provides redundant information, leave **AccessibleLabel** empty or set it to the empty string "" . Screen readers will ignore these graphics.

For example, you might place a **Lock** icon next to a **Label** that says **This form cannot be modified**. You don't need an **AccessibleLabel** for the icon because the **Label** already explains its meaning.

> **Important**
>
> When **TabIndex** is zero or greater, the icon or shape becomes a button. Its appearance doesn't change, but screen readers will treat it as a button. They will not ignore the control, even if **AccessibleLabel** is empty. When **TabIndex** is less than zero, screen readers treat the icon or shape as an image.

Keyboard support

- **TabIndex** must be zero or greater if the graphic is used as a button. Keyboard users can then navigate to it.
- Focus indicators must be clearly visible if the graphic is used as a button. Use **FocusedBorderColor** and **FocusedBorderThickness** to achieve this result.

Slider control in Power Apps

Article • 12/16/2022

A control with which the user can specify a value by dragging a handle.

Description

The user can indicate a value, between a minimum and a maximum value that you specify, by dragging the handle of a slider left-right or up-down, depending on the direction that you choose.

Key properties

Default – The initial value of a control before it is changed by the user.

Max – The maximum value to which the user can set a slider or a rating.

Min – The minimum value to which the user can set a slider.

Value – The value of an input control.

Additional properties

AccessibleLabel – Label for screen readers.

BorderColor – The color of a control's border.

BorderStyle – Whether a control's border is **Solid**, **Dashed**, **Dotted**, or **None**.

BorderThickness – The thickness of a control's border.

DisplayMode – Whether the control allows user input (**Edit**), only displays data (**View**), or is disabled (**Disabled**).

DisabledBorderColor – The color of a control's border if the control's DisplayMode property is set to **Disabled**.

FocusedBorderColor – The color of a control's border when the control is focused.

FocusedBorderThickness – The thickness of a control's border when the control is focused.

HandleActiveFill – The color of the handle for a slider as the user changes its value.

HandleFill – The color of the handle (the element that changes position) in a toggle or slider control.

HandleHoverFill – The color of the handle in a slider when the user keeps the mouse pointer on it.

HandleSize – The diameter of the handle.

Height – The distance between a control's top and bottom edges.

HoverBorderColor – The color of a control's border when the user keeps the mouse pointer on that control.

Layout – Whether the user scrolls through a gallery or adjusts a slider top to bottom (**Vertical**) or left to right (**Horizontal**).

OnChange – Actions to perform when the user changes the value of a control (for example, by adjusting a slider).

OnSelect – Actions to perform when the user taps or clicks a control.

PressedBorderColor – The color of a control's border when the user taps or clicks that control.

RailFill – The background color of the rectangle in a toggle control when its value is **false** or the color of the line to the right of the handle in a slider control.

RailHoverFill – When you hover on a toggle control or a slider, the background color of the rectangle in a toggle control when its value is **false** or the color of the line to the right of the handle in a slider control.

ReadOnly – Whether a user can change the value of a slider or rating control.

Reset – Whether a control reverts to its default value.

ShowValue – Whether a slider's or rating's value appears as the user changes that value or hovers over the control.

TabIndex – Keyboard navigation order in relation to other controls.

Tooltip – Explanatory text that appears when the user hovers over a control.

ValueFill – The background color of the rectangle in a toggle control when its value is **true** or the color of the line to the left of the handle in a slider control.

ValueHoverFill – When you keep the mouse pointer on a toggle control or a slider, the background color of the rectangle in a toggle control when its value is **true** or the color

of the line to the left of the handle in a slider control.

Visible – Whether a control appears or is hidden.

Width – The distance between a control's left and right edges.

X – The distance between the left edge of a control and the left edge of its parent container (screen if no parent container).

Y – The distance between the top edge of a control and the top edge of the parent container (screen if no parent container).

Related functions

Sum(*Value1*, *Value2*)

Example

1. Add a button, and set its **OnSelect** property to this formula:
   ClearCollect(CityPopulations, {City:"London", Country:"United Kingdom", Population:8615000}, {City:"Berlin", Country:"Germany", Population:3562000}, {City:"Madrid", Country:"Spain", Population:3165000}, {City:"Rome", Country:"Italy", Population:2874000}, {City:"Paris", Country:"France", Population:2273000}, {City:"Hamburg", Country:"Germany", Population:1760000}, {City:"Barcelona", Country:"Spain", Population:1602000}, {City:"Munich", Country:"Germany", Population:1494000}, {City:"Milan", Country:"Italy", Population:1344000})

   Don't know how to add, name, and configure a control?

   Want more information about the **ClearCollect** function or other functions?

2. Press F5, select the button, and then press Esc.

3. Add a slider, move it below the button, and name the slider **MinPopulation**.

4. Set the slider's **Max** property to **5000000** and its **Min** property to **1000000**.

5. Add a text gallery in vertical/portrait orientation, move it below the slider, and set the gallery's **Items** property to this formula:
   Filter(CityPopulations, Population > MinPopulation)

6. In the first item of the gallery, set the **Text** property of the top label to **ThisItem.City**, and set the **Text** property of the bottom label to this formula:

Text(ThisItem.Population, "##,###")

7. Press F5, and then adjust **MinPopulation** to show only those cities that have a population that's greater than the value that you specify.

8. To return to the default workspace, press Esc.

Accessibility guidelines

Color contrast

There must be adequate color contrast between:

- **ValueFill** and **RailFill**
- **ValueHoverFill** and **RailHoverFill**
- FocusedBorderColor and color outside the control
- **ValueFill** and background color
- **RailFill** and background color
- **ValueHoverFill** and background color
- **RailHoverFill** and background color

Screen reader support

- AccessibleLabel must be present.

Keyboard support

- TabIndex must be zero or greater so that keyboard users can navigate to it.
- Focus indicators must be clearly visible. Use FocusedBorderColor and FocusedBorderThickness to achieve this.
- Slider value must be shown when interacting with the keyboard. This can be achieved by any one of these methods:
  - Set **ShowValue** to **true**.
  - Add a Label adjacent to the slider. Set the label's Text to the slider's Value.

Label control in Power Apps

Article • 12/16/2022

A box that shows data such as text, numbers, dates, or currency.

Description

A label shows data that you specify as a literal string of text, which appears exactly the way you type it, or as a formula that evaluates to a string of text. Labels often appear outside of any other control (such as a banner that identifies a screen), as a label that identifies another control (such as a rating or audio control), or in a gallery to show a specific type of information about an item.

Key properties

AutoHeight – Set to true to allow the label to auto-grow its height to show all text. Set to false to truncate the text to the height assigned.

Color – The color of text in a control.

Font – The name of the family of fonts in which text appears.

Text – Text that appears on a control or that the user types into a control.

DelayOutput – Set to true to delay action during text input.

Additional properties

Align – The location of text in relation to the horizontal center of its control.

AutoHeight – Whether a label automatically increases its **Height** property if its **Text** property contains more characters than the control can show at one time.

BorderColor – The color of a control's border.

BorderStyle – Whether a control's border is **Solid**, **Dashed**, **Dotted**, or **None**.

BorderThickness – The thickness of a control's border.

DisplayMode – Whether the control allows user input (**Edit**), only displays data (**View**), or is disabled (**Disabled**).

DisabledBorderColor – The color of a control's border if the control's DisplayMode property is set to **Disabled**.

DisabledColor – The color of text in a control if its DisplayMode property is set to **Disabled**.

DisabledFill – The background color of a control if its DisplayMode property is set to **Disabled**.

Fill – The background color of a control.

FocusedBorderColor – The color of a control's border when the control is focused.

FocusedBorderThickness – The thickness of a control's border when the control is focused.

FontWeight – The weight of the text in a control: **Bold**, **Semibold**, **Normal**, or **Lighter**.

Height – The distance between a control's top and bottom edges.

HoverBorderColor – The color of a control's border when the user keeps the mouse pointer on that control.

HoverColor – The color of the text in a control when the user keeps the mouse pointer on it.

HoverFill – The background color of a control when the user keeps the mouse pointer on it.

Italic – Whether the text in a control is italic.

LineHeight – The distance between, for example, lines of text or items in a list.

Live – How a screen reader announces changes to the value of the label's **Text** property.

- When set to **Off**, the screen reader doesn't announce changes.
- When set to **Polite**, the screen reader finishes speaking before announcing any changes that occurred while the screen reader was speaking.
- When set to **Assertive**, the screen reader interrupts itself to announce any changes that occurred while the screen reader was speaking.

OnSelect – Actions to perform when the user taps or clicks a control.

Overflow – Whether a scrollbar appears in a label if its **Wrap** property is set to **true** and the value of the control's Text property contains more characters than the control can show at one time.

PaddingBottom – The distance between text in a control and the bottom edge of that control.

PaddingLeft – The distance between text in a control and the left edge of that control.

PaddingRight – The distance between text in a control and the right edge of that control.

PaddingTop – The distance between text in a control and the top edge of that control.

PressedBorderColor – The color of a control's border when the user taps or clicks that control.

PressedColor – The color of text in a control when the user taps or clicks that control.

PressedFill – The background color of a control when the user taps or clicks that control.

Role - The semantic role of the label text, such as Heading 1. Doesn't change the style of the label but makes the output semantically correct for interpretation by screen readers.

Size – The font size of the text that appears on a control.

Strikethrough – Whether a line appears through the text that appears on a control.

TabIndex – Keyboard navigation order in relation to other controls.

Tooltip – Explanatory text that appears when the user hovers over a control.

Underline – Whether a line appears under the text that appears on a control.

VerticalAlign – The location of text on a control in relation to the vertical center of that control.

Visible – Whether a control appears or is hidden.

Width – The distance between a control's left and right edges.

Wrap – Whether the text should ever wrap to multiple lines.

X – The distance between the left edge of a control and the left edge of its parent container (screen if no parent container).

Y – The distance between the top edge of a control and the top edge of the parent container (screen if no parent container).

Related functions

Text(*Number*, "*FormatCodes*")

Examples

Show a literal string

- Add a label, and set its **Text** property to **"Hello, world"** (including the double quotation marks).

  Don't know how to add and configure a control?

Show the result of a formula

- Add a label, and set its **Text** property to a formula such as this one:
  Today()

  > ⓘ **Note**
  >
  > When you specify a formula, you don't use quotation marks unless an argument of the formula is a literal string. In that case, enclose the argument, not the formula, in double quotation marks.

  Want more information about the **Today** function or other functions?

Show data in a gallery

In this procedure, you'll create a collection, called **CityPopulations**, that contains data about the population of various cities in Europe. Next, you'll show that data in a gallery that contains three labels, and you'll specify the type of data that each label will show.

1. Add a button, and set its **OnSelect** property to this formula:
   ClearCollect(CityPopulations, {City:"London", Country:"United Kingdom", Population:8615000}, {City:"Berlin", Country:"Germany", Population:3562000}, {City:"Madrid", Country:"Spain", Population:3165000}, {City:"Rome", Country:"Italy", Population:2874000}, {City:"Paris", Country:"France", Population:2273000}, {City:"Hamburg", Country:"Germany", Population:1760000}, {City:"Barcelona", Country:"Spain", Population:1602000}, {City:"Munich", Country:"Germany", Population:1494000}, {City:"Milan", Country:"Italy", Population:1344000})

2. Press F5, select the button, and then press Esc.
3. Add a text gallery, and set its **Items** property to **CityPopulations**.

   When the gallery is selected, the right pane shows options for that gallery.
4. In the **Gallery1** pane, set the top list to **Population**, set the middle list to **City**, and set the bottom list to **Country**.

Accessibility guidelines

Despite its name, a **Label** control does not have to be used as a label for another control. It can be used to display any piece of text.

A **Label** can be used as a button or link by specifying **OnSelect** behavior. When used this way, there are similar accessibility considerations as with buttons.

Color contrast

There must be adequate color contrast between:

- **Color** and **Fill**
- Other standard color contrast requirements apply (if used as a button or link)

Screen-reader support

- **Text** must be present.
- **Live** should be set to **Polite** or **Assertive** if a screen reader should announce changes to the value of the **Text** property.

  > ⓘ **Note**
  >
  > Screen readers will treat **Label**s as buttons when **TabIndex** is zero or greater.

Low vision support

- **Label** should look like a link, if it is used as a link.
  - Set **Underline** to **true**
  - **HoverColor** should be different from **Color**

Keyboard support

- **TabIndex** must be zero or greater, if the text is used as a button or link. This allows keyboard users to navigate to it.
- Focus indicators must be clearly visible, if the text is used as a button or link. Use **FocusedBorderColor** and **FocusedBorderThickness** to achieve this.

Text input control in Power Apps

Article • 12/16/2022

A box in which the user can type text, numbers, and other data.

Description

The user can specify data by typing into a text-input control. Depending on how you configure the app, that data might be added to a data source, used to calculate a temporary value, or incorporated in some other way.

Key properties

Default – The initial value of a control before it is changed by the user.

Text – Text that appears on a control or that the user types into a control.

Additional properties

AccessibleLabel – Label for screen readers.

Align – The location of text in relation to the horizontal center of its control.

BorderColor – The color of a control's border.

BorderStyle – Whether a control's border is **Solid**, **Dashed**, **Dotted**, or **None**.

BorderThickness – The thickness of a control's border.

Clear – Whether a text-input control shows an "X" that the user can tap or click to clear the contents of that control. Only works in **SingleLine** mode.

Color – The color of text in a control.

DelayOutput – When set to true, user input is registered after half a second delay. Useful for delaying expensive operations until user completes inputting text (i.e. for filtering when input is used in other formulas).

DisplayMode – Whether the control allows user input (**Edit**), only displays data (**View**), or is disabled (**Disabled**).

DisabledBorderColor – The color of a control's border if the control's DisplayMode property is set to **Disabled**.

DisabledColor – The color of text in a control if its DisplayMode property is set to **Disabled**.

DisabledFill – The background color of a control if its DisplayMode property is set to **Disabled**.

EnableSpellCheck – Whether a text-input control should use the browser spell check function. Power Apps for Windows doesn't support this property.

Fill – The background color of a control.

FocusedBorderColor – The color of a control's border when the control is focused.

FocusedBorderThickness – The thickness of a control's border when the control is focused.

Font – The name of the family of fonts in which text appears.

FontWeight – The weight of the text in a control: **Bold**, **Semibold**, **Normal**, or **Lighter**.

Format – Whether the user input is restricted to numbers only or can be any text. When set to **Number**, only digits and certain numeric symbols can be entered. Supported symbols and formats depend on the browser language and cannot be set on individual controls.

Height – The distance between a control's top and bottom edges.

HintText – Light-grey text that appears in an input-text control if it's empty.

HoverBorderColor – The color of a control's border when the user keeps the mouse pointer on that control.

HoverColor – The color of the text in a control when the user keeps the mouse pointer on it.

HoverFill – The background color of a control when the user keeps the mouse pointer on it.

Italic – Whether the text in a control is italic.

LineHeight – The distance between, for example, lines of text or items in a list.

MaxLength – The number of characters that the user can type into a text-input control.

Mode – The control is in **SingleLine**, **MultiLine**, or **Password** mode.

OnChange – Actions to perform when the user changes the value of a control (for example, by adjusting a slider).

OnSelect – Actions to perform when the user taps or clicks a control.

PaddingBottom – The distance between text in a control and the bottom edge of that control.

PaddingLeft – The distance between text in a control and the left edge of that control.

PaddingRight – The distance between text in a control and the right edge of that control.

PaddingTop – The distance between text in a control and the top edge of that control.

PressedBorderColor – The color of a control's border when the user taps or clicks that control.

PressedColor – The color of text in a control when the user taps or clicks that control.

PressedFill – The background color of a control when the user taps or clicks that control.

RadiusBottomLeft – The degree to which the bottom-left corner of a control is rounded.

RadiusBottomRight – The degree to which the bottom-right corner of a control is rounded.

RadiusTopLeft – The degree to which the top-left corner of a control is rounded.

RadiusTopRight – The degree to which the top-right corner of a control is rounded.

Reset – Whether a control reverts to its default value.

Size – The font size of the text that appears on a control.

Strikethrough – Whether a line appears through the text that appears on a control.

TabIndex – Keyboard navigation order in relation to other controls.

Tooltip – Explanatory text that appears when the user hovers over a control.

Underline – Whether a line appears under the text that appears on a control.

VirtualKeyboardMode – Type of virtual keyboard, text or numeric, that appears on an app user's touch screen. The **Format** property determines the default value. Device support varies. Devices that are running iOS must have at least version 12.2. The

recommended version of Android is 9.0, and capabilities of numeric keyboards vary for Android devices. Windows 10 doesn't support this property.

Visible – Whether a control appears or is hidden.

Width – The distance between a control's left and right edges.

X – The distance between the left edge of a control and the left edge of its parent container (screen if no parent container).

Y – The distance between the top edge of a control and the top edge of the parent container (screen if no parent container).

DateTimeValue(*String*)

Examples

Collect data

1. Add two text-input controls, and name them **inputFirst** and **inputLast**.

   Don't know how to add, name, and configure a control?

2. Add a button, set its **Text** property to **Add**, and set its **OnSelect** property to this formula:
   Collect(Names, {FirstName:inputFirst.Text, LastName:inputLast.Text})

   Want more information about the **Collect** function or other functions?

3. Add a text gallery in portrait/vertical orientation, set its **Items** property to **Names**, and set the **Text** property of **Subtitle1** to **ThisItem.FirstName**.

4. (optional) In the template gallery, delete the bottom label, named **Body1**, and set the **TemplateSize** property of the gallery to **80**.

5. Press F5, type a string of text into **inputFirst** and **inputLast**, and then click or tap the **Add** button.

6. (optional) Add more names to the collection, and then press Esc to return to the default workspace.

Prompt for a password

1. Add a text-input control, name it **inputPassword**, and set its **Mode** property to **Password**.

2. Add a label, and set its **Text** property to this formula:
   If(inputPassword.Text = "P@ssw0rd", "Access granted", "Access denied")

   Want more information about the **If** function or other functions?

3. Press F5, and then type **P@ssw0rd** in **inputPassword**.

   When you finish typing the password, the label stops showing **Access denied** and starts to show **Access granted**.

4. To return to the default workspace, press Esc.

5. (optional) Add a control such as an arrow, configure it to navigate to another screen, and show it only after the user types the password.

6. (optional) Add a button, configure its **Text** property to show **Sign in**, add a timer, and disable the input-text control for a certain amount of time if the user types the wrong password and then clicks or taps the **Sign in** button.

Accessibility guidelines

Color contrast

- Standard color contrast requirements apply.

Screen reader support

- **AccessibleLabel** must be present.

Keyboard support

- **TabIndex** must be zero or greater so that keyboard users can navigate to it.
- Focus indicators must be clearly visible. Use **FocusedBorderColor** and **FocusedBorderThickness** to achieve this.

Timer control in Power Apps

Article • 12/16/2022

A control that can determine how your app responds after a certain amount of time passes.

Description

Timers can, for example, determine how long a control appears or change other properties of a control after a certain amount of time has passed.

> ⓘ **Note**
>
> In Power Apps Studio, timers run only in Preview mode.

Key properties

Duration – How long a timer runs in milliseconds. The maximum is 24 hours expressed in milliseconds. Default is 60 seconds.

OnTimerEnd – Actions to perform when a timer finishes running.

Repeat – Whether a timer automatically restarts when it finishes running.

Additional properties

Align – The location of text in relation to the horizontal center of its control.

AutoPause – Whether the timer control automatically pauses if the user navigates to a different screen.

AutoStart – Whether the timer control automatically starts to play when the user navigates to the screen that contains that control.

BorderColor – The color of a control's border.

BorderStyle – Whether a control's border is **Solid**, **Dashed**, **Dotted**, or **None**.

BorderThickness – The thickness of a control's border.

Color – The color of text in a control.

DisplayMode – Whether the control allows user input (**Edit**), only displays data (**View**), or is disabled (**Disabled**).

DisabledBorderColor – The color of a control's border if the control's DisplayMode property is set to **Disabled**.

DisabledColor – The color of text in a control if its DisplayMode property is set to **Disabled**.

DisabledFill – The background color of a control if its DisplayMode property is set to **Disabled**.

Fill – The background color of a control.

FocusedBorderColor – The color of a control's border when the control is focused.

FocusedBorderThickness – The thickness of a control's border when the control is focused.

Font – The name of the family of fonts in which text appears.

FontWeight – The weight of the text in a control: **Bold**, **Semibold**, **Normal**, or **Lighter**.

Height – The distance between a control's top and bottom edges.

HoverBorderColor – The color of a control's border when the user keeps the mouse pointer on that control.

HoverColor – The color of the text in a control when the user keeps the mouse pointer on it.

HoverFill – The background color of a control when the user keeps the mouse pointer on it.

Italic – Whether the text in a control is italic.

OnSelect – Actions to perform when the user taps or clicks a control.

OnTimerStart – Actions to perform when a timer starts to run.

PressedBorderColor – The color of a control's border when the user taps or clicks that control.

PressedColor – The color of text in a control when the user taps or clicks that control.

PressedFill – The background color of a control when the user taps or clicks that control.

Reset – Whether a control reverts to its default value.

Size – The font size of the text that appears on a control.

Start – Whether the timer starts.

Strikethrough – Whether a line appears through the text that appears on a control.

TabIndex – Keyboard navigation order in relation to other controls.

Text – Text that appears on a control or that the user types into a control.

Tooltip – Explanatory text that appears when the user hovers over a control.

Underline – Whether a line appears under the text that appears on a control.

Visible – Whether a control appears or is hidden.

Width – The distance between a control's left and right edges.

X – The distance between the left edge of a control and the left edge of its parent container (screen if no parent container).

Y – The distance between the top edge of a control and the top edge of the parent container (screen if no parent container).

Related functions

Refresh(*DataSource*)

Examples

Show a countdown

1. Add a timer, and name it **Countdown**.

   Don't know how to add, name, and configure a control?

2. Set the timer's **Duration** property to **10000** and its **Repeat** and **Autostart** properties to **true**.

3. (optional) Make the timer easier to read by setting its **Height** property to **160**, its **Width** property to **600**, and its **Size** property to **60**.

4. Add a label, and set its **Text** property to this formula:
   "Number of seconds remaining: " & RoundUp(10-Countdown.Value/1000, 0)

Want more information about the **RoundUp** function or other functions?

The label shows how many seconds remain before the timer restarts.

Animate a control

1. Add a timer, and name it **FadeIn**.

   Don't know how to add, name, and configure a control?

2. Set the timer's **Duration** property to **5000**, its **Repeat** property to **true**, and its **Text** property to **Toggle animation**.

3. (optional) Make the timer easier to read by setting its **Height** property to **160**, its **Width** property to **600**, and its **Size** property to **60**.

4. Add a label, set its **Text** property to show **Welcome!** and set its **Color** property to this formula:
   ColorFade(Color.BlueViolet, FadeIn.Value/5000)

   Want more information about the **ColorFade** function or other functions?

5. Select the timer button to start or stop the animation. The text in the label fades to white, returns to full intensity, and repeats the process.

Accessibility guidelines

The same guidelines for the **Button** control apply to the **Timer** control if users can interact with it.

Background timers

Background timers run automatically and are hidden. Use them in a supporting role where the elapsed time is of little interest to the user. For example, you can refresh data every minute or show a notification message only for a certain amount of time.

Background timers should have their **Visible** property set to false so that they are hidden from all users.

Timing considerations

If a **Timer** runs automatically, consider whether users have enough time to read and use content. Keyboard and screen-reader users may need more time to react to a timed

event.

Any of these strategies is sufficient:

- Allow users to cancel the timed event.
- Allow users to adjust the time limit before it begins.
- Warn 20 seconds before the time limit expires and provide an easy way to extend the limit.

Some scenarios are exempt from these requirements. Learn more in the WCAG 2.0 guideline for time limits.

Screen reader support

- If a timer triggers changes on the current screen, use a live region to tell screen-reader users what changed.

  > **Note**
  >
  > If the timer is visible and running, screen readers will announce the elapsed time every five seconds.

- Don't use the **Text** property of a control for time-sensitive and important information. Screen readers won't announce changes to **Text**.

- For interactive timers:
  - **Text** must be present.
  - Consider adding a **Label** control to show the elapsed time. Use the timer's **Text** property to instruct the user to start or stop the timer.

Toggle control in Power Apps

Article • 12/16/2022

A control that the user can turn on or off by moving its handle.

Description

A toggle is designed for recent GUIs but behaves the same way as a check box.

Key properties

Default – The initial value of a control before it is changed by the user.

Value – The value of an input control.

Additional properties

AccessibleLabel – Label for screen readers.

BorderColor – The color of a control's border.

BorderStyle – Whether a control's border is **Solid**, **Dashed**, **Dotted**, or **None**.

BorderThickness – The thickness of a control's border.

DisplayMode – Whether the control allows user input (**Edit**), only displays data (**View**), or is disabled (**Disabled**).

DisabledBorderColor – The color of a control's border if the control's DisplayMode property is set to **Disabled**.

FalseFill – The toggle fill color when the toggle is off.

FalseHoverFill – The toggle hover fill color when toggle is off.

FalseText – The text shown when the toggle is off.

Fill – The background color of a control.

FocusedBorderColor – The color of a control's border when the control is focused.

FocusedBorderThickness – The thickness of a control's border when the control is focused.

HandleFill – The fill color of the toggle handle.

Height – The distance between a control's top and bottom edges.

HoverBorderColor – The color of a control's border when the user keeps the mouse pointer on that control.

OnChange – Actions to perform when the user changes the value of a control (for example, by adjusting a slider).

OnCheck – Actions to perform when the value of a checkbox or a toggle changes to **true**.

OnSelect – Actions to perform when the user taps or clicks a control.

OnUncheck – Actions to perform when the value of a checkbox or a toggle changes to **false**.

PressedBorderColor – The color of a control's border when the user taps or clicks that control.

RailFill – The background color of the rectangle in a toggle control when its value is **false** or the color of the line to the right of the handle in a slider control.

RailHoverFill – When you hover on a toggle control or a slider, the background color of the rectangle in a toggle control when its value is **false** or the color of the line to the right of the handle in a slider control.

Reset – Whether a control reverts to its default value.

ShowLabel – Whether a text label is shown beside the toggle control.

TabIndex – Keyboard navigation order in relation to other controls.

TextPosition – Whether the label is to the left or the right of the toggle control.

Tooltip – Explanatory text that appears when the user hovers over a control.

TrueFill – Toggle fill color when the toggle is on.

TrueHoverFill – Toggle hover fill color when the toggle is on.

TrueText – Text shown when the toggle is on.

ValueFill – The background color of the rectangle in a toggle control when its value is **true** or the color of the line to the left of the handle in a slider control.

ValueHoverFill – When you keep the mouse pointer on a toggle control or a slider, the background color of the rectangle in a toggle control when its value is **true** or the color of the line to the left of the handle in a slider control.

Visible – Whether a control appears or is hidden.

Width – The distance between a control's left and right edges.

X – The distance between the left edge of a control and the left edge of its parent container (screen if no parent container).

Y – The distance between the top edge of a control and the top edge of the parent container (screen if no parent container).

Related functions

If(*Condition*, *Result*)

Example

1. Add a toggle, and name it **MemberDiscount**.

   Don't know how to add, name, and configure a control?

2. Add a label, and set its **Text** property to this formula:
   If(MemberDiscount.Value = true, "Price: $75", "Price: $100")

   Want more information about the **If** function or other functions?

3. Press F5, and change the value of **MemberDiscount**.

   The label shows a different price, depending on whether **MemberDiscount** is on or off.

4. To return to the default workspace, press Esc.

Accessibility guidelines

Color contrast

There must be adequate color contrast between:

- **HandleFill** and **FalseFill**

- **HandleFill** and **FalseHoverFill**
- **HandleFill** and **TrueFill**
- **HandleFill** and **TrueHoverFill**
- **FalseFill** and color outside the control
- **FalseHoverFill** and color outside the control
- **TrueFill** and color outside the control
- **TrueHoverFill** and color outside the control

This is in addition to the standard color contrast requirements.

Screen reader support

- **AccessibleLabel** must be present.
- **FalseText** must be present.
- **TrueText** must be present.

Low vision support

- Consider setting **ShowLabel** to **true** so that users can quickly determine the toggle value.

Keyboard support

- **TabIndex** must be zero or greater so that keyboard users can navigate to it.
- Focus indicators must be clearly visible. Use **FocusedBorderColor** and **FocusedBorderThickness** to achieve this.

Vertical container control in Power Apps

Article • 03/23/2023

Vertical container control determines the position of the child components so that you never have to set X, Y for a component inside the container.

Description

Vertical container control distributes the available space to its child components based on the settings, as well as determines alignment of the child components.

Properties

BorderColor – The color of a control's border.

BorderStyle – Whether a control's border is **Solid**, **Dashed**, **Dotted**, or **None**.

BorderThickness – The thickness of a control's border.

Color - The color of the container control.

Drop shadow - Adds shadow effects around the control.

Fill – The background color of a control.

Height – The distance between a control's top and bottom edges.

Direction - Defines in what direction the container layouts its child components. **Horizontal** and **Vertical**.

Justify (vertical) - Defines how child elements are aligned with the primary axis. **Start**, **End**, **Center**, **Space Between**.

Align (horizontal) - Defines how child components are positioned in the container, in the off axis (opposite from `LayoutDirection`). **Start**, **Center**, **End**, **Stretch**.

Gap - Defines the space between containers child components in pixels.

Horizontal Overflow - Defines whether the container shows scrollbars or remove content when it is too large to fit. **Scroll** and **Hide**.

RadiusBottomLeft – The degree to which the bottom-left corner of a control is rounded.

RadiusBottomRight – The degree to which the bottom-right corner of a control is rounded.

RadiusTopLeft – The degree to which the top-left corner of a control is rounded.

RadiusTopRight – The degree to which the top-right corner of a control is rounded.

Vertical Overflow - Defines whether the container shows scrollbars or remove content when it is too large to fit. **Scroll** and **Hide**.

Wrap - Defines whether the content wraps to a new row or column when it cannot fit.

Align in container - Defines how the individual component is aligned to the parent. The default value, **Set by container**, inherits the value from the parent's `LayoutAlignItems` property, while other properties can be used to customize the alignment for the individual child component. **Set by container**, **Start**, **End**, **Center**, and **Stretch**.

Fill portions - Defines how the individual component grows when there is more screen real-estate assigned to its parent. The number represents the portion of the extra space given to the component out of all the available extra space claimed by children of its parent. For example, if child A has `Fill portions` set to 1 and child B has `Fill portions` set to 2, child A gets 1/3 of the extra space available while child B gets 2/3 of the extra available space.

Minimum width - Represent the minimum size of the component in the direction of the `Fill portions` (that is, the parent's `Direction`).

PaddingBottom – The distance between text in a control and the bottom edge of that control.

PaddingLeft – The distance between text in a control and the left edge of that control.

PaddingRight – The distance between text in a control and the right edge of that control.

PaddingTop – The distance between text in a control and the top edge of that control.

Visible – Whether a control appears or is hidden.

Width – The distance between a control's left and right edges.

X – The distance between the left edge of a control and the left edge of its parent container (screen if no parent container).

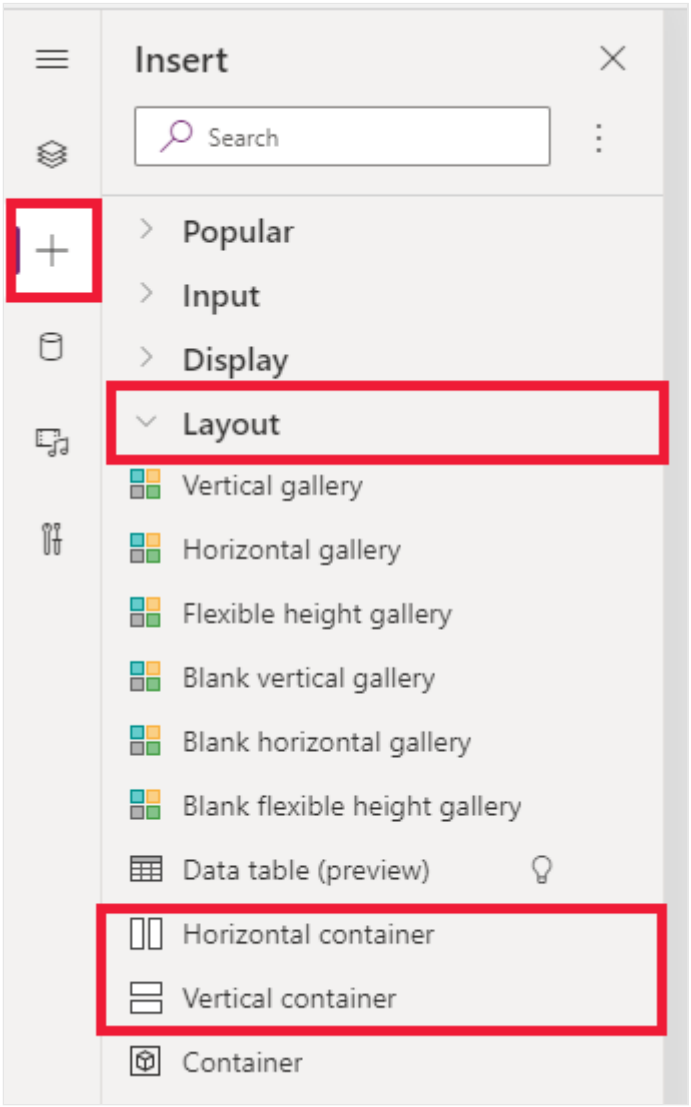
Y – The distance between the top edge of a control and the top edge of the parent container (screen if no parent container).

Example

1. Create a blank canvas app with **Tablet** layout.

2. Select **Settings** > **Display** and disable **Scale to fit**, **Lock aspect ratio**, and **Lock orientation** and select **Apply**.

3. Now from the **Insert** panes in the left sidebar, under **Layout** tab, select **Vertical container**.



4. Set the following properties to occupy the full available space of the screen:
   a. X = 0
   b. Y= 0
   c. Width = Parent.Width
   d. Height = Parent. Height

5. Add few buttons, text inputs, media, icons, and select **F5** to see how the app adjusts to the screen changes.

Audio and Video controls in Power Apps (retired)

Article • 04/03/2024

A control that plays an audio file, a video file, or a video on YouTube.

Description

An **Audio** control plays a sound clip from a file, a recording from a Microphone control, or the audio track from a video file.

A **Video** control plays a video clip from a file or from YouTube or any external source. Closed captions can optionally be shown when specified.

> **Important**
>
> Videos on Azure Media services are no longer supported. For more information, see Retirement of the service.

Limitations

The audio and video control has these limitations:

- Power Apps Mobile runs on various types of devices, and some of them have limitations that are specific to that platform:
  - You can play videos in multiple **Video** controls at the same time on all platforms except iPhone devices.
  - You can record audio with multiple **Microphone** controls at the same time on all platforms except the web player.

Key properties

Loop – Whether an audio or video clip automatically starts over as soon as it finishes playing.

Media – An identifier for the clip that an audio or video control plays.

> **Note**

- Use HTTPS for all external videos to ensure compatibility with modern browsers.
- External videos must be accessible anonymously (without any authentication).

ShowControls – Whether an audio or video player shows, for example, a play button and a volume slider, and a pen control shows, for example, icons for drawing, erasing, and clearing.

Additional properties

AccessibleLabel – Label for screen readers. Should be the title of the video or audio clip.

AutoPause – Whether an audio or video clip automatically pauses if the user navigates to a different screen.

AutoStart – Whether an audio or video control automatically starts to play a clip when the user navigates to the screen that contains that control.

BorderColor – The color of a control's border.

BorderStyle – Whether a control's border is **Solid**, **Dashed**, **Dotted**, or **None**.

BorderThickness – The thickness of a control's border.

ClosedCaptionsUrl – Video control only. URL of closed captions file in WebVTT format. Both video and captions URLs must be HTTPS. Server hosting both video and captions file needs to be CORS enabled.

DisplayMode – Whether the control allows user input (**Edit**), only displays data (**View**), or is disabled (**Disabled**).

Fill – The background color of a control.

FocusedBorderColor – The color of a control's border when the control is focused.

FocusedBorderThickness – The thickness of a control's border when the control is focused.

Height – The distance between a control's top and bottom edges.

Image – The name of the image that appears in an image, audio, or microphone control.

ImagePosition – The position (**Fill**, **Fit**, **Stretch**, **Tile**, or **Center**) of an image in a screen or a control if it isn't the same size as the image.

OnEnd – Actions to perform when an audio or video clip finishes playing.

OnPause – Actions to perform when the user pauses the clip that an audio or video control is playing.

OnStart – Actions to perform when the user starts to record with a microphone control.

Paused – *True* if a media playback control is currently paused, *false* otherwise.

Reset – Whether a control reverts to its default value.

Start – Whether an audio or video clip plays.

StartTime – The time after the start of an audio or video clip when the clip starts to play.

Time – A media control's current position.

TabIndex – Keyboard navigation order in relation to other controls.

Tooltip – Explanatory text that appears when the user hovers over a control.

Visible – Whether a control appears or is hidden.

Width – The distance between a control's left and right edges.

X – The distance between the left edge of a control and the left edge of its parent container (screen if no parent container).

Y – The distance between the top edge of a control and the top edge of the parent container (screen if no parent container).

Related functions

First(*TableName*)

Examples

Play an audio or video file

1. On the **File** menu, click or tap **Media**, click or tap **Videos** or **Audio**, and then click or tap **Browse**.

2. Browse to the file you want to use, click or tap it, and then click or tap **Open**.

3. Press Esc to return to the default workspace, add an **Audio** or **Video** control, and set its **Media** property to the file that you added.

   Don't know how to add and configure a control?

4. Press F5, and then play the clip by clicking or tapping the play button of the control that you added.

   > **Tip**
   >
   > The play button of the **Video** control appears when you hover over the control.

5. Press Esc to return to the default workspace.

Play a YouTube video

1. Add a **Video** control, and set its **Media** property to the URL of the YouTube video, enclosed in double quotation marks.
2. Press F5, and then play the clip by clicking or tapping the play button of the **Video** control.
3. Press Esc to return to the default workspace.

Accessibility guidelines

Audio and video alternatives

- **ShowControls** must be true so that users can listen or watch multimedia at their own pace. This also allows users to toggle closed captions and full-screen mode on video players.
- Closed captions must be provided for videos.
  - For YouTube videos, use authoring tools provided by YouTube to add captions.
  - For other videos, create captions in WebVTT format, upload them, and set **ClosedCaptionsUrl** to the url location. There are several limitations. Server(s) hosting video and captions needs to be CORS-enabled and serve them using HTTPS protocol.
- Consider providing an audio or video transcript using one of these methods:

  1. Put the text in a **Label** and position it adjacent to the multimedia player. Optionally, create a **Button** to toggle the display of the text.

2. Put the text in a different screen. Create a **Button** that navigates to the screen and position the button adjacent to the multimedia player.
3. If the description is short, it can be put it in the **AccessibleLabel**.

Color contrast

There must be adequate color contrast between:

- **FocusedBorderColor** and the outside color
- **Image** and the multimedia player controls (if applicable)
- **Fill** and the multimedia player controls (if the fill is visible)

Provide closed captions and/or transcript if the video content has color contrast issues.

Screen reader support

- **AccessibleLabel** must be present.

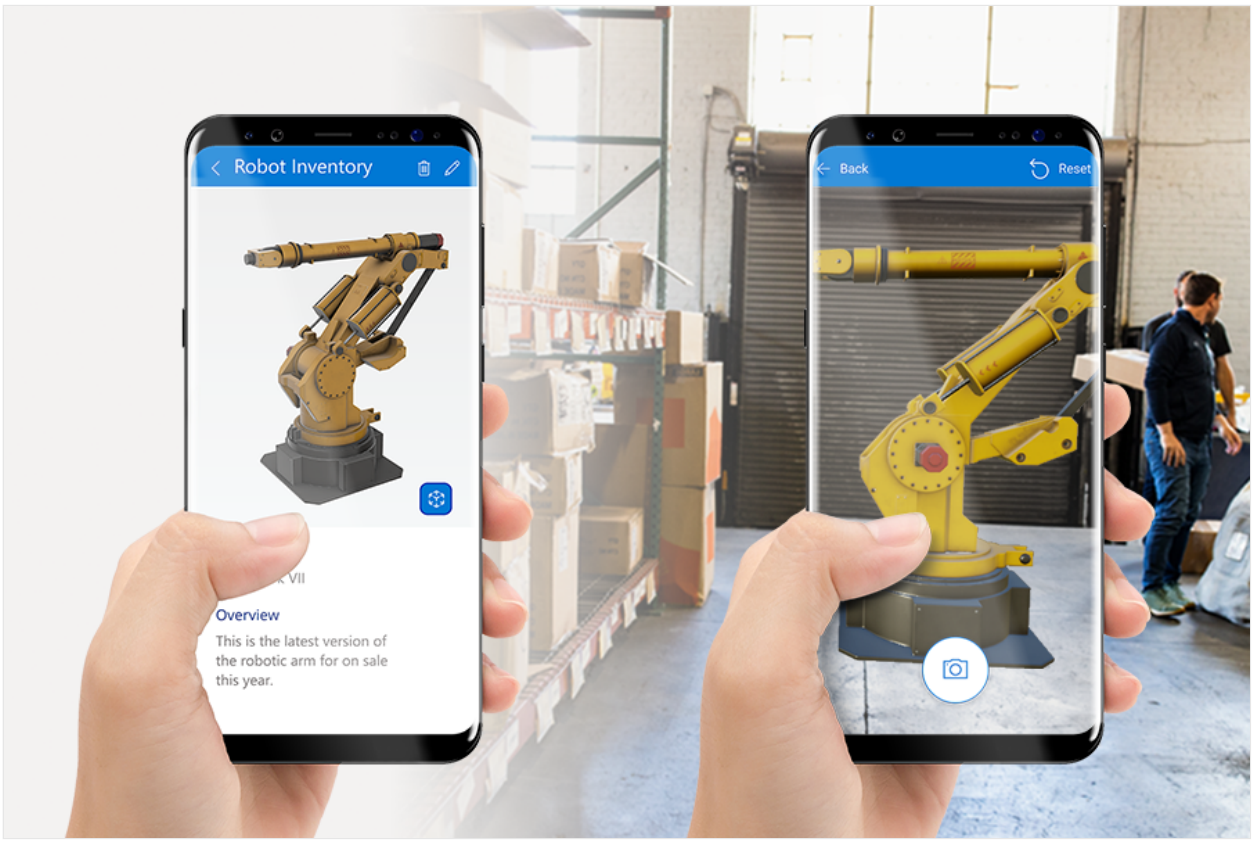
Keyboard support

- **TabIndex** must be zero or greater so that keyboard users can navigate to it.
- Focus indicators must be clearly visible. Use **FocusedBorderColor** and **FocusedBorderThickness** to achieve this.
- **AutoStart** should be false because it can be difficult for keyboard users to stop playback quickly.

View 3D content in Power Apps

Article • 05/09/2022

Easily add interactive 3D content to your canvas apps. You can select from a gallery of 3D content then rotate and zoom into the model with simple gestures.



Important

Your 3D content must be in the .glb, .obj, or .stl file formats. You can **convert your existing 3D models into the .glb file format** from a variety of 3D formats.

Tip

The mixed reality (MR) controls in Power Apps use Babylon and Babylon React Native. Mixed reality content that works in the **Babylon sandbox** should work in Power Apps through this shared MR platform. If your content works in Babylon but not in Power Apps, ask a question in the **Power Apps Community Forum**. (Tag it with "mixed reality.")

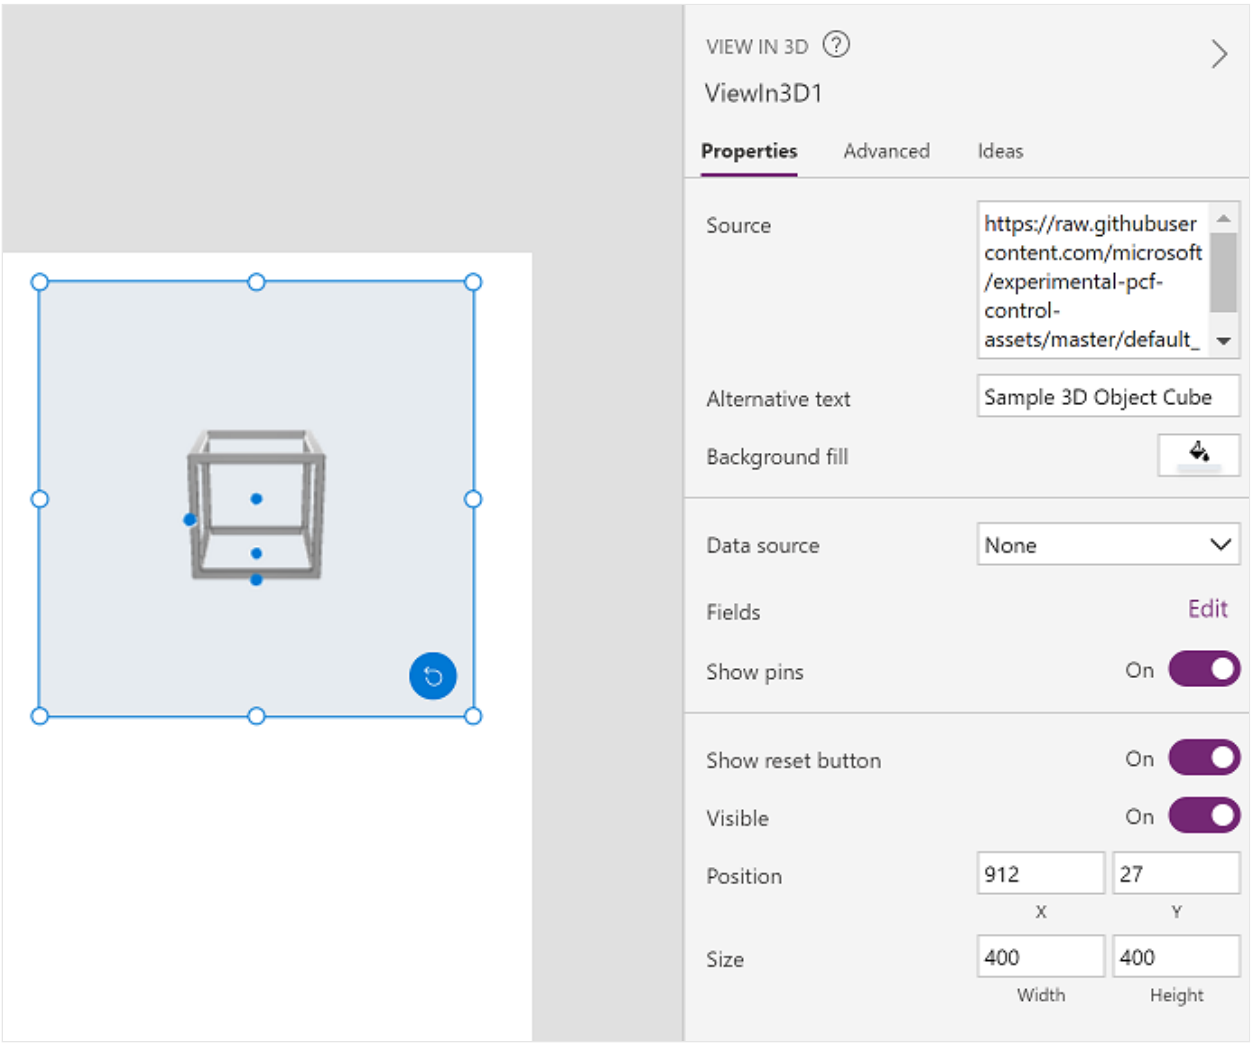
Add 3D object control to an app screen

With your app open for editing in Power Apps Studio:

1. Open the **Insert** tab and expand **Media**.
2. Select **3D object** to place the control in the app screen, or drag the control to the screen to position it more precisely.

Key properties

Change the 3D content control's behavior and appearance using properties. Some properties are only available on the **Advanced** tab.



Property	Description	Type	Location
Source	Identifies the object file to display. The **3D object** control supports loading models from various sources. See Loading external 3D models for details.	Not applicable	Properties; Advanced: **Source**
Alternative text	Specifies the text to be displayed if the model can't load or if the user hovers over the model.	String	Properties; Advanced: **AltText**

Property	Description	Type	Location
Background fill	Sets the control's background color.	Color picker	Properties; Advanced: **BackgroundFill** (accepts RGBA or HTML hexadecimal color codes)
Pins(Items)	Shows pins on the model at specific coordinates, provided in a data source (**Items**). If *None*, no pins are shown.	Data table	Properties; Advanced: **Items**
Show pins	Shows the pins described in **Items**.	Boolean	Properties; Advanced: **ShowPins**
MaxPins	Specifies the maximum number of pins that can be shown on the model.	Integer	Advanced
PinsX	Specifies the location of pins on the X axis in 3D coordinate space.	Floating point number	Advanced
PinsY	Specifies the location of pins on the Y axis in 3D coordinate space.	Floating point number	Advanced
PinsZ	Specifies the location of pins on the Z axis in 3D coordinate space.	Floating point number	Advanced
Show reset button	Shows or hides a button that resets the model to its initial state.	Boolean	Properties; Advanced; **ShowReset**
OnModelLoad	Contains behavior formula that runs when a model is loaded.	Event	Advanced
OnChange	Contains behavior formula that runs when any property of the control is changed.	Event	Advanced
OnSelect	Contains behavior formula that runs when the user selects a pin or the control.	Event	Advanced

Additional properties

Property	Description	Type	Location

Property	Description	Type	Location
ContentLanguage	Determines the display language of the control, if it's different from the language used in the app.	String	Advanced
DisplayMode	Determines whether the control allows user input (*Edit*), only displays data (*View*), or is disabled (*Disabled*).	Dropdown list	Advanced
Position	Places the upper-left corner of the control at the screen coordinates specified in *x* and *y*.	Floating point number	Properties; Advanced: **X**, **Y**
Size	Determines the size of the control using the pixel values provided in *Width* and *Height*.	Integer	Properties; Advanced: **Width**, **Height**
TabIndex	Specifies the order the control is selected if the user navigates the app using the Tab key.	Integer	Advanced
Tooltip	Determines the text to display when the user hovers over a pin.	String	Advanced
Visible	Shows or hides the control.	Boolean	Properties; Advanced: **Visible**

Performance considerations

We recommend that you use one 3D control on a screen for the best user experience. Multiple instances of the **3D object** control on one screen will try to load their 3D models at the same time, which can severely degrade the performance of your app.

Other mixed reality controls

- View 3D content and images in the real world with the **View in mixed reality** control.
- Measure distance, area, and volume with the **Measure in mixed reality** control.
- Create and view predefined 3D shapes with the **View shape in mixed reality** control.
- Paint 3D lines or draw 3D arrows to specify an area or asset in your environment with the **Markup in MR** control.

See also

Create an app with 3D and mixed reality controls

View 3D content or images in mixed reality

Article • 07/15/2022

Use the **View in MR** control to place a 3D model of an object or an image in a real-world space. For instance, preview a painting on a wall before you hang it, or see whether a 3D virtual bookcase will fit where you intend it to go.

What if you don't have a 3D model of the object? Load an image of the object and set its dimensions to the object's size. The control applies the image as the face of a virtual cube of the desired size. Place this stand-in for the 3D model in your space.

The **View in MR** control adds a button to your app. When a user selects the button, the app overlays a selected 3D model (in .glb, .stl, or .obj file formats) or image (in .jpg or .png file formats) on the device camera feed.

You can also take photos using the **View in MR** control and upload them to OneDrive.

> **Important**
>
> Your 3D content must be in the .glb, .stl, or .obj file formats. You can convert your existing 3D models into the .glb file format from a variety of 3D formats. 3D content compressed with Draco compression Draco is not supported.

> **Tip**
>
> - Make sure your 3D models are optimized for use with Power Apps to minimize load times.
> - The mixed-reality (MR) controls work best in well-lit environments with flat-textured surfaces. Tracking is better on LIDAR-enabled devices.

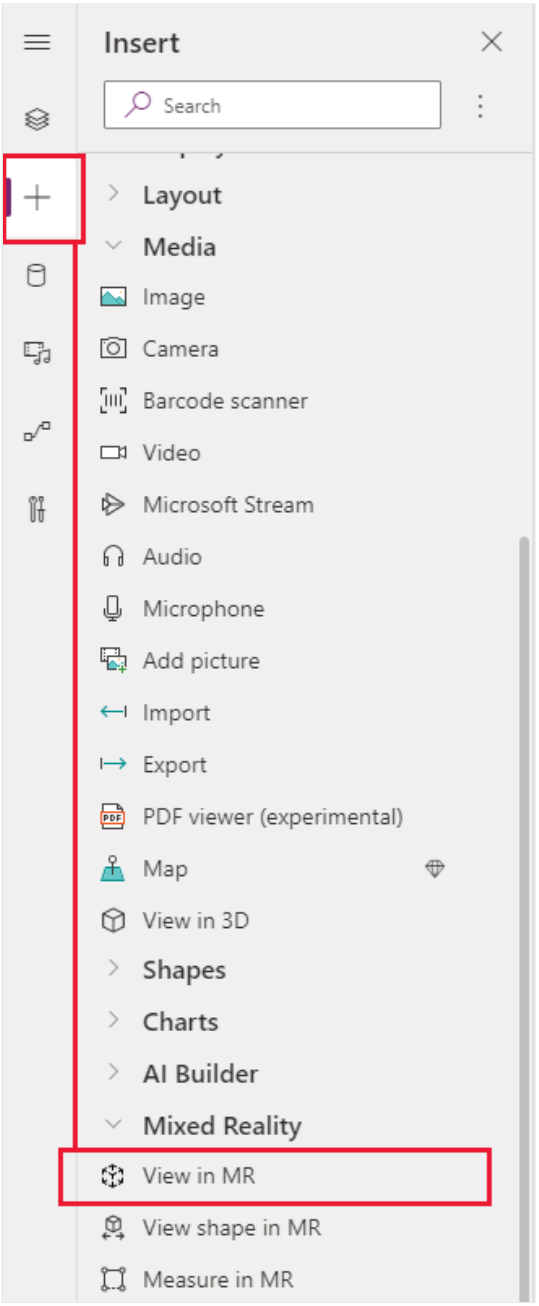
- The MR controls in Power Apps use Babylon and Babylon React Native. Mixed reality content that works in the Babylon sandbox should work in Power Apps through this shared MR platform. If your content works in Babylon but not in Power Apps, ask a question in the Power Apps Community Forum. (Tag it with "mixed reality.")

Add a View in MR button to an app screen

With your app open for editing in Power Apps Studio:

1. Open the **Insert** tab and expand **Mixed Reality**.
2. Select **View in MR** to place the control in the app screen, or drag the control to the screen to position it more precisely.

The control is a button that's labeled with an icon of a cube and the text *View in MR*. Change the label and hide the icon if you like in the **Text** and **Display type** properties.



View different models in a single session

The View in MR control displays one media file by default. To view different media files selected through a media gallery during the MR experience, use the control's *Items* advanced property. This property creates a table that lists media files the user can choose from in the mixed reality experience.

When you use the *Items* property, you need to set a value for the following additional advanced properties to map the columns of your table:

Expand table

Property	Description
ItemsSource (required)	Specifies which column in *Items* identifies the 3D model or image to show in the mixed reality view. See Connect 3D models to Power Apps to learn more about bringing models into Power Apps.
ItemsLabel	Specifies which column in *Items* contains the label to show in the media gallery. The *Alternative text* property is used for items that don't have a label specified.
ItemsThumbnail	Specifies which column in *Items* identifies the thumbnail to show in the media gallery. A default thumbnail is provided for items that don't have one specified.
ItemsObjectWidth, ItemsObjectHeight, ItemsObjectDepth	Specifies an explicit size for each media item in the table. *Object width*, *Object height*, and *Object depth* are used for items that don't have a specific size.

To test it, let's create a media gallery that shows three different plants in a room setting. Our *Items* table looks like this:

Expand table

label	source	thumbnail
Birds of Paradise	https://raw.githubusercontent.com/microsoft/experimental-pcf-control-assets/master/bird_of_paradise_blue.glb	https://raw.githubusercontent.com/microsoft/experimental-pcf-control-assets/master/bird_of_paradise_blue.png
Fiddle Leaf Fig	https://raw.githubusercontent.com/microsoft/experimental-pcf-control-assets/master/flf_orange.glb	https://raw.githubusercontent.com/microsoft/experimental-pcf-control-assets/master/flf_orange.png
Small Palm Tree	https://raw.githubusercontent.com/microsoft/experimental-pcf-control-assets/master/palm_green.glb	https://raw.githubusercontent.com/microsoft/experimental-pcf-control-assets/master/palm_green.png

With your app open for editing in Power Apps Studio:

1. Open the **Insert** tab and expand **Mixed Reality**.
2. Select **View in MR** to place the control in the app screen, or drag the control to the screen to position it more precisely.
3. On the **Advanced** properties tab, select the *Items* property and type or paste the following code:

```
Power Fx

Table(
{
label: "Birds of Paradise",
source: "https://raw.githubusercontent.com/microsoft/experimental-pcf-control-
assets/master/bird_of_paradise_blue.glb",
thumbnail: "https://raw.githubusercontent.com/microsoft/experimental-pcf-control-
assets/master/bird_of_paradise_blue.png"
},
{
label: "Fiddle Leaf Fig",
source: "https://raw.githubusercontent.com/microsoft/experimental-pcf-control-
```

```
assets/master/flf_orange.glb",
thumbnail: "https://raw.githubusercontent.com/microsoft/experimental-pcf-control-
assets/master/flf_orange.png"
},
{
label: "Small Palm Tree",
source: "https://raw.githubusercontent.com/microsoft/experimental-pcf-control-
assets/master/palm_green.glb",
thumbnail: "https://raw.githubusercontent.com/microsoft/experimental-pcf-control-
assets/master/palm_green.png"
}
)
```

4. Set the *ItemsLabel* property to `"label"`.

5. Set the *ItemsSource* property to `"source"`.

6. Set the *ItemsThumbnail* property to `"thumbnail"`.

> **Note**
>
> The *Items* property is set to your data source which can be a collection, from a connector, or a hardcoded table like in this example. The *ItemsSource*, *ItemsLabel*, and *ItemsThumbnail* properties are set to the column names of that data source within quotation marks.

7. Save and publish the app, then open it on your mobile device to try it out.

How objects are scaled if you resize them

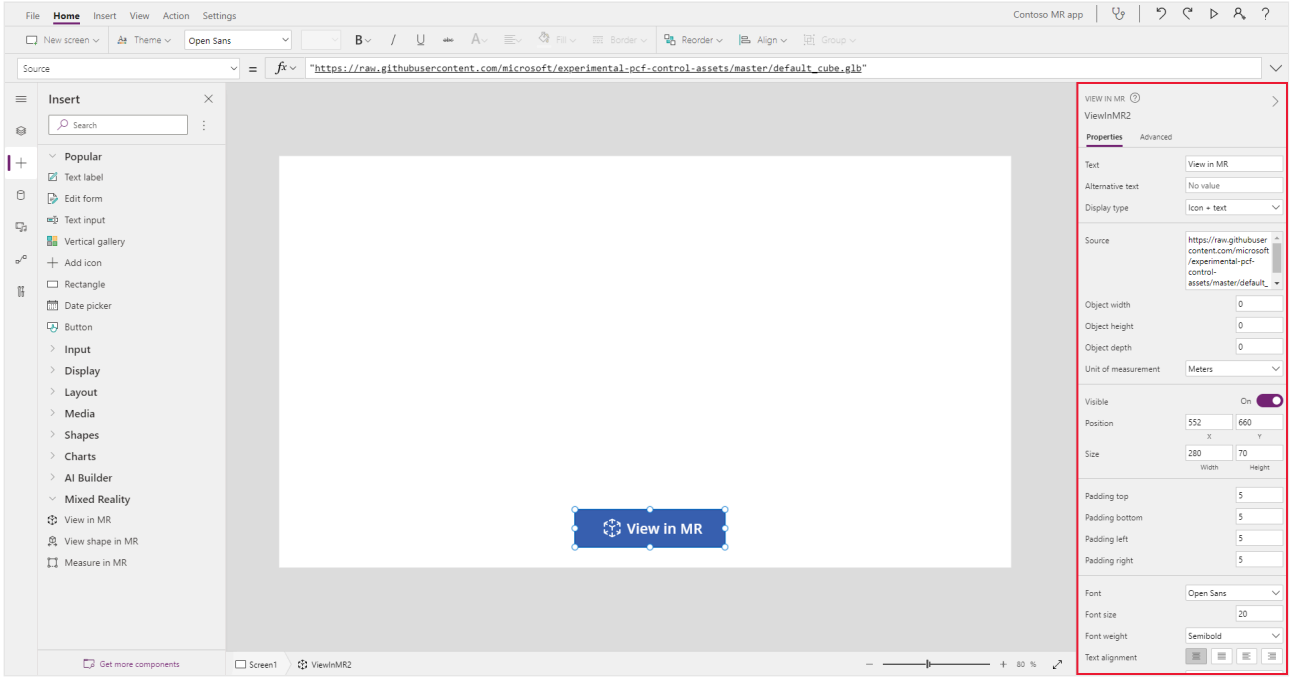
If you don't specify dimensions when you place a model, the **View in MR** control follows the dimensions given in the object file. You can resize the model by entering a value other than 0 in one or more of the control's width, height, and depth properties (**Object width**, **Object height**, and **Object depth**). How the model is scaled depends on how many dimensions you change.

- If all dimensions are *0* (the default), the model's size is left as it's set in the object file.
- If one dimension is set, the model is scaled equally based on the changed dimension, similar to setting "keep aspect ratio" when you resize an image.
- If two dimensions are set, the model scales to the two given dimensions and an average of the first two. For example, say you have a model that is 12 m high, 6 m wide, and 3 m deep. You set the **View in MR** control's properties as follows: **Object height**: **24**, **Object width**: **9**, **Object depth**: **0** (unchanged). The height increases by a factor of 2, and the width increases by a factor of 1.5. The increase in height and width is averaged to find the factor by which the depth should be increased: 2 + 1.5 = 3.5 / 2 = 1.75. The final dimensions of the model are **Object height** 24, **Object width** 9, and **Object depth** 5.25 (3 x 1.75).
- If all three dimensions are set, the model's size is changed to what you specified.

> **Note**
>
> If the measurements don't adhere to the original aspect ratio, the model could be squashed or distorted when it's viewed in MR.

Properties

Change the **View in MR** button's behavior and appearance using properties. Some properties are only available on the **Advanced** tab.



Expand table

Property	Description	Type	Location
Text	Sets the button label text.	String	Properties; Advanced: **Text**

Property	Description	Type	Location
Alternative text	Specifies the text to be displayed if the model can't load or if the user hovers over the model.	String	Properties; Advanced: **AltText**
Display type	Determines whether the button label shows an icon of a cube, text, or both.	Drop-down selection	Properties; Advanced: **DisplayType**
Source	Identifies the data source (.glb, .stl, or .obj file) to display.	Not applicable	Properties; Advanced: **Source**
Sources List (Items)	Data source (table) that lists multiple media files to view in a single mixed reality session.	Table	Properties; Advanced: **Items**
Object width	Sets the width of the model.	Integer	Properties; Advanced: **ObjectWidth**
Object height	Sets the height of the model.	Integer	Properties; Advanced: **ObjectHeight**
Object depth	Sets the depth of the model.	Integer	Properties; Advanced: **ObjectDepth**
Unit of measurement	Sets the measurement unit used for the model's width, height, and depth.	List	Properties; Advanced: **Units**
Enable shadows	Determines whether shadows are used to enhance the 3D effect when the model is shown.	Boolean	Properties; Advanced: **EnableShadows**
Enable marker detection	Determines whether marker detection will be used to determine model position and rotation. See Use marker detection with mixed reality controls	Boolean	Properties; Advanced: **EnableMarkerDetection**
Visible	Shows or hides the button.	Boolean	Properties; Advanced: **Visible**
Position	Places the upper-left corner of the button at the screen coordinates specified in *x* and *y*.	Floating point number	Properties; Advanced: **X**, **Y**
Size	Determines the size of the button using the pixel values provided in *Width* and *Height*.	Integer	Properties; Advanced: **Width**, **Height**
Padding top	Sets the distance between the button label text and the top of the button.	Floating point number	Properties; Advanced: **PaddingTop**
Padding bottom	Sets the distance between the button label text and the bottom of the button.	Floating point number	Properties; Advanced: **PaddingBottom**
Padding left	Sets the distance between the button label text and the left edge of the button.	Floating point number	Properties; Advanced: **PaddingLeft**
Padding right	Sets the distance between the button label text and the right edge of the button.	Floating point number	Properties; Advanced: **PaddingRight**
Font	Sets the name of the family of fonts used for the button label text.	List	Properties; Advanced: **Font**
Font size	Sets the size of the button label text.	Floating point	Properties; Advanced: **FontSize**

Property	Description	Type	Location
		number	
Font weight	Sets the weight of the button label text, either *Bold*, *Lighter*, *Normal*, or *Semibold*.	List	Properties; Advanced: **FontWeight**
Text alignment	Sets the horizontal alignment of the label text in the button, either *Center*, *Justify*, *Left*, or *Right*.	Not applicable	Properties; Advanced: **TextAlignment**
Vertical alignment	Sets the vertical alignment of the label text in the button, either *Bottom*, *Middle*, or *Top*.	List	Properties; Advanced: **VerticalAlign**
Font style	Sets the style of the button label text, either *Italic*, *Underline*, *Strikethrough*, or none.	Not applicable	Properties; Advanced: **Italic**, **Underline**, **Strikethrough**
Border radius	Determines the corner radius of the button border.	Floating point number	Properties; Advanced: **BorderRadius**
Color	Sets the colors of the button label text and the button background.	Not applicable	Properties; Advanced: **FillColor**, **TextColor**
Border	Determines the style, width, and color of the button border.	Not applicable	Properties; Advanced: **BorderStyle**, **BorderThickness**, **BorderFillColor**
Disabled	Turns off the button but leaves it visible.	Boolean	Properties; Advanced: **Disabled**
Disabled color	Sets the colors of the button label text, the button background, and the button border if DisplayMode is **Disabled**.	Not applicable	Properties; Advanced: **DisabledContentColor**, **DisabledFillColor**, **DisabledBorderColor**
Pressed color	Sets the colors of the button label text, the button background, and the button border when the user selects the button.	Not applicable	Properties; Advanced: **PressedContentColor**, **PressedFillColor**, **PressedBorderColor**
Hover color	Sets the colors of the button label text, the button background, and the button border when the user hovers the mouse pointer over it.	Not applicable	Properties; Advanced: **HoverContentColor**, **HoverFillColor**, **HoverBorderColor**
OnMixedRealitySelect	Behavior that is triggered when user selects the button to launch into the mixed reality experience.	Defined action	Advanced
OnChange	Behavior that is triggered when any property on the button is changed.	Defined action	Advanced
Tooltip	Determines the text to display when the user hovers over the button.	String	Advanced
ContentLanguage	Determines the display language of the button label, if it's different from the language used in the app.	String	Advanced
DisplayMode	Determines whether the button allows user input (*Edit*), only displays data (*View*), or is disabled (*Disabled*).	Enum	Advanced
TabIndex	Specifies the order the button is selected if the user navigates the app using the Tab key.	Integer	Properties; Advanced: **TabIndex**

Output properties

Your app can make use of more properties when a user interacts with the **View in MR** control. These are known as output properties. You can use output properties in other controls or to customize the app experience.

Expand table

Property	Description	Type
Photos	Collects the photos captured during the mixed reality session. You can upload the mixed-reality photos to OneDrive and show them in a gallery.	Not applicable

Other mixed reality controls

- View 3D content with the **3D object** control.
- Measure distance, area, and volume with the **Measure in mixed reality** control.
- Create and view predefined 3D shapes with the **View shape in mixed reality** control
- Paint 3D lines or draw 3D arrows to specify an area or asset in your environment with the **Markup in MR** control.

View predefined 3D shapes in mixed reality

Article • 06/17/2022

Use the **View shape in MR** control in a canvas app to see whether a digital cube of a given size fits in a real-world space. (To compare a 3D model of an object instead, use the View in MR control.)

The **View shape in MR** control adds a button to your app. When a user selects the button, the app overlays a cube on the device camera feed. The cube's dimensions are set as a property on the control when you author the app in Microsoft Power Apps Studio. Users may not change the size of the cube while they use the app.

Tip

The mixed-reality (MR) controls work best in well-lit environments with flat-textured surfaces. Tracking is better on LIDAR-enabled devices.

Tip

The MR controls in Power Apps use Babylon and Babylon React Native. Mixed reality content that works in the **Babylon sandbox** should work in Power Apps

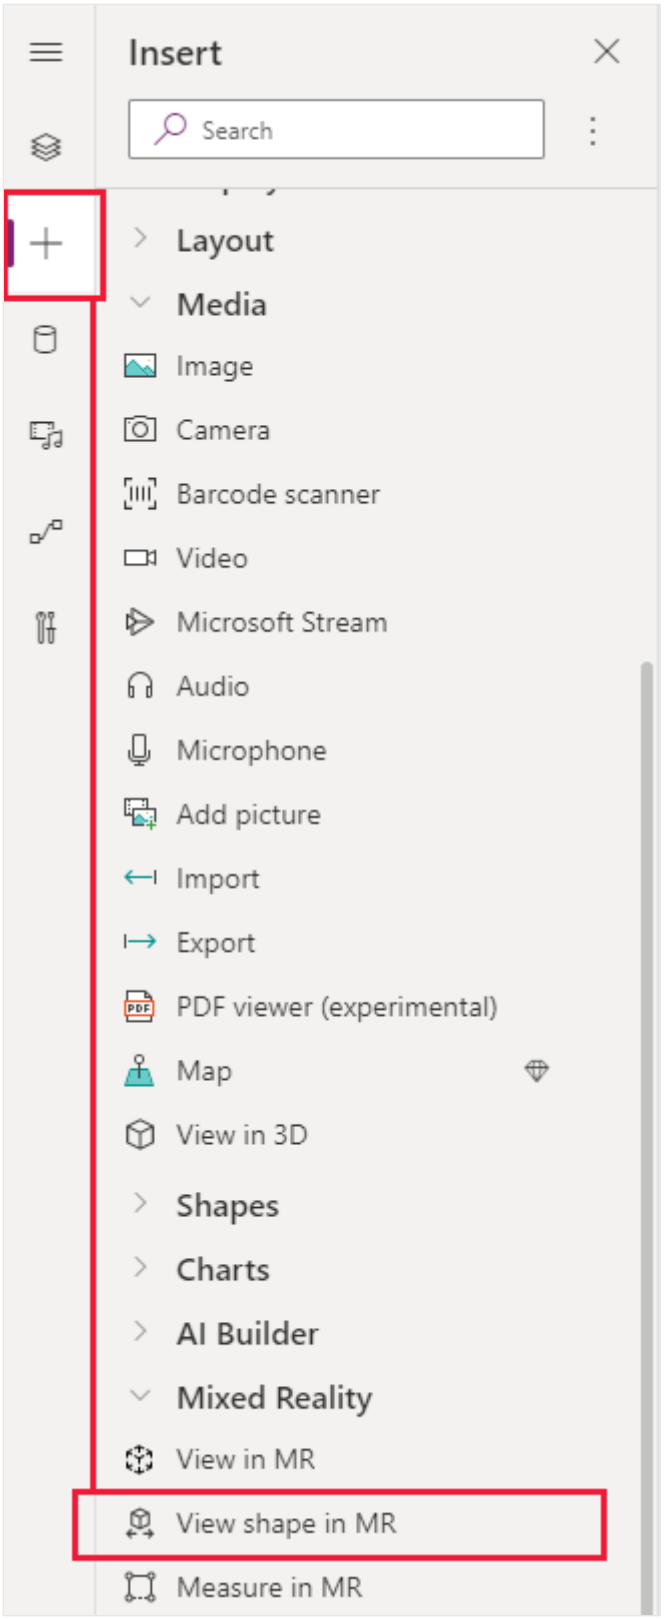
through this shared MR platform. If your content works in Babylon but not in Power Apps, ask a question in the **Power Apps Community Forum**. (Tag it with "mixed reality.")

Add a View shape in MR button to an app screen

With your app open for editing in Power Apps Studio:

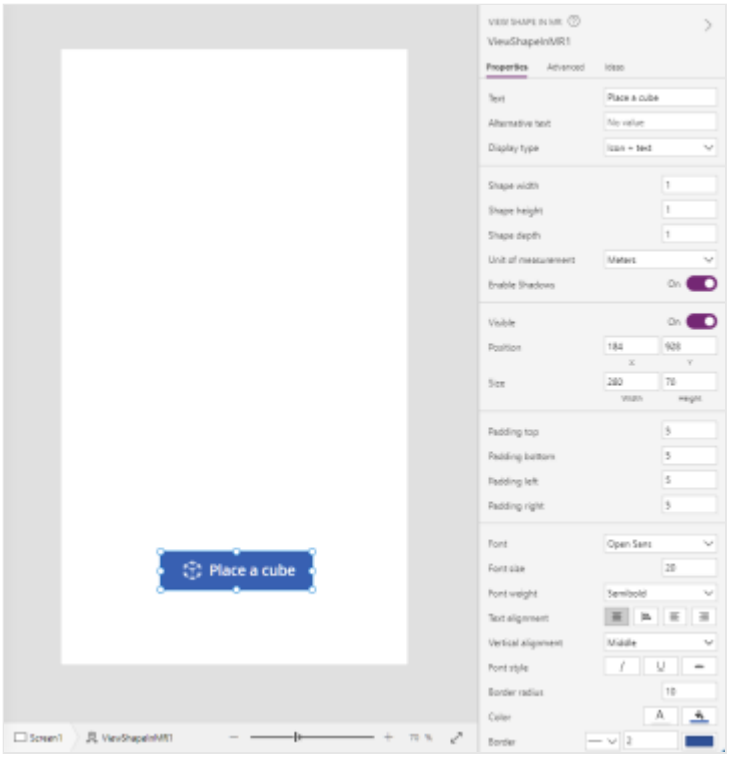
1. Open the **Insert** tab and expand **Mixed Reality**.
2. Select **View shape in MR** to place the control in the app screen, or drag the control to the screen to position it more precisely.

The control is a button that's labeled with an icon of a cube and the text *Place a cube*. Change the label and hide the icon if you like in the **Text** and **Display type** properties.



Properties

Change the **View shape in MR** button's behavior and appearance using properties. Some properties are only available on the **Advanced** tab.



Property	Description	Type	Location
Text	Sets the button label text.	String	Properties; Advanced: **Text**
Alternative text	Specifies the text to be displayed if the model can't load or if the user hovers over the model.	String	Properties; Advanced: **AltText**
Display type	Determines whether the button label shows an icon of a cube, text, or both.	Drop-down selection	Properties; Advanced: **DisplayType**
Shape width	Sets the width of the cube.	Integer	Properties; Advanced: **ShapeWidth**
Shape height	Sets the height of the cube.	Integer	Properties; Advanced: **ShapeHeight**
Shape depth	Sets the depth of the cube.	Integer	Properties; Advanced: **ShapeDepth**
Unit of measurement	Sets the measurement unit used for the cube's width, height, and depth.	Drop-down selection	Properties; Advanced: **Units**
Enable Shadows	Determines whether shadows are used to enhance the 3D effect when the cube is shown.	Boolean	Properties; Advanced: **EnableShadows**

Property	Description	Type	Location
Enable Marker Detection	Determines whether marker detection will be used to to determine model position and rotation. See Use marker detection with mixed reality controls	Boolean	Properties; Advanced: **EnableMarkerDetection**
Visible	Shows or hides the button.	Boolean	Properties; Advanced: **Visible**
Position	Places the upper-left corner of the button at the screen coordinates specified in *x* and *y*.	Floating point number	Properties; Advanced: **X**, **Y**
Size	Determines the size of the button using the pixel values provided in *Width* and *Height*.	Integer	Properties; Advanced: **Width**, **Height**
Padding top	Sets the distance between the button label text and the top of the button.	Floating point number	Properties; Advanced: **PaddingTop**
Padding bottom	Sets the distance between the button label text and the bottom of the button.	Floating point number	Properties; Advanced: **PaddingBottom**
Padding left	Sets the distance between the button label text and the left edge of the button.	Floating point number	Properties; Advanced: **PaddingLeft**
Padding right	Sets the distance between the button label text and the right edge of the button.	Floating point number	Properties; Advanced: **PaddingRight**
Font	Sets the name of the family of fonts used for the button label text.	Dropdown list	Properties; Advanced: **Font**
Font size	Sets the size of the button label text.	Floating point number	Properties; Advanced: **FontSize**
Font weight	Sets the weight of the button label text, either *Bold*, *Lighter*, *Normal*, or *Semibold*.	Dropdown list	Properties; Advanced: **FontWeight**
Text alignment	Sets the horizontal alignment of the label text in the button, either *Center*, *Justify*, *Left*, or *Right*.	Not applicable	Properties; Advanced: **TextAlignment**

Property	Description	Type	Location
Vertical alignment	Sets the vertical alignment of the label text in the button, either *Bottom*, *Middle*, or *Top*.	Dropdown list	Properties; Advanced: VerticalAlign
Font style	Sets the style of the button label text, either *Italic*, *Underline*, *Strikethrough*, or none.	Not applicable	Properties; Advanced: **Italic**, **Underline**, **Strikethrough**
Border radius	Determines the corner radius of the button border.	Floating point number	Properties; Advanced: **BorderRadius**
Color	Sets the colors of the button label text and the button background.	Not applicable	Properties; Advanced: **FillColor**, **TextColor**
Border	Determines the style, width, and color of the button border.	Not applicable	Properties; Advanced: BorderStyle, BorderThickness, BorderFillColor
Disabled	Turns off the button but leaves it visible.	Boolean	Properties; Advanced: **Disabled**
Disabled color	Sets the colors of the button label text, the button background, and the button border if DisplayMode is **Disabled**.	Not applicable	Properties; Advanced: **DisabledContentColor**, **DisabledFillColor**, **DisabledBorderColor**
Pressed color	Sets the colors of the button label text, the button background, and the button border when the user selects the button.	Not applicable	Properties; Advanced: **PressedContentColor**, **PressedFillColor**, **PressedBorderColor**
Hover color	Sets the colors of the button label text, the button background, and the button border when the user hovers the mouse pointer over it.	Not applicable	Properties; Advanced: **HoverContentColor**, **HoverFillColor**, **HoverBorderColor**
OnMixedRealitySelect	Behavior that is triggered when user selects the button to launch into the mixed reality experience.	Defined action	Advanced

Property	Description	Type	Location
OnChange	Behavior that is triggered when any property on the button is changed. This is a common property across multiple controls.	Defined action	Advanced
Tooltip	Determines the text to display when the user hovers over the button.	String	Advanced
ContentLanguage	Determines the display language of the button label, if it's different from the language used in the app.	String	Advanced
DisplayMode	Determines whether the button allows user input (*Edit*), only displays data (*View*), or is disabled (*Disabled*).	Enum	Advanced
TabIndex	Specifies the order the button is selected if the user navigates the app using the Tab key.	Integer	Properties; Advanced: **TabIndex**

Output properties

Web barcode scanner control (experimental) in Power Apps

Article • 03/13/2023

The legacy barcode scanning control, which is obsolete but might be useful for scanning codes in a web browser.

Description

The control shows the camera feed in the app so that users can scan barcodes on all devices. The control is obsolete because of poor performance, and the mobile Barcode reader control replaces this control.

> ⓘ Note
>
> The web barcode scanner control is only supported on Microsoft Edge, Chrome, Firefox, and Opera browsers. All other browsers will show a warning that some features of the app won't work.

Key properties

BarcodeType - The barcode type to scan. Supported types: Codabar, Code39, Code128, EAN, I2of5, UPC. **Default: UPC**

Camera – On a device that has more than one camera, the numeric ID of the camera that the app uses for scanning barcodes.

Additional properties

AccessibleLabel – Label for screen readers.

BorderColor – The color of a control's border.

BorderStyle – Whether a control's border is **Solid**, **Dashed**, **Dotted**, or **None**.

BorderThickness – The thickness of a control's border.

DisplayMode – Whether the control allows user input (**Edit**), only displays data (**View**), or is disabled (**Disabled**).

Height – The distance between a control's top and bottom edges.

ShowLiveBarcodeDetection – Whether visual cues are shown to indicate the status of barcode detection. Yellow rectangles represent areas that are being examined. A green line across a rectangle indicates successful barcode identification.

Stream – Automatically updated image based on the **StreamRate** property.

StreamRate – How often to update the image on the **Stream** property, in milliseconds. This value can range from 100 (1/10th of a second) to 3,600,000 (1 hour).

Text – Value of barcode that was last identified by the scanner.

Tooltip – Explanatory text that appears when the user hovers over a control.

Visible – Whether a control appears or is hidden.

Width – The distance between a control's left and right edges.

X – The distance between the left edge of a control and the left edge of its parent container (screen, if no parent container).

Y – The distance between the top edge of a control and the top edge of the parent container (screen, if no parent container).

Related functions

Patch(*DataSource*, *BaseRecord*, *ChangeRecord*)

Example

Add barcode scanner control

1. Add a **barcode scanner** control, name it "Mybarcode scanner".

   Don't know how to add, name, and configure a control?

2. Add a **Label** control, and set its output to the barcode scanner's **Text** property.

3. Scan a barcode of the type set under **BarcodeType** property.

   The label displays the scanned barcode.

Accessibility guidelines

Video alternatives

- Consider adding a **Label** with its **Text** set to the barcode scanner's **Text**. Since the barcode scanner doesn't display the identified barcode value, doing the above makes the scanner accessible to everyone, not just those with visual disabilities.

Screen reader support

- **AccessibleLabel** must be present.

  > **Note**
  >
  > Screen readers will announce when a new barcode has been found. The value won't be announced. As long as the barcode is in view, screen readers will remind the user every five seconds that the same barcode is still being identified.

Accessibility properties for Power Apps

Article • 07/13/2024

Configuration of properties that aid alternative ways of interacting with controls suitable for users with disabilities.

Properties

AccessibleLabel

Label for screen readers.

An empty value for Image, Icon, and Shape controls will hide the controls from screen reader users.

Live

How screen readers should announce changes to content. Available only in the **Label** control.

- When set to **Off**, the screen reader doesn't announce changes.
- When set to **Polite**, the screen reader finishes speaking before announcing any changes that occurred while the screen reader was speaking.
- When set to **Assertive**, the screen reader interrupts itself to announce any changes that occurred while the screen reader was speaking.

Learn how to announce dynamic changes with live regions.

Role

Intended purpose of a control. Available only in the **Label** control.

This lets screen reader users know whether a **Label** is a heading and allows them to navigate quickly to different parts of the app. There should be exactly one **Heading1** in each screen that serves as the main heading. Use **Heading2** for subheadings. **Heading3** and **Heading4** can be used for finer hierarchies of headings.

Use **Default** for normal text.

AcceptsFocus and TabIndex

Determines if the control participates in keyboard navigation.

You can use **AcceptsFocus** to configure keyboard navigation for modern controls. Classic controls use **TabIndex**.

Expand table

AcceptsFocus	TabIndex	Behavior	Default for
true	0 or greater	Control participates in keyboard navigation, unless it's hidden or disabled.	**Button**, **Text input**, **Combo box**, and other typically interactive controls.
false	−1 or less than 0	Control does not participate in keyboard navigation.	**Label**, **Image**, **Icon**, and other typically non-interactive controls.

Any keyboard navigation sequence can be achieved with just these properties, along with the use of the **Container** control. For **TabIndex**, we recommend using either 0 or -1 for simplicity.

Controls that have a **Visible** property value of *false* or a **DisplayMode** property value of **Disabled** are not included in keyboard navigation.

> **Important**
>
> **TabIndex** only affects keyboard navigation. A logical control order is still necessary for screen reader users to understand app structure. Some screen reader users don't even use keyboards.

Color and border properties in Power Apps

Article • 12/16/2022

Overview

Configure the style of a control based on how the user interacts with it.

You can specify colors in many ways:

- Color enumeration: Specify color names from cascading style sheets, as in these examples:
  - **Color.Red**
  - **Color.Indigo**
- ColorValue function: Specify text strings such as color names from cascading style sheets and hex-code notation (#), as in these examples:
  - **ColorValue("AliceBlue")**
  - **ColorValue("#ff00ff")**
- ColorFade function: Specify how faded a color is, from fully black (-100%) to fully white (100%), as in this example:
  - **ColorFade(Color.Red, 50%)**
- RGBA function: Specify the red, green, and blue components of a color from 0 to 255, and specify an alpha channel from 0% (fully transparent) to 100% (fully opaque), as in this example:
  - **RGBA(255, 0, 255, 25%)**

Color properties can also reference other color properties. For example, **Label.PressedColor** may be set to the formula **Label1.Color**, automatically cascading a change from one property to another.

Normal

These properties are in effect normally, when the user is not interacting with the control.

BorderColor – The color of a control's border.

- Applies to Add picture, Audio, Button, Camera, Card, Check box, Column chart, Date Picker, Display form, Drop down, Edit form, Export, Gallery, HTML text,

Image, Import, Label, Line chart, List Box, Microphone, PDF viewer, Pen input, Pie chart, Radio, Rating, Slider, Text input, Timer, Toggle, and Video controls.

BorderStyle – Whether a control's border is **Solid**, **Dashed**, **Dotted**, or **None**.

- Applies to Add picture, Audio, Button, Camera, Card, Check box, Column chart, Date Picker, Display form, Drop down, Edit form, Export, Gallery, HTML text, Image, Import, Label, Line chart, List Box, Microphone, PDF viewer, Pen input, Pie chart, Radio, Rating, Slider, Text input, Timer, Toggle, and Video controls.

BorderThickness – The thickness of a control's border.

- Applies to Add picture, Audio, Button, Camera, Card, Check box, Column chart, Date Picker, Display form, Drop down, Edit form, Export, Gallery, HTML text, Image, Import, Label, Line chart, List Box, Microphone, PDF viewer, Pen input, Pie chart, Radio, Rating, Slider, Text input, Timer, Toggle, and Video controls.

Color – The color of text in a control.

- Applies to Add picture, Button, Check box, Column chart, Date Picker, Drop down, Export, HTML text, Import, Label, Line chart, List Box, Microphone, Pen input, Pie chart, Radio, Text input, and Timer controls.

Drop Shadow - Adds shadow effects around the control.

- Applies to Horizontal container and Vertical container controls.

Fill – The background color of a control.

- Applies to Add picture, Audio, Button, Card, Check box, Date Picker, Display form, Drop down, Edit form, Export, Gallery, HTML text, Icon, Image, Import, Label, List Box, Microphone, PDF viewer, Pen input, Radio, Rating, Screen, Shape, Text input, Timer, Toggle, and Video controls.

Focused

These properties are in effect when the control is focused.

FocusedBorderColor – The color of a control's border when it has focus.

FocusedBorderThickness – The thickness of a control's border when it has focus.

- These properties apply to Add picture, Attachments, Audio, Button, Camera, Check box, Combo box, Date Picker, Drop down, Export, Gallery, Icon, Image,

Import, Label, List Box, Microphone, Radio, Rating, Shape, Slider, Text input, Timer, Toggle, and Video controls.

Disabled

These properties are in effect when the control is disabled. A control can be disabled if the DisplayMode property is set to **Disabled**.

DisabledBorderColor – The color of a control's border if the control's DisplayMode property is set to **Disabled**.

- Applies to Add picture, Button, Check box, Column chart, Date Picker, Drop down, Export, HTML text, Image, Import, Label, Line chart, List Box, Microphone, PDF viewer, Pie chart, Radio, Slider, Text input, Timer, and Toggle controls.

DisabledColor – The color of text in a control if its DisplayMode property is set to **Disabled**.

- Applies to Add picture, Button, Check box, Date Picker, Drop down, Export, Import, Label, List Box, Microphone, Radio, Text input, and Timer controls.

DisabledFill – The background color of a control if its DisplayMode property is set to **Disabled**.

- Applies to Add picture, Button, Check box, Date Picker, Drop down, Export, HTML text, Image, Import, Label, List Box, Microphone, Radio, Text input, and Timer controls.

Hover

These properties are in effect when the user hovers over the control with a mouse.

HoverBorderColor – The color of a control's border when the user keeps the mouse pointer on that control.

- Applies to Add picture, Button, Check box, Column chart, Drop down, Export, HTML text, Image, Import, Label, Line chart, List Box, Microphone, PDF viewer, Pie chart, Slider, Text input, Timer, and Toggle controls.

HoverColor – The color of the text in a control when the user keeps the mouse pointer on it.

- Applies to Add picture, Button, Check box, Drop down, Export, Import, Label, List Box, Microphone, Radio, Text input, and Timer controls.

HoverFill – The background color of a control when the user keeps the mouse pointer on it.

- Applies to **Add picture**, **Button**, **Check box**, **Drop down**, **Export**, **Icon**, **Image**, **Import**, **Label**, **List Box**, **Microphone**, **Radio**, **Shape**, **Text input**, and **Timer** controls.

Pressed

These properties are in effect when a button or image control is pressed.

PressedBorderColor – The color of a control's border when the user taps or clicks that control.

- Applies to **Add picture**, **Button**, **Check box**, **Column chart**, **Drop down**, **Export**, **Icon**, **Image**, **Import**, **Label**, **Line chart**, **List Box**, **Microphone**, **PDF viewer**, **Pie chart**, **Shape**, **Slider**, **Text input**, **Timer**, and **Toggle** controls.

PressedColor – The color of text in a control when the user taps or clicks that control.

- Applies to **Add picture**, **Button**, **Check box**, **Drop down**, **Export**, **Import**, **Label**, **List Box**, **Microphone**, **Radio**, **Text input**, and **Timer** controls.

PressedFill – The background color of a control when the user taps or clicks that control.

- Applies to **Add picture**, **Button**, **Check box**, **Drop down**, **Export**, **Image**, **Import**, **Label**, **List Box**, **Microphone**, **Radio**, **Text input**, and **Timer** controls.

Selection

These properties are in effect when the user selects an item in a control.

SelectionColor – The text color of a selected item or items in a list or the color of the selection tool in a pen control.

- Applies to **Drop down**, **List Box**, and **Pen input** controls.

SelectionFill – The background color of a selected item or items in a list or a selected area of a pen control.

- Applies to **Drop down** and **List Box** controls.

Order of color

A control can be in multiple states. For example: focused and hovered. Only one color is used, in this order:

1. Disabled
2. Pressed
3. Hover
4. Focus
5. Normal

Core properties in Power Apps

07/25/2025

Configure whether the user can see and interact with a control.

Properties

Default – The initial value of a control before it is changed by the user.

- Applies to Card, Check box, Drop down, Gallery, List Box, Radio, Rating, Rich Text Editor, Slider, Text input, and Toggle controls.

DelayOutput – Set to true to delay action during text input.

- Applies to Text input, Card

DisplayMode – Values can be **Edit, View,** or **Disabled**. Configures whether the control allows user input (**Edit**), only displays data (**View**) or is disabled (**Disabled**). In **View** mode, input controls such as Text input, Drop down, Date Picker will only display the text value and will not render any interactive elements or decorations. This makes them suitable to be displayed in Forms or as readable output.

- Applies to Add picture, Audio, Button, Camera, Check box, Column chart, Combo box, Date Picker, Drop down, Export, Gallery, HTML text, Icon, Image, Import, Label, Line chart, List Box, Microphone, PDF viewer, Pen input, Pie chart, Radio, Rating, Rich text editor, Shape, Slider, Text input, Timer, Toggle, and Video controls.

Items – The source of data that appears in a control such as a gallery, a list, or a chart.

- Applies to Column chart, Combo box, Drop down, Gallery, Line chart, List Box, Pie chart, and Radio controls.

OnChange – Actions to perform when the user changes the value of a control (for example, by adjusting a slider).

- Applies to Add picture, Combo box, Drop down, List Box, Radio, Rating, Rich text editor, Slider, Text input, and Toggle controls.

OnSelect – Actions to perform when the user taps or clicks a control.

- Applies to Add picture, Button, Camera, Check box, Column chart, Combo box, Date Picker, Drop down, Export, HTML text, Icon, Image, Import, Label, Line chart, List Box, Microphone, PDF viewer, Pen input, Pie chart, Radio, Rating, Shape, Slider, Text input, Timer, and Toggle controls.

Reset – Whether a control reverts to its default value. Also see the Reset function.

- Applies to Audio, Check box, Combo box, Drop down, List Box, Microphone, Radio, Rating, Slider, Text input, Timer, Toggle, and Video controls.

Text – Text that appears on a control or that the user types into a control.

- Applies to Add picture, Button, Check box, Export, Import, Label, Text input, and Timer controls.

Tooltip – Explanatory text that appears when the user hovers over a control.

- Applies to Audio, Button, Camera, Check box, Combo box, Drop down, HTML text, Image, Label, List Box, Microphone, PDF viewer, Pen input, Radio, Rating, Slider, Text input, Timer, Toggle, and Video controls.

Value – The value of an input control.

- Applies to Check box, Radio, Slider, and Toggle controls.

Visible – Whether a control appears or is hidden.

- Applies to Add picture, Audio, Button, Camera, Card, Check box, Column chart, Combo box, Date Picker, Display form, Drop down, Edit form, Export, Gallery, HTML text, Icon, Image, Import, Label, Line chart, List Box, Microphone, PDF viewer, Pen input, Pie chart, Radio, Rating, Rich text editor, Shape, Slider, Text input, Timer, Toggle, and Video controls.

Image properties in Power Apps

Article • 12/16/2022

Configure graphical elements in your app, including images, photos, and elements of a pen control.

BackgroundImage – The name of an image file that appears in the background of a screen.

- Applies to the **Screen** control.

Image – The name of the image that appears in an image, audio, or microphone control.

- Applies to **Audio**, **Image**, **Microphone**, and **Video** controls.

ImagePosition – The position (**Fill**, **Fit**, **Stretch**, **Tile**, or **Center**) of an image in a screen or a control if it isn't the same size as the image.

- Fill - Fills the entire specified size with the image. Scales the image proportionally. Crops the image as needed.
- Fit - Fits the entire image into the specified size. Scales the image proportionally. Doesn't crop the image.
- Stretch - Fills the entire specified size with the image. Stretches the image disproportionately as needed. Doesn't crop the image.
- Tile - Repeats the image across the control into the specified size. Doesn't scale the image. Crops the image as needed.
- Center - Places the image in the center of the control. Doesn't scale the image. Crops the image as needed.

- Applies to **Audio**, **Image**, **Microphone**, **Screen**, and **Video** controls.

Size and location properties in Power Apps

Article • 05/25/2023

Overview

Configure how big a control (or an element of a control) is and where it is in relation to the screen it's on.

Position

X – The distance between the left edge of a control and the left edge of its parent container (screen if no parent container). For a **Card** control in a container that has multiple columns, this property determines the column in which the card appears.

- Applies to **Add picture**, **Audio**, **Button**, **Camera**, **Card**, **Check box**, **Column chart**, **Date Picker**, **Display form**, **Drop down**, **Edit form**, **Export**, **Gallery**, **HTML text**, **Icon**, **Image**, **Import**, **Label**, **Line chart**, **List Box**, **Microphone**, **PDF viewer**, **Pen input**, **Pie chart**, **Radio**, **Rating**, **Shape**, **Slider**, **Text input**, **Timer**, **Toggle**, and **Video** controls.

Y – The distance between the top edge of a control and the top edge of the parent container (screen if no parent container). For a **Card** control in a container that has multiple rows, this property determines the row in which the card appears.

- Applies to **Add picture**, **Audio**, **Button**, **Camera**, **Card**, **Check box**, **Column chart**, **Date Picker**, **Display form**, **Drop down**, **Edit form**, **Export**, **Gallery**, **HTML text**, **Icon**, **Image**, **Import**, **Label**, **Line chart**, **List Box**, **Microphone**, **PDF viewer**, **Pen input**, **Pie chart**, **Radio**, **Rating**, **Shape**, **Slider**, **Text input**, **Timer**, **Toggle**, and **Video** controls.

Size

Height – The distance between a control's top and bottom edges.

- Applies to **Add picture**, **Audio**, **Button**, **Camera**, **Card**, **Check box**, **Column chart**, **Date Picker**, **Display form**, **Drop down**, **Edit form**, **Export**, **Gallery**, **HTML text**, **Icon**, **Image**, **Import**, **Label**, **Line chart**, **List Box**, **Microphone**, **PDF viewer**, **Pen**

input, Pie chart, Radio, Rating, Shape, Slider, Text input, Timer, Toggle, and Video controls.

AutoHeight – Whether a control automatically changes its height to fit the size of its contents, given a fixed width.

Not supported in Horizontal containers because the control's width is not fixed. In Vertical containers, the **Fill portions** and **Minimum width** properties take precedence over **Autoheight**.

- Applies to Label and HTML text

Width – The distance between a control's left and right edges.

- Applies to Add picture, Audio, Button, Camera, Card, Check box, Column chart, Date Picker, Display form, Drop down, Edit form, Export, Gallery, HTML text, Icon, Image, Label, Import, Line chart, List Box, Microphone, PDF viewer, Pen input, Pie chart, Radio, Rating, Shape, Slider, Text input, Timer, Toggle, and Video controls.

WidthFit – Whether a control automatically grows horizontally to fill any empty space of a container control such as an Edit form control. If multiple cards have this property set to **true**, the space is divided between them. For more information, see Understand data form layout.

- Applies to Card

Padding

Padding – The distance between the text on an import or export button and the edges of that button.

- Applies to Add picture, Export, and Import controls.

PaddingBottom – The distance between text in a control and the bottom edge of that control.

- Applies to Button, Check box, Column chart, Date Picker, Drop down, HTML text, Image, Label, Line chart, List Box, PDF viewer, Radio, and Text input controls.

PaddingLeft – The distance between text in a control and the left edge of that control.

- Applies to Button, Check box, Column chart, Date Picker, Drop down, HTML text, Image, Label, Line chart, List Box, PDF viewer, Radio, and Text input controls.

PaddingRight – The distance between text in a control and the right edge of that control.

- Applies to **Button**, **Check box**, **Column chart**, **Date Picker**, **Drop down**, **HTML text**, **Image**, **Label**, **Line chart**, **List Box**, **PDF viewer**, **Radio**, and **Text input** controls.

PaddingTop – The distance between text in a control and the top edge of that control.

- Applies to **Button**, **Check box**, **Column chart**, **Date Picker**, **Drop down**, **HTML text**, **Image**, **Label**, **Line chart**, **List Box**, **PDF viewer**, **Radio**, and **Text input** controls.

Radius

RadiusBottomLeft – The degree to which the bottom-left corner of a control is rounded.

- Applies to **Button**, **Export**, **Image**, **Import**, and **Text input** controls.

RadiusBottomRight – The degree to which the bottom-right corner of a control is rounded.

- Applies to **Button**, **Export**, **Image**, **Import**, and **Text input** controls.

RadiusTopLeft – The degree to which the top-left corner of a control is rounded.

- Applies to **Button**, **Export**, **Image**, **Import**, and **Text input** controls.

RadiusTopRight – The degree to which the top-right corner of a control is rounded.

- Applies to **Button**, **Export**, **Image**, **Import**, and **Text input** controls.

Text properties in Power Apps

Article • 12/16/2022

Configure the text that appears on a control, as a hint when the user types data, and specify other text-related characteristics.

Text appearance

Font – The name of the family of fonts in which text appears.

- Applies to **Add picture**, **Button**, **Check box**, **Column chart**, **Date Picker**, **Drop down**, **Export**, **HTML text**, **Import**, **Label**, **Line chart**, **List Box**, **Pie chart**, **Radio**, **Text input**, and **Timer** controls.

FontWeight – The weight of the text in a control: **Bold**, **Semibold**, **Normal**, or **Lighter**.

- Applies to **Add picture**, **Button**, **Check box**, **Date Picker**, **Drop down**, **Export**, **Import**, **Label**, **List Box**, **Radio**, **Text input**, and **Timer** controls.

Italic – Whether the text in a control is italic.

- Applies to **Add picture**, **Button**, **Check box**, **Date Picker**, **Drop down**, **Export**, **Import**, **Label**, **List Box**, **Radio**, **Text input**, and **Timer** controls.

Size – The font size of the text that appears on a control.

- Applies to **Add picture**, **Button**, **Check box**, **Column chart**, **Date Picker**, **Drop down**, **Export**, **HTML text**, **Import**, **Label**, **Line chart**, **List Box**, **Pen input**, **Pie chart**, **Radio**, **Text input**, and **Timer** controls.

Strikethrough – Whether a line appears through the text that appears on a control.

- Applies to **Add picture**, **Button**, **Check box**, **Drop down**, **Export**, **Import**, **Label**, **List Box**, **Radio**, **Text input**, and **Timer** controls.

Underline – Whether a line appears under the text that appears on a control.

- Applies to **Add picture**, **Button**, **Check box**, **Drop down**, **Export**, **Import**, **Label**, **List Box**, **Radio**, **Text input**, and **Timer** controls.

Text placement

Align – The location of text in relation to the horizontal center of its control.

- Applies to **Add picture**, **Button**, **Export**, **Import**, **Label**, **Radio**, **Text input**, and **Timer** controls.

LineHeight – The distance between, for example, lines of text or items in a list.

- Applies to **List Box**, **Label**, **Radio**, and **Text input** controls.

VerticalAlign – The location of text on a control in relation to the vertical center of that control.

- Applies to **Add picture**, **Button**, **Check box**, **Export**, **Import**, and **Label** controls.

Building responsive canvas apps

Article • 12/16/2022

Responsiveness refers to the ability of an app to automatically align to different screen sizes and form factors to use the available screen space sensibly, providing great UI and UX in every device, form factor, and screen size.

Responsiveness allows different elements of the app to specify how they:

- Stretch or resize with the screen size changes.
- Maintain or change positions with the screen size changes.

Why should you build responsive apps

End users can access your app from different devices such as phones, tablets, laptops, and desktops with large monitors, different screen sizes, and with varied number of pixels.

To ensure great user experience and usability of the app on each form factor and device, designing the app with responsive design principles is necessary. Even if the app is intended to be used only on the web browser or on mobile phones, user device screen sizes can be different, so designing the app with responsive principles is a good idea.

Designing the app with responsiveness principles

Before you start designing the UI for your app, you need to consider the following aspects:

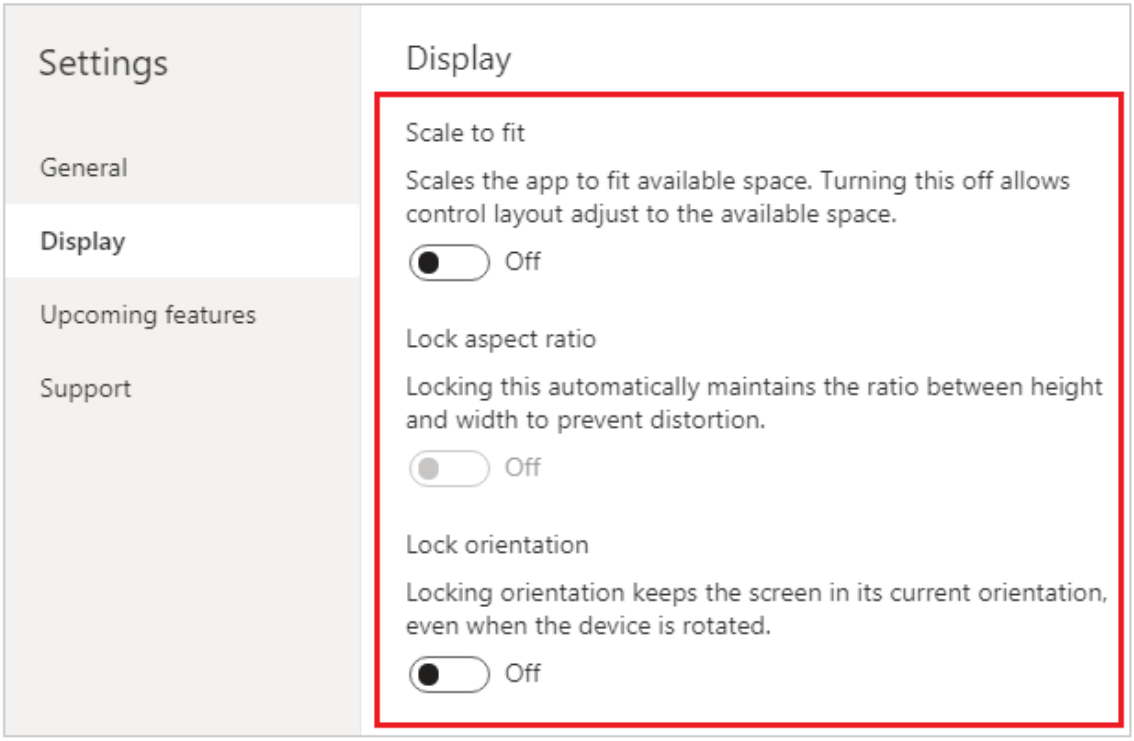
- What form factors or devices do you want to support.
- How the app should look on each form factor?
- What elements of the app need to stretch or resize?
- Are the elements hidden on some form factors?
- Does the app behave different in some form factors?

Once all these requirements are gathered, you should start thinking about how these different UI layouts can be created in a single application with the responsive tools

available in Power Apps.

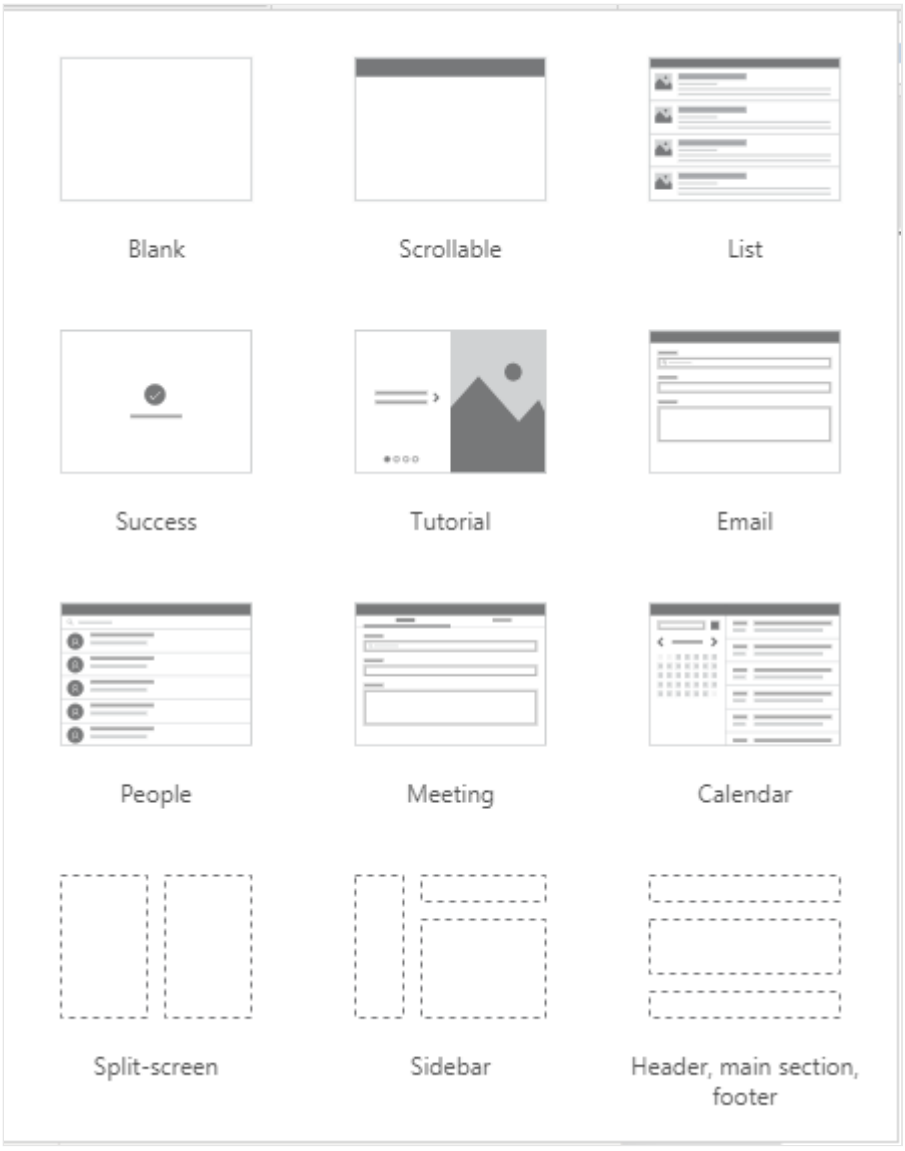
Before you start using the responsive layouts, you need to do the following:

1. Go to Power Apps.
2. Open the app where you want to use the responsive layout.
3. Go to **Settings** > **Display** to disable **Scale to fit**, **Lock aspect ratio**, and **Lock orientation** and select **Apply**.



Responsive layouts

The following responsive layouts can be created by adding a new screen and selecting the appropriate option from the **Layout** tab:



> ⓘ **Note**
>
> The new responsive layouts are available to the apps formats but the new screen templates are available only for **Tablet** format.

Split-screen

The Split-screen layout has two sections, each occupying 50% width of the screen on desktops. On mobile devices, the sections are placed one below the other, each occupying up the entire screen width.

Sidebar

The Sidebar layout has a fixed width sidebar on the left. The main body consists of a fixed height header, and the main section takes up the rest of the screen width. By

default, the template has the same behavior on mobile, however some customizations are recommended based on the UI pattern desired for the mobile experience.

Working with containers

Containers are building blocks of all the responsive design. A container can be an auto-layout container in vertical or horizontal direction, or a fixed-layout container, which in the future will support constraints.

Below are some tips for building your app's UI with containers:

- Always create UI elements that form a UI table inside a container.
- Allows the container to have its own responsive properties and settings to specify how it is positioned or resized on different screen sizes.
- Allows you to change how its child components are laid out with respect to responsiveness.

Choose one of two layout modes for a container: Manual layout or auto-layout (Horizontal or Vertical)

Auto-layout containers

Two controls, Horizontal container and Vertical container can be used to automatically lay out the child components. These containers determine the position of the child components so that you never have to set X, Y for a component inside the container. Also, it can distribute the available space to its child components based on the settings, as well as determines both the vertical and horizontal alignment of the child components.

When to use auto-layout containers

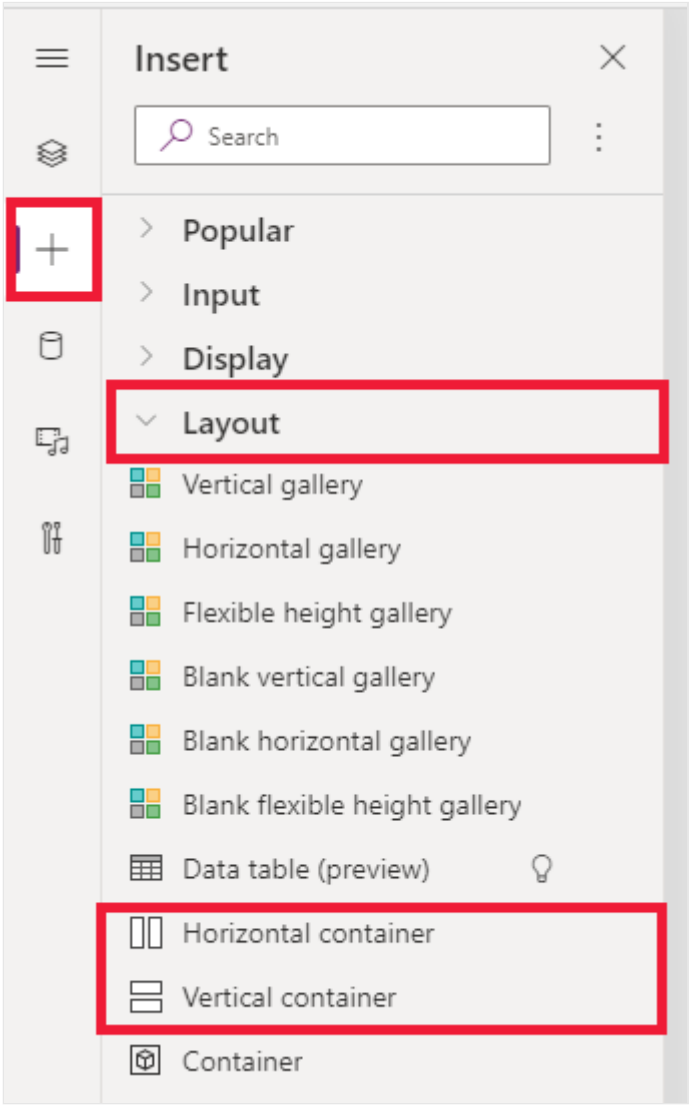
You can use auto-layout containers in the following scenarios:

- UI needs to be responsive to screen size or form factor changes.
- There is more than one child component that needs to resize or move around based on the screen size or form factor changes.
- When you need to stack items vertically or horizontally (regardless of their size).
- When you need to space items evenly on the screen.

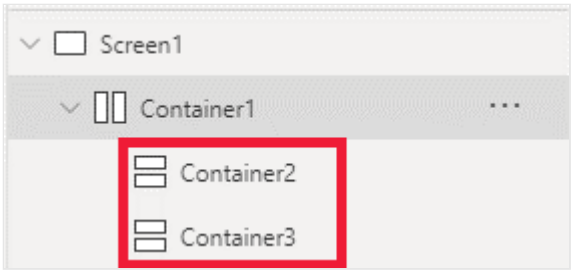
Example for auto-layout container

To build a responsive screen:

1. Create a blank canvas app with **Tablet** layout.
2. Select **Settings** > **Display** and disable **Scale to fit**, **Lock aspect ratio**, and **Lock orientation** and select **Apply**.
3. Now from the **Insert** panes in the left sidebar, under **Layout** tab, select **Horizontal container**.



4. The top-most container needs to be sized to take the entire space with these properties. It will be the same size as the screen as it resizes.
   a. X = 0
   b. Y= 0
   c. Width = Parent.Width
   d. Height = Parent. Height
5. Now, from the **Insert** pane add two **Vertical containers** into the Horizontal container.

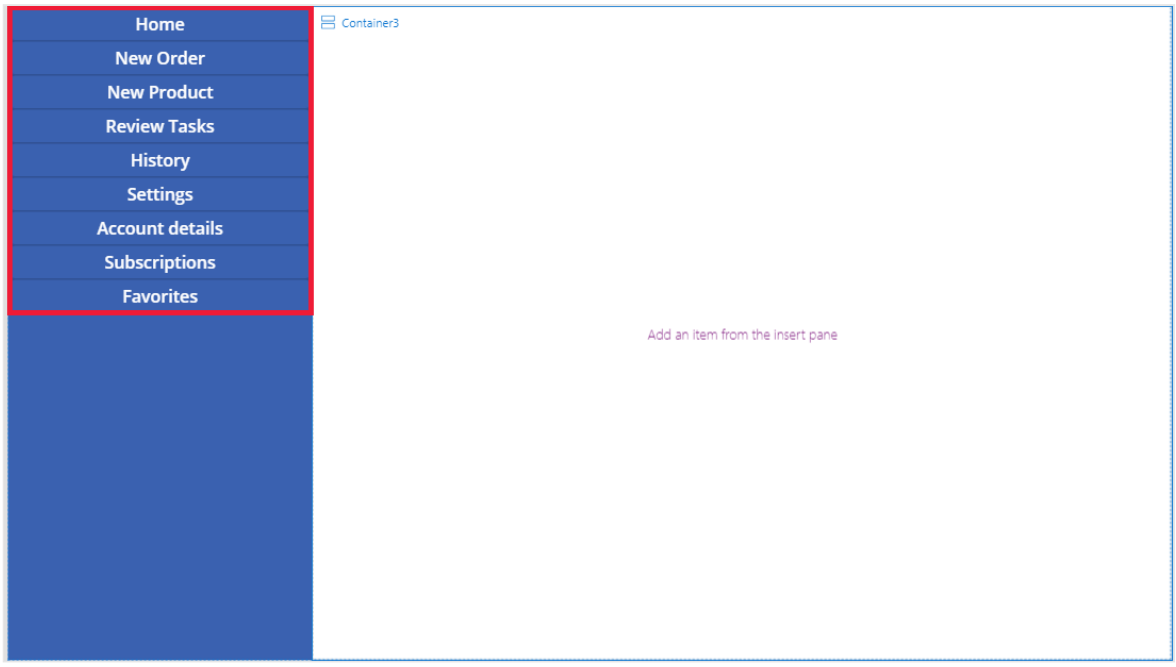


6. To make the containers, fill the full vertical space, Select **Container1** and set the `Align (vertical)` property to `Stretch`.

7. To divide the screen between the content, use the `Fill portions` property on the two child containers. The left container will take up 1/4 of the screen space.
   a. Select **Container2**. You'll see that the `Flexible width` property is turned on. Set the `Fill portions` to 1.
   b. Select **Container3**. You'll see that the `Flexible width` property is turned on. Set the `Fill portions` to 3.

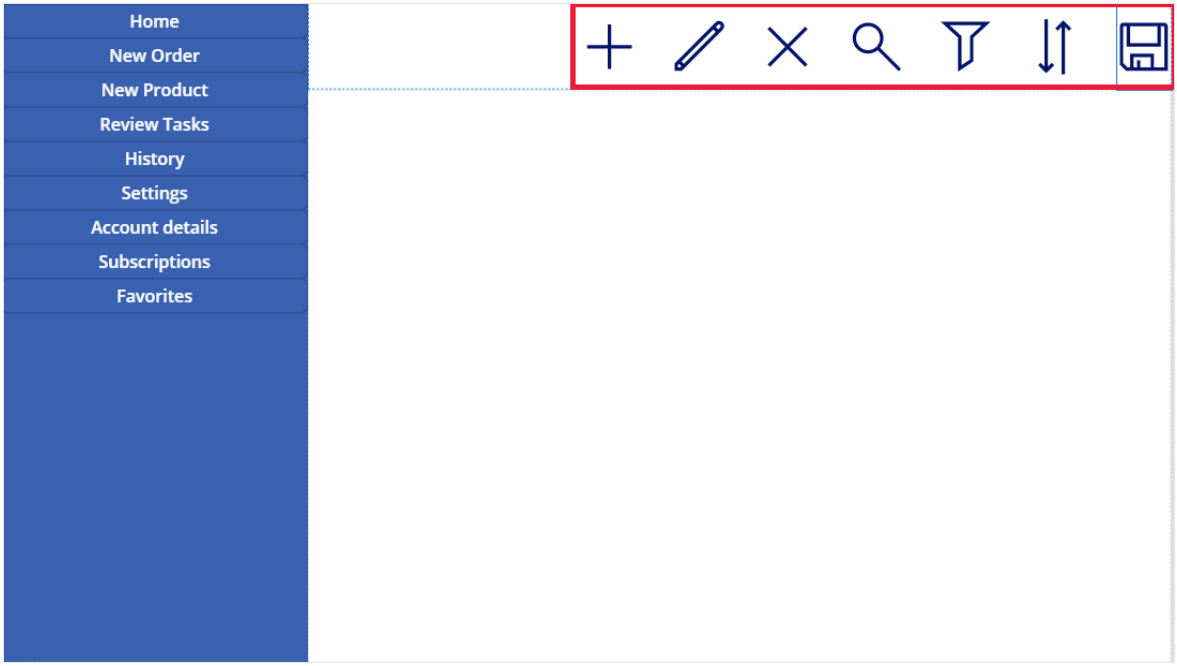
8. Select **Container2**. Set the `Fill = RGBA(56, 96, 178, 1)` property in the formula bar. Set `Align (horizontal)` to `Stretch`.

9. Add few buttons to create a menu. Rename the buttons as needed.



10. Select **Container3** and add a Horizontal container and turn off the `Flexible height` property. Set `Height` to 100. Set `Align (vertical)` to `Stretch`.

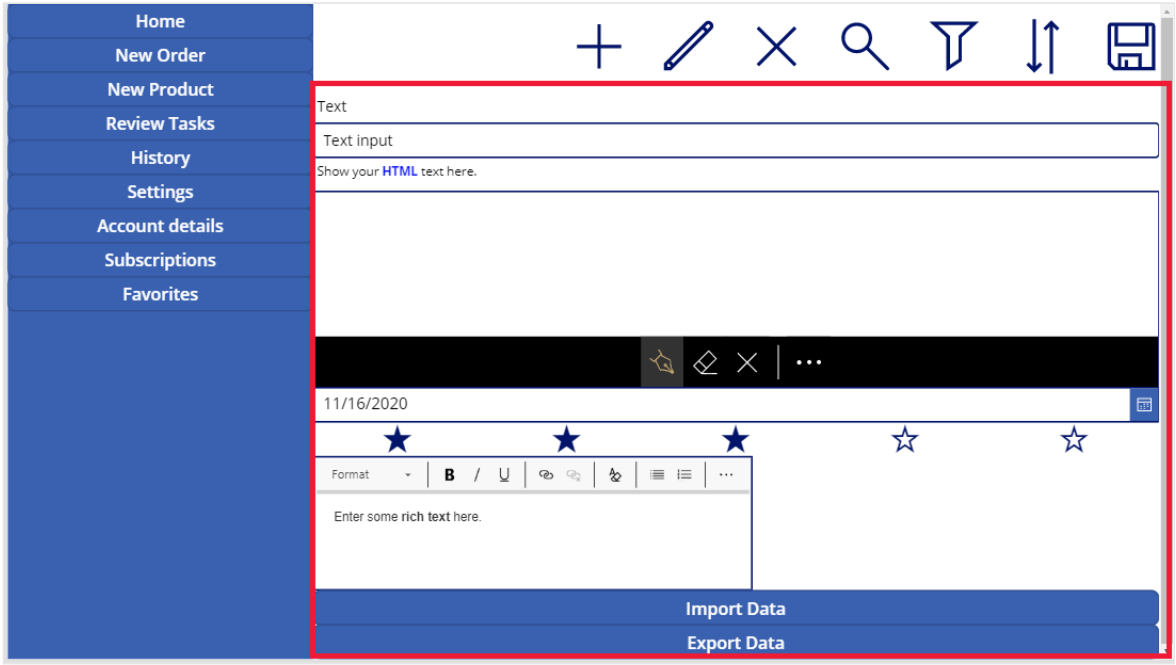
11. Add some **Icons** into **Container4**. Change the icons to be different with the icon property.



12. Select **Container4**. Set the `Justify (horizontal)` property to `End`. Set the `Align (vertical)` to `Center`. Set `Gap` to 40 to create space between the icons.

13. Select **Container3**. Set `Align (horizontal)` to `Stretch`. Set `Vertical Overflow` to `Scroll`.

14. Add different **Label**, **Inputs**, **Media** until they extend beyond the container. Change the color of the rectangles to be different. You'll see a scroll bar to access the unseen content.



15. Select Preview or F5. Change the size of the browser window to see how your app adjusts to different screen sizes.

Known issues

- Certain combinations of layout container properties are incompatible or can produce undesirable outputs, for example:
  - If the container's `Wrap` property is enabled, the `Align` property setting is ignored on child controls.
  - If the container's `Wrap` property is disabled and the container's primary-axis overflow is set to **Scroll** (Horizontal Overflow for Horizontal containers or Vertical Overflow for Vertical containers), it is recommended to set the `Justify` property to either **Start** or **Space Between**.
  - The **Center** or **End** options can cause child controls inaccessible when the container is too small to display all the controls, even though the `Overflow` property is set to **Scroll**.

- You can't resize or reposition the controls on the canvas app because the drag & drop controls are disabled in the layout containers. Instead, use the layout container properties to achieve the desired size and positioning. Control ordering can be changed via the **Tree view**, or by using the arrow keys as shortcuts.

- The **Data table**, **Charts**, and **Add Picture** controls are currently not supported in the layout containers.

- Some of the layout containers properties are hidden for child controls. The hidden properties can still be accessible via the formula bar or from the advanced panel. However, these properties will be ignored even if they are set in these places.

- When controls are moved into a layout container (for example, when copy or pasting the controls), they are inserted into the container by their order in the **Tree view**.

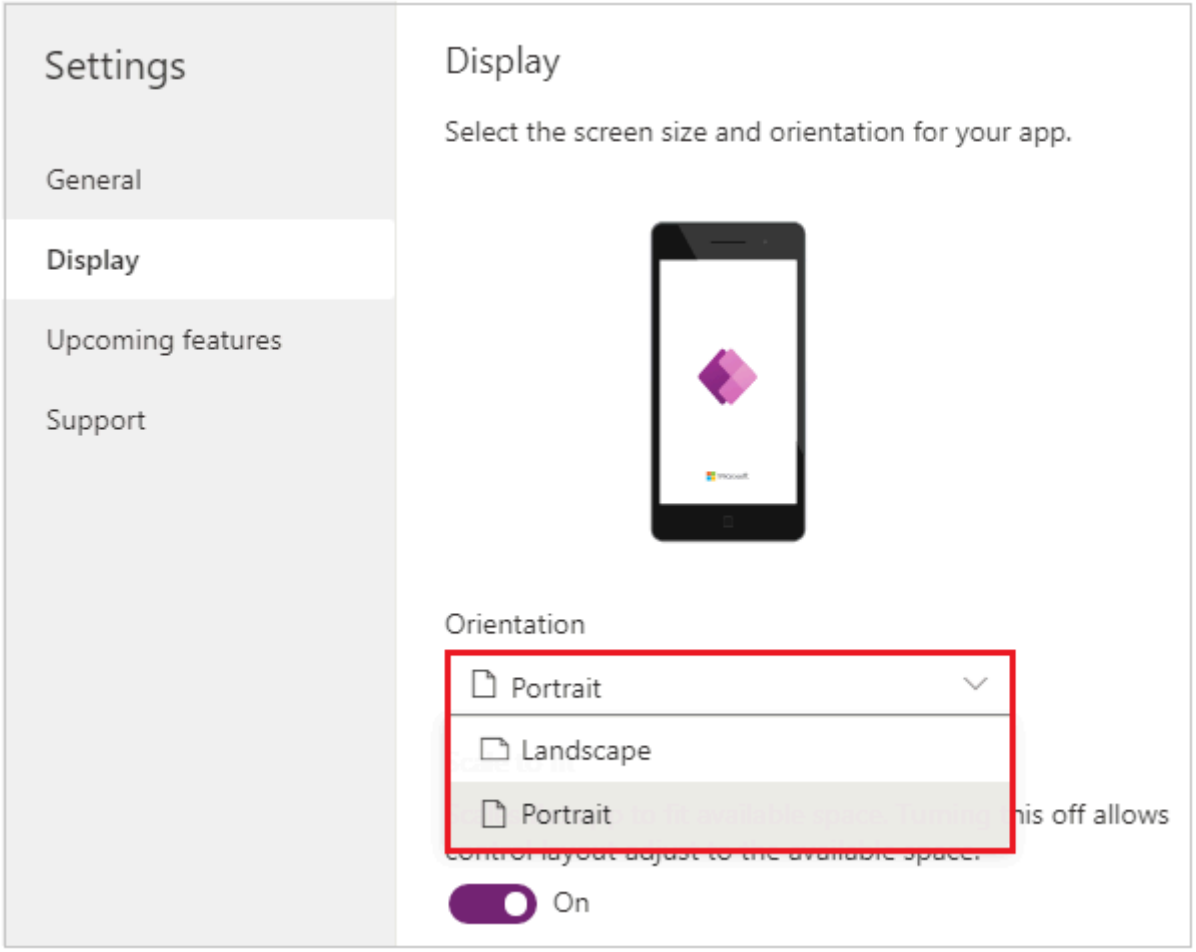
Change screen size and orientation of canvas apps

Article • 05/21/2025

Customize a canvas app by changing its screen size and orientation.

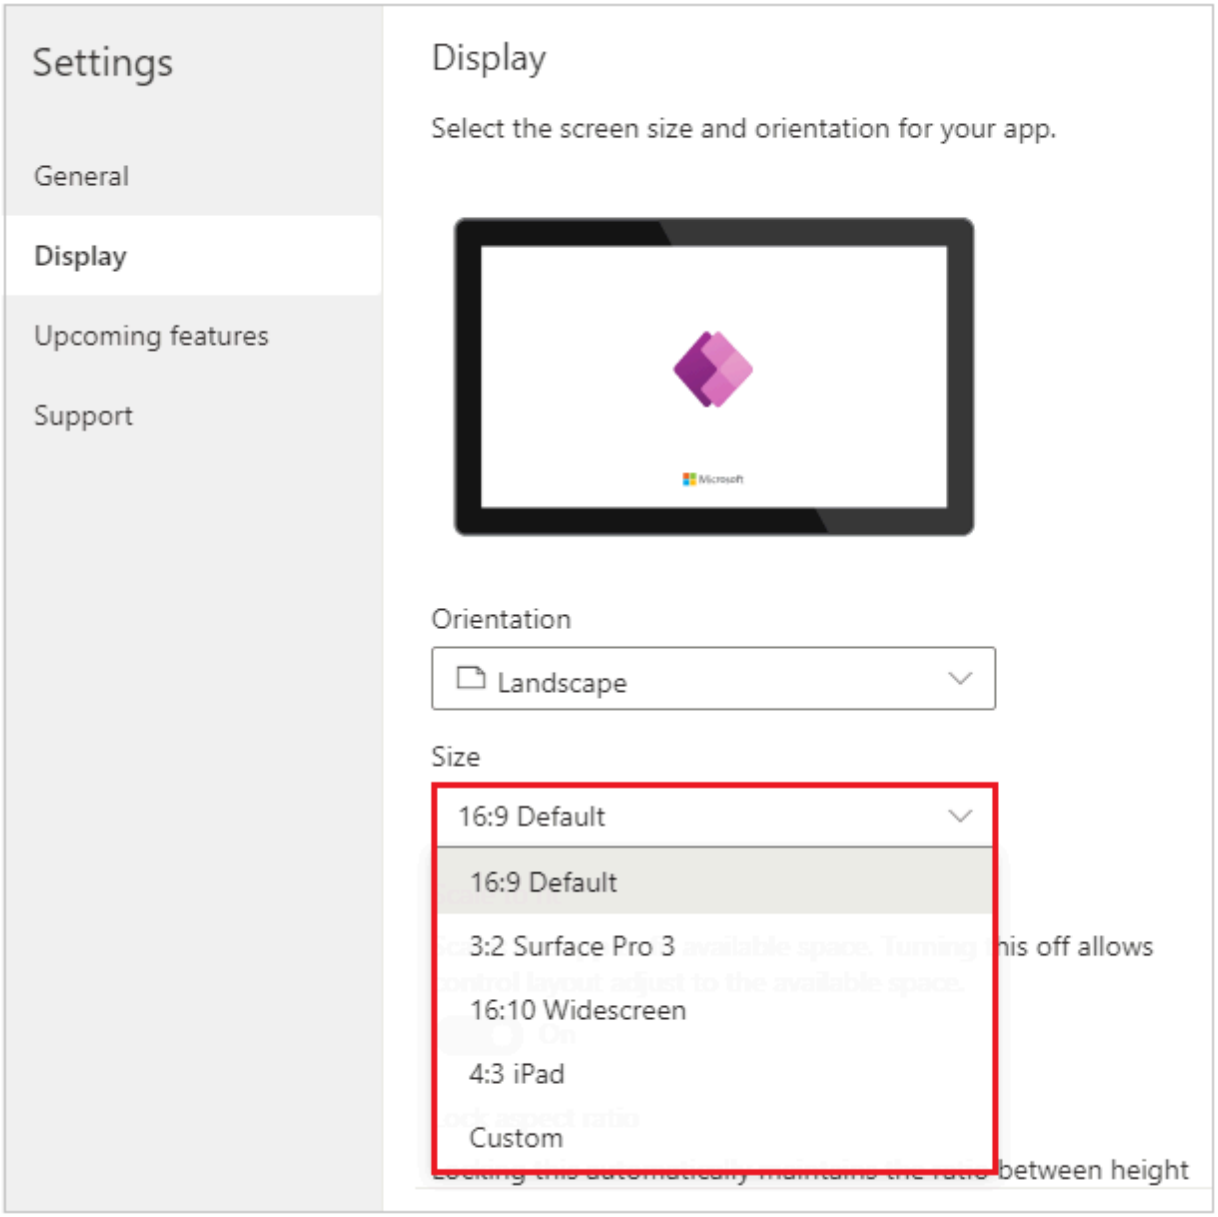
Change screen size and orientation

1. Sign in to Power Apps.
2. Open the app to edit.
3. Select **Settings**.
4. Select **Display**.
5. Under **Orientation** list, select **Portrait** or **Landscape**.



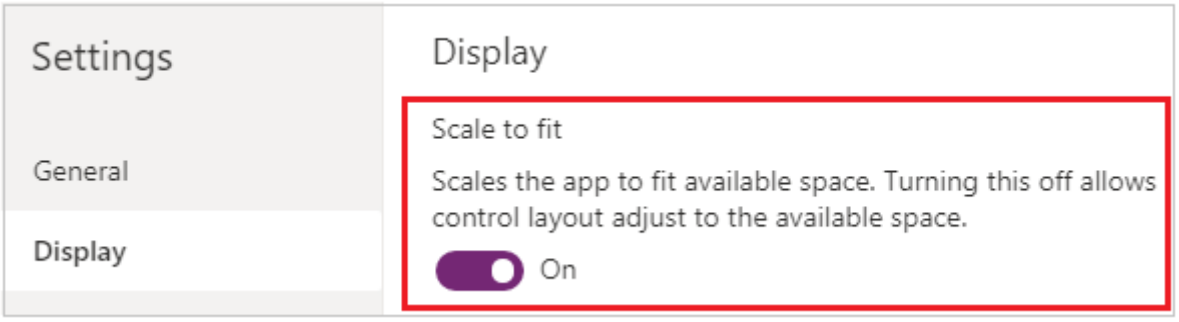
6. (Tablet apps only) Under **Aspect ratio**, perform either of these steps:
   - Select the ratio that matches the target device for this app.

- Select **Custom** to set your own size, and then specify a width between 50 - 3840 and a height between 50 - 2160.



> ⓘ **Note**
>
> **Size** is only available for apps with **Tablet** layout.

7. Under **Scale to fit**, specify either **On** or **Off**.

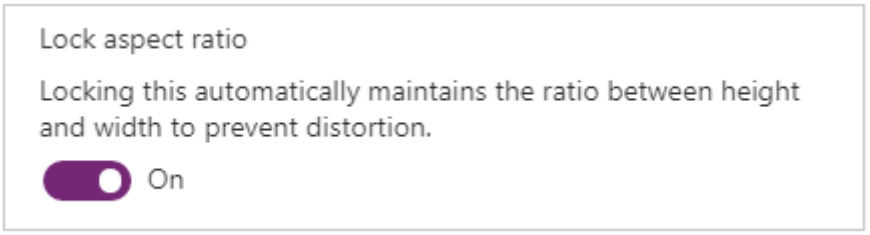


This setting is on by default so that app screens resize to fit the available space on the device. When this setting is on, the app's **Width** property matches its **DesignWidth**, and the app's **Height** matches its **DesignHeight**.

If you turn this setting off, the app adjusts to the aspect ratio of the device on which it's running and takes up all of the available space. The app doesn't scale and, as a result, screens can show more information.

When this setting is turned off, **Lock aspect ratio** is automatically turned off and disabled. In addition, the **Width** property of all screens is set to `Max(App.Width, App.DesignWidth)`, and their **Height** property is set to `Max(App.Height, App.DesignHeight)` so that they track the dimensions of the window in which the app is running. With this change, you can create apps that respond to different devices and window dimensions. More information: Create responsive layout

8. Under **Lock aspect ratio**, specify either **On** or **Off**.



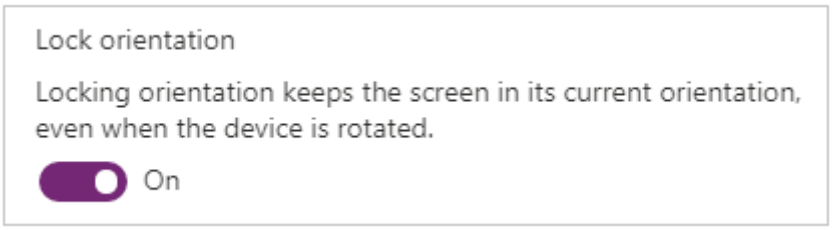
If this setting is on, the app retains the screen orientation and aspect ratio that you specified in steps 2 and 3, no matter the device. For example, a phone app that's running in a web browser retains the ratio for a phone, showing a dark bar on each side instead of filling the window.

If this setting is off, the app adjusts to the aspect ratio of the device on which it's running. We don't recommend this because the app can be distorted to the point of being unusable, depending on the screen size. For example, controls may overlap or text might be clipped.

> **Note**

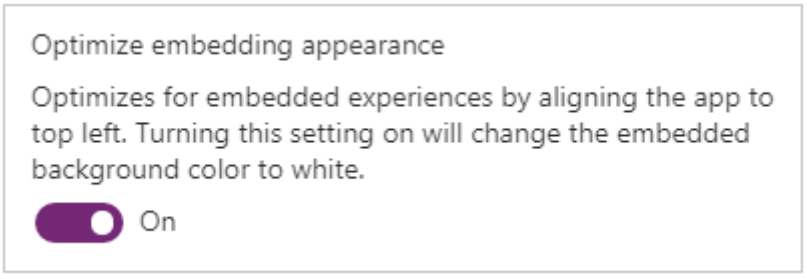
This setting can't be turned off for certain controls such as Rich text editor and Fluent UI controls. They won't distort according to screen size. Create a responsive layout to specify how these controls should adapt to different screen sizes.

9. Under **Lock orientation**, specify either **On** or **Off**.



If you lock the app's orientation, the app retains the orientation that you specify. If the app is running on a device for which the screen is in a different orientation, the app displays incorrectly and may show unwanted results. If you unlock the app's orientation, it adjusts to the screen orientation of the device on which it's running.

You can also modify the app's orientation by enabling **Optimize embedding appearance** in **Settings** > **Display**. This feature top-left aligns the app when it's embedded and changes the background color of the hosting canvas to white.



10. Close **Settings** dialog.

11. Save and publish your app.

Enumerated app behavior for scale to fit and lock aspect ratio settings

Expand table

Scenario	Scale to fit	Lock aspect ratio	App layout behavior on 'screen resize'	Notes to include in docs
1	Enabled	Enabled	The screen width and height are set by the maker. The screen scales to the	

Scenario	Scale to fit	Lock aspect ratio	App layout behavior on 'screen resize'	Notes to include in docs
			window size available.	
2	Disabled	Enabled	Not applicable. When scale to fit is disabled, lock aspect ratio is also disabled.	
3	Enabled	Disabled	In Power Apps Studio, the screen scales to the window size available. In the end-user experience, Power Apps scales to the smallest edge (width or height), and then fills the UI for the larger edge.	For apps built for mobile, we recommend makers use **lock orientation** with this setting.
4	Disabled	Disabled	App experiences can be responsive. Makers can manipulate control locations using Power Fx to set X and Y values as well as width and height.	For more information, see Responsive layout documentation and consider using auto-layout containers.

Create responsive layouts in canvas apps

Summarize this article for me

Before you building a canvas app in Power Apps, specify whether to tailor the app for a phone or a tablet. This choice determines the size and shape of the canvas on which you build your app.

After you make that choice, you can make a few more choices if you select **Settings** > **Display**. You can choose portrait or landscape orientation and screen size (tablet only). You can also lock or unlock the aspect ratio and support device rotation (or not).

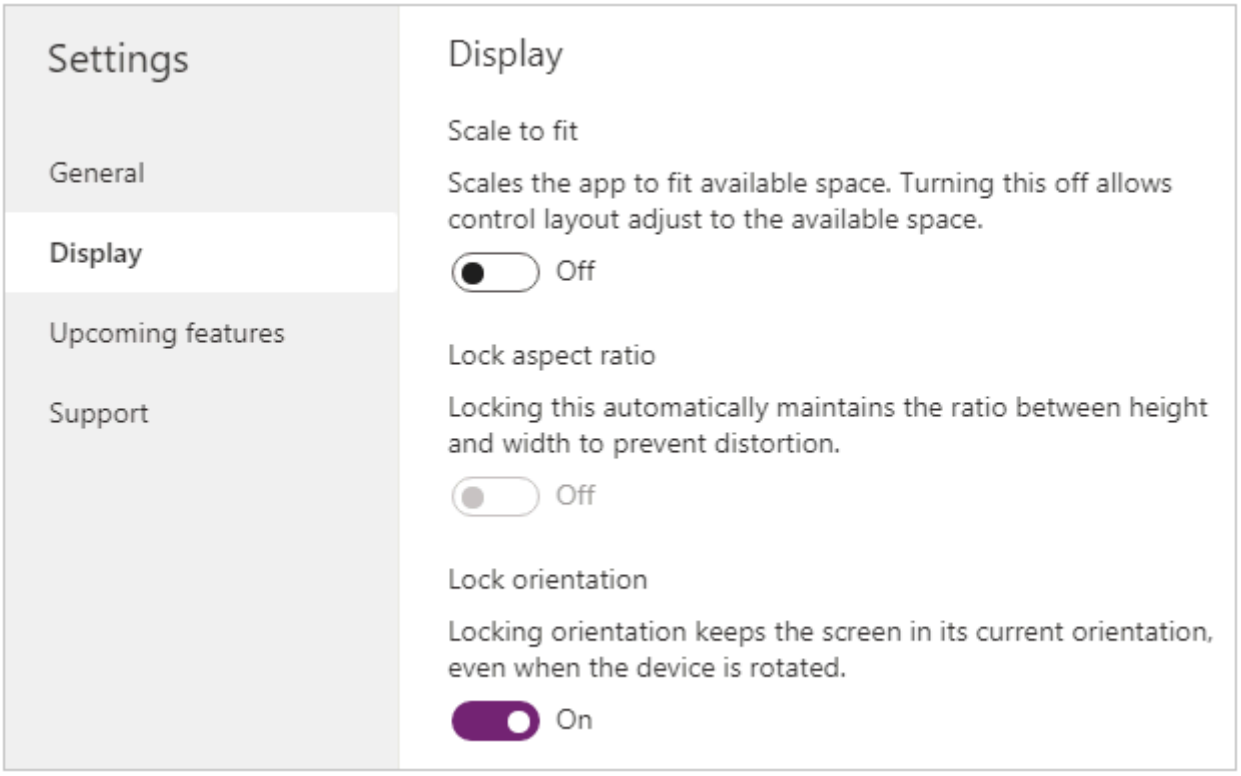
Those choices underlie every other choice you make as you design screen layouts. If your app runs on a device of a different size or on the web, your entire layout scales to fit the screen where the app is running. If an app designed for a phone runs in a large browser window, for example, the app scales to compensate and looks oversized for its space. The app can't take advantage of the additional pixels by showing more controls or more content.

If you create a responsive layout, controls can respond to different devices or window sizes, making various experiences feel more natural. To achieve a responsive layout, you adjust some settings and write expressions throughout your app.

Disable Scale to fit

You can configure each screen control so that its layout adapts to the actual space in which the app is running.

You activate responsiveness by turning off the app's **Scale to fit** setting, which is on by default. When you turn this setting off, you also turn off **Lock aspect ratio** because you're no longer designing for a specific screen shape. (You can still specify whether your app supports device rotation.)



To make your app responsive, you must take additional steps, but this change is the first step toward making responsiveness possible.

Understand app and device screen dimensions

To make your app's layouts respond to changes in the device screen, or web browser, dimensions, you'll write formulas that use the **Width** and **Height** properties of the screen. To show these properties, open an app in Power Apps Studio, and then select a screen control. The default formulas for these properties appear on the **Advanced** tab of the right-hand pane.

Width = `Max(App.Width, App.MinScreenWidth)`

Height = `Max(App.Height, App.MinScreenHeight)`

These formulas refer to the **Width**, **Height**, **MinScreenWidth**, and **MinScreenHeight** properties of the app. The app's **Width** and **Height** properties correspond to the dimensions of the device or browser window in which your app is running. If the user resizes the browser window (or rotates the device if you've turned off **Lock orientation**), the values of these properties change dynamically. The formulas in the screen control's **Width** and **Height** properties are reevaluated when these values change.

The values in the **App.Width** and **App.Height** properties come from the dimensions that you specify in the **Display** pane of **Settings**. For example, if you select the landscape "16:9 Default" size, **App.Width** is 1366, and **App.Height** is 768.

As they're used in the formulas for the screen control's **Width** and **Height** properties, **MinScreenWidth** and **MinScreenHeight** are the minimum dimensions for which you'll design the app. If the actual area available to your app is even smaller than these minimum dimensions, the formulas for the screen control's **Width** and **Height** properties ensure that their values won't become any smaller than minimums. In that case, the user must scroll to view all of the layout's content. The **MinScreenWidth** and **MinScreenHeight** properties can be set in the **App Object** > **Properties** > **Advanced**.

After you establish your app's **MinScreenWidth** and **MinScreenHeight**, you won't (in most cases) need to change default formulas for each screen control's **Width** and **Height** properties. Later, this topic discusses cases in which you might want to customize these formulas.

Use formulas for dynamic layout

To create a responsive design, you locate and size each control by using formulas instead of absolute (constant) coordinate values. These formulas express each control's position and size in terms of the overall screen size or relative to other controls in the current screen.

> **Important**
>
> After you write formulas for the **X**, **Y**, **Width** and **Height** properties of a control, your formulas will be overwritten with constant values if you subsequently drag the control in the canvas editor. When you start to use formulas to achieve dynamic layout, you should avoid dragging controls.

In the simplest case, one control fills an entire screen. To create this effect, set the control's properties to these values:

Expand table

Property	Value
X	`0`
Y	`0`
Width	`Parent.Width`
Height	`Parent.Height`

These formulas use the **Parent** operator. For any control placed directly on a screen, **Parent** refers to the screen. With these property values, the control appears in the upper-left corner of the screen (0, 0) and has the same **Width** and **Height** as the screen.

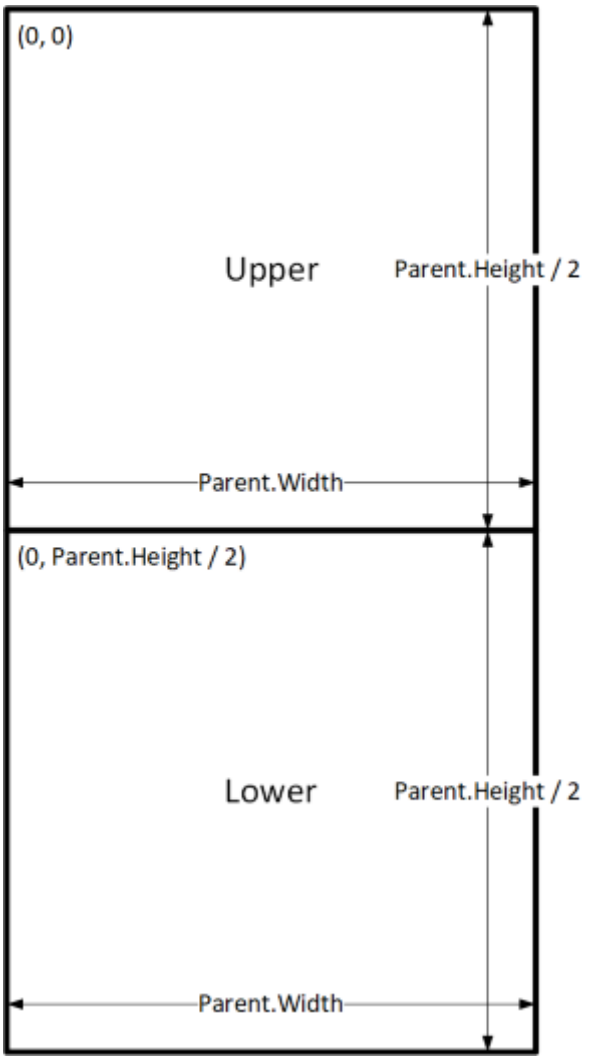
Later in this topic, you'll apply these principles (and the **Parent** operator) to position controls inside other containers, such as galleries, group controls, and components.

As an alternative, the control can fill only the top half of the screen. To create this effect, set the **Height** property to **Parent.Height** / 2, and leave the other formulas unchanged.

If you want a second control to fill the bottom half of the same screen, you can take at least two other approaches to constructing its formulas. For simplicity, you might take this approach:

Expand table

Control	Property	Formula
Upper	X	`0`
Upper	Y	`0`
Upper	Width	`Parent.Width`
Upper	Height	`Parent.Height / 2`
Lower	X	`0`
Lower	Y	`Parent.Height / 2`
Lower	Width	`Parent.Width`
Lower	Height	`Parent.Height / 2`



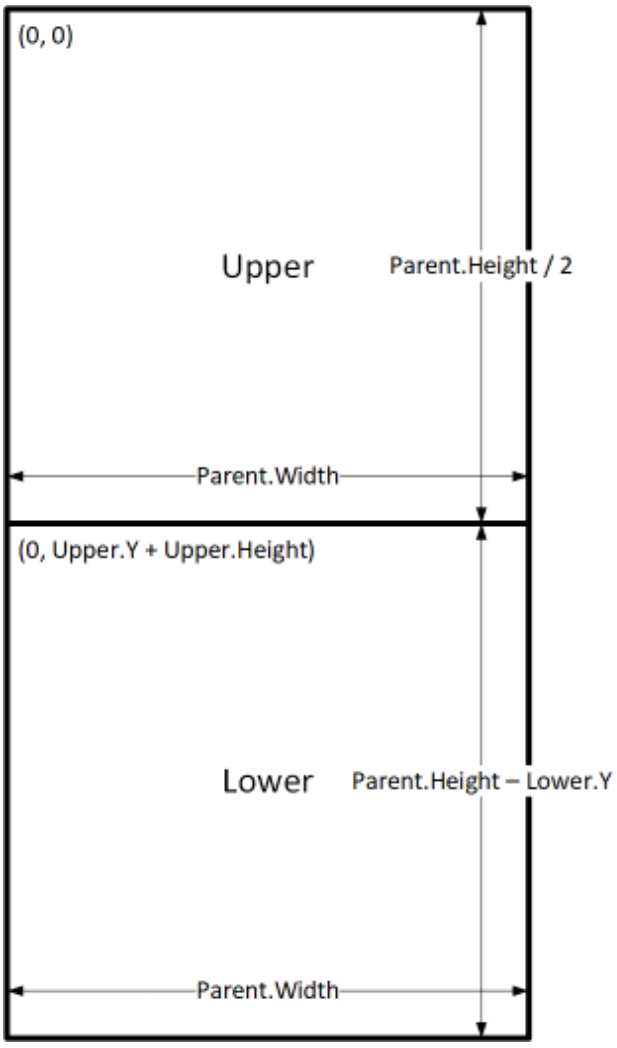
This configuration would achieve the effect that you want, but you'd need to edit each formula if you changed your mind about the relative sizes of the controls. For example, you might decide that the top control should occupy only the top one-third of the screen, with the bottom control filling the lower two-thirds.

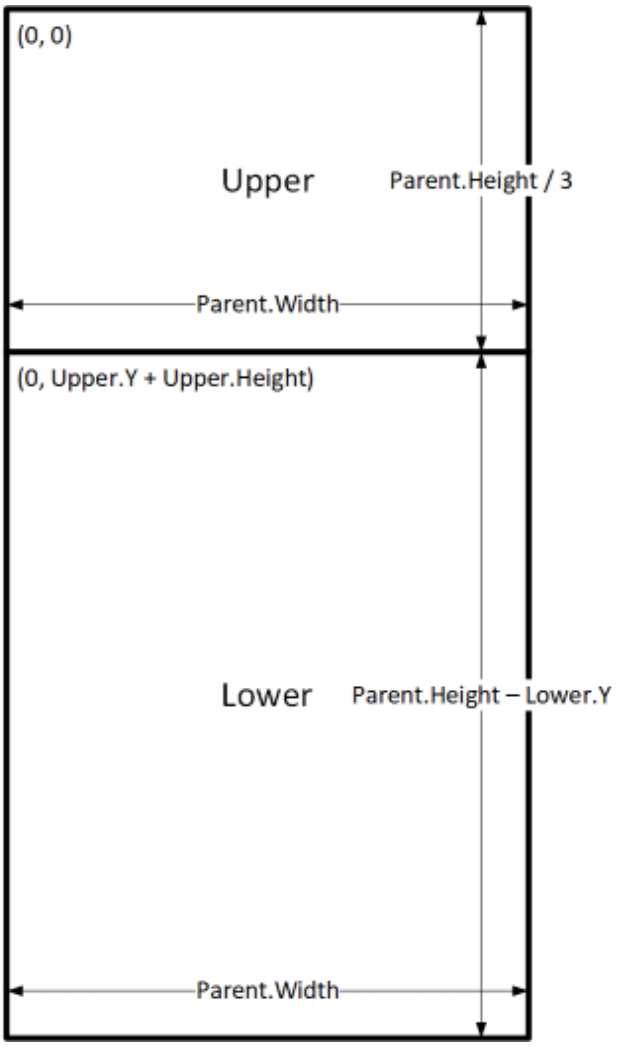
To create that effect, you'd need to update the **Height** property of the **Upper** control and the **Y** and **Height** properties of the **Lower** control. Instead, consider writing the formulas for the **Lower** control in terms of the **Upper** control (and itself), as in this example:

Expand table

Control	Property	Formula
Upper	X	`0`
Upper	Y	`0`
Upper	Width	`Parent.Width`
Upper	Height	`Parent.Height / 3`
Lower	X	`0`

Control	Property	Formula
Lower	Y	`Upper.Y + Upper.Height`
Lower	Width	`Parent.Width`
Lower	Height	`Parent.Height - Lower.Y`





With these formulas in place, you need only change the **Height** property of the **Upper** control to express a different fraction of the height of the screen. The **Lower** control automatically moves and resizes to account for the change.

You can use these formula patterns for expressing common layout relationships between a control, named **C**, and its parent or a sibling control, named **D**.

Expand table

Relationship between C and its parent	Property	Formula	Illustration
C fills width of parent, with a margin of *N*	**X**	`N`		Width	`Parent.Width - (N * 2)`	
C fills height of parent, with a margin of *N*	**Y**	`N`		Height	`Parent.Height - (N * 2)`	
C aligned with right edge of parent, with margin of *N*	**X**	`Parent.Width - (C.Width + N)`	C aligned with bottom edge of parent, with margin of *N*	**Y**	`Parent.Height - (C.Height + N)`	C centered horizontally on parent	**X**	`(Parent.Width - C.Width) / 2`	C centered vertically on parent	**Y**	`(Parent.Height - C.Height) / 2`	
Expand table

Relationship between C and D	Property	Formula	Illustration
C horizontally aligned with D and the same width as D	**X**	`D.X`	
Relationship between C and D	Property	Formula	Illustration
	Width	`D.Width`	
C vertically aligned with **D** and same height as **D**	**Y**	`D.Y`		Height	`D.Height`	
Right edge of **C** aligned with right edge of **D**	**X**	`D.X + D.Width - C.Width`	Bottom edge of **C** aligned with bottom edge of **D**	**Y**	`D.Y + D.Height - C.Height`	C centered horizontally relative to **D**	**X**	`D.X + (D.Width - C.Width) / 2`	C centered vertically relative to **D**	**Y**	`D.Y + (D.Height - C.Height) /2`	C positioned to the right of **D** with a gap of N	**X**	`D.X + D.Width + N`	C positioned below **D** with a gap of *N*	**Y**	`D.Y + D.Height + N`	C fills space between **D** and right edge of parent	**X**	`D.X + D.Width`	
Relationship between C and D	Property	Formula	Illustration
	Width	`Parent.Width - C.X`	
C fills space between **D** and bottom edge of parent	Y	`D.Y + D.Height`		Height	`Parent.Height - C.Y`	

Hierarchical layout

As you construct screens that contain more controls, it will become more convenient (or even necessary) to position controls relative to a parent control, rather than relative to the screen or a sibling control. By organizing your controls into a hierarchical structure, you can make your formulas easier to write and maintain.

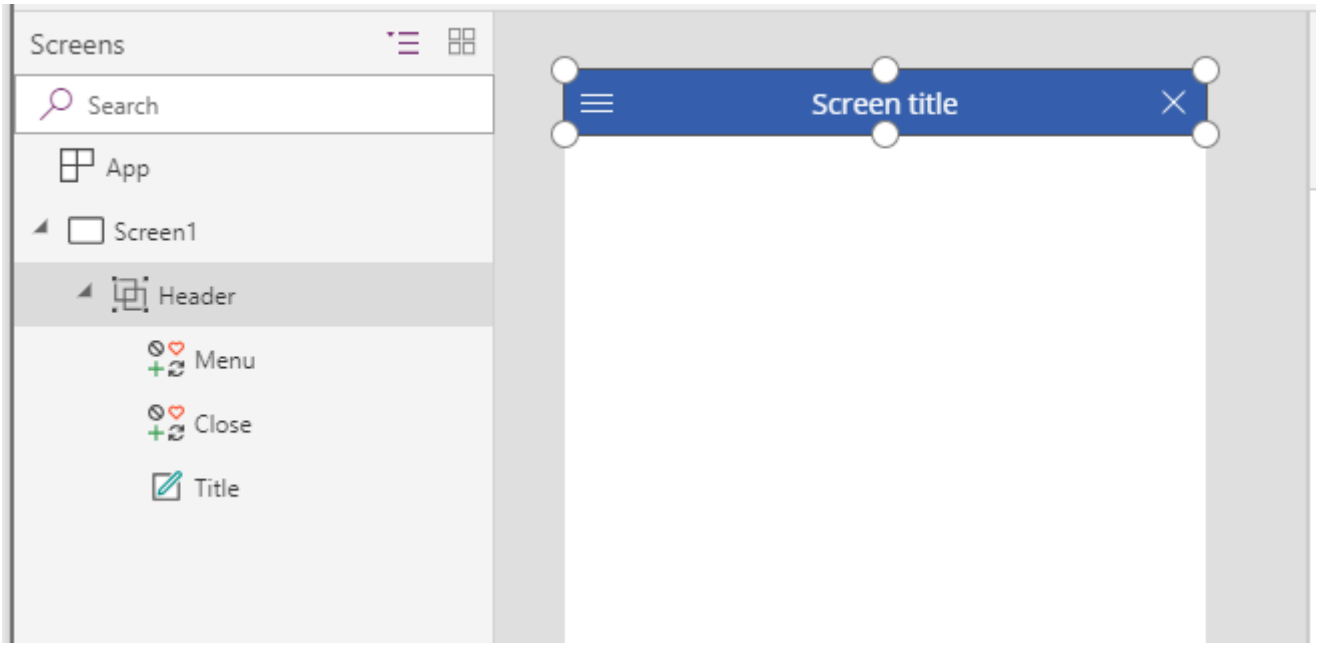
Galleries

If you use a gallery in your app, you'll need to lay out controls within the gallery's template. You can position these controls by writing formulas that use the **Parent** operator, which will refer to the gallery template. In the formulas on controls within a gallery template, use the **Parent.TemplateHeight** and **Parent.TemplateWidth** properties; don't use **Parent.Width** and **Parent.Height**, which refer to the overall size of the gallery.

Container control

You can use the **Layout container** control, as a parent control.

Consider the example of a header at the top of a screen. It's common to have a header with a title and several icons with which your users can interact. You can construct such a header using the **Container** control, containing a **Label** control and two **Icon** controls:



Set the properties for these controls to these values:

Expand table

Property	Header	Menu	Close	Title
X	`0`	`0`	`Parent.Width - Close.Width`	`Menu.X + Menu.Width`
Y	`0`	`0`	`0`	`0`
Width	`Parent.Width`	`Parent.Height`	`Parent.Height`	`Close.X - Title.X`
Height	`64`	`Parent.Height`	`Parent.Height`	`Parent.Height`

For the **Header** control, `Parent` refers to the screen. For the others, `Parent` refers to the **Header** control.

Having written these formulas, you can adjust the size or position of the **Header** control by changing the formulas for its properties. The sizes and positions of the child controls will automatically adjust accordingly.

Auto-layout container controls

You can use an feature, the **Auto-layout** container controls to automatically lay out the child components. These containers determine the position of the child components so that you never have to set X, Y for a component inside the container. Also, it can distribute the available space to its child components based on the settings, as well as determines both the vertical and horizontal alignment of the child components. More information: Auto-layout container controls

Components

If you use another feature, named Components, you can construct building blocks and reuse them throughout your app. As with the **Container** control, the controls that you place within a component should base their position and size formulas on `Parent.Width` and `Parent.Height`, which refer to the size of the component. More information: Create a component.

Adapting layout for device size and orientation

So far, you've learned how to use formulas to change each control's size in response to the available space, while keeping controls aligned relative to each other. But you might want or need to make more substantial layout changes in response to different device sizes and orientations. When a device is rotated from portrait to landscape orientation, for example, you might want to switch from a vertical layout to a horizontal one. On a larger device, you can

present more content or rearrange it to provide a more appealing layout. On a smaller device, you might need to split up content across multiple screens.

Device orientation

The default formulas for a screen's **Width** and **Height** properties, as this topic described earlier, won't necessarily provide a good experience if a user rotates a device. For example, an app designed for a phone in portrait orientation has a **DesignWidth** of 640 and a **DesignHeight** of 1136. The same app on a phone in landscape orientation will have these property values:

- The screen's **Width** property is set to `Max(App.Width, App.DesignWidth)`. The app's **Width** (1136) is larger than its **DesignWidth** (640), so the formula evaluates to 1136.
- The screen's **Height** property is set to `Max(App.Height, App.DesignHeight)`. The app's **Height** (640) is smaller than its **DesignHeight** (1136), so the formula evaluates to 1136.

With a screen **Height** of 1136 and a device height (in this orientation) of 640, the user must scroll the screen vertically to show all of its content, which might not be the experience that you want.

To adapt the screen's **Width** and **Height** properties to the device orientation, you can use these formulas:

Width = `Max(App.Width, If(App.Width < App.Height, App.DesignWidth, App.DesignHeight))`

Height = `Max(App.Height, If(App.Width < App.Height, App.DesignHeight, App.DesignWidth))`

These formulas swap the app's **DesignWidth** and **DesignHeight** values, based on whether the device's width is less than its height (portrait orientation) or more than its height (landscape orientation).

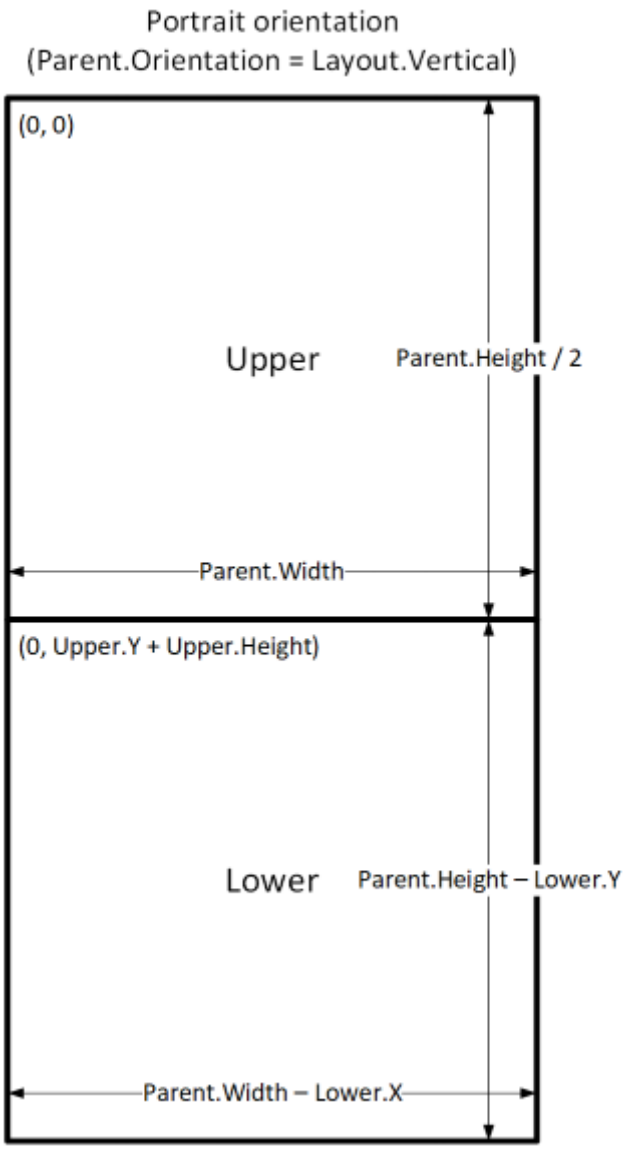
After you adjust the screen's **Width** and **Height** formulas, you might also want to rearrange controls within your screen to better use the available space. For example, if each of two controls occupies half of the screen, you might stack them vertically in portrait but arrange them side by side in landscape.

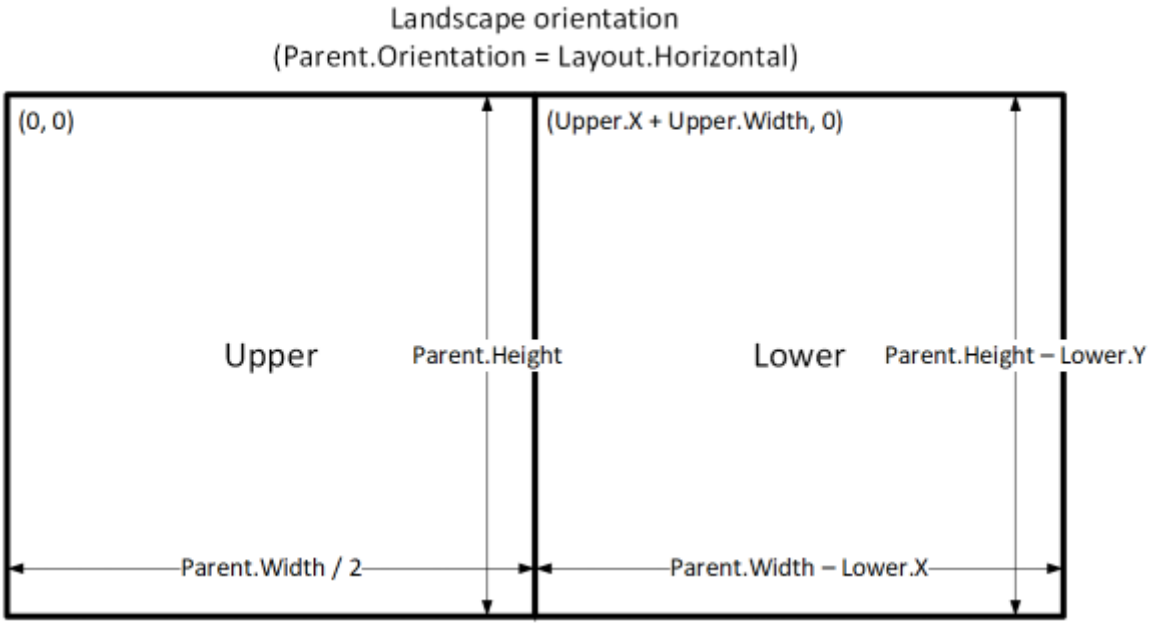
You can use the screen's **Orientation** property to determine whether the screen is oriented vertically or horizontally.

> ⓘ **Note**
>
> In landscape orientation, the **Upper** and **Lower** controls appear as left and right controls.

Expand table

Control	Property	Formula
Upper	X	`0`
Upper	Y	`0`
Upper	Width	`If(Parent.Orientation = Layout.Vertical, Parent.Width, Parent.Width / 2)`
Upper	Height	`If(Parent.Orientation = Layout.Vertical, Parent.Height / 2, Parent.Height)`
Lower	X	`If(Parent.Orientation = Layout.Vertical, 0, Upper.X + Upper.Width)`
Lower	Y	`If(Parent.Orientation = Layout.Vertical, Upper.Y + Upper.Height, 0)`
Lower	Width	`Parent.Width - Lower.X`
Lower	Height	`Parent.Height - Lower.Y`





Screen sizes and breakpoints

You can adjust your layout based on the size of the device. The screen's **Size** property classifies the current device size. The size is a positive integer; the ScreenSize type provides named constants to help with readability. This table lists the constants:

Expand table

Constant	Value	Typical device type (using default app settings)
ScreenSize.Small	1	Phone
ScreenSize.Medium	2	Tablet, held vertically
ScreenSize.Large	3	Tablet, held horizontally
ScreenSize.ExtraLarge	4	Desktop computer

Use these sizes to make decisions about your app's layout. For example, if you want a control to be hidden on a phone-sized device but visible otherwise, you could set the control's **Visible** property to this formula:

Power Fx

```
Parent.Size >= ScreenSize.Medium
```

This formula evaluates to **true** when the size is medium or larger and **false** otherwise.

If you want a control to occupy a different fraction of the screen width based on the screen size, set the control's **Width** property to this formula:

Power Fx

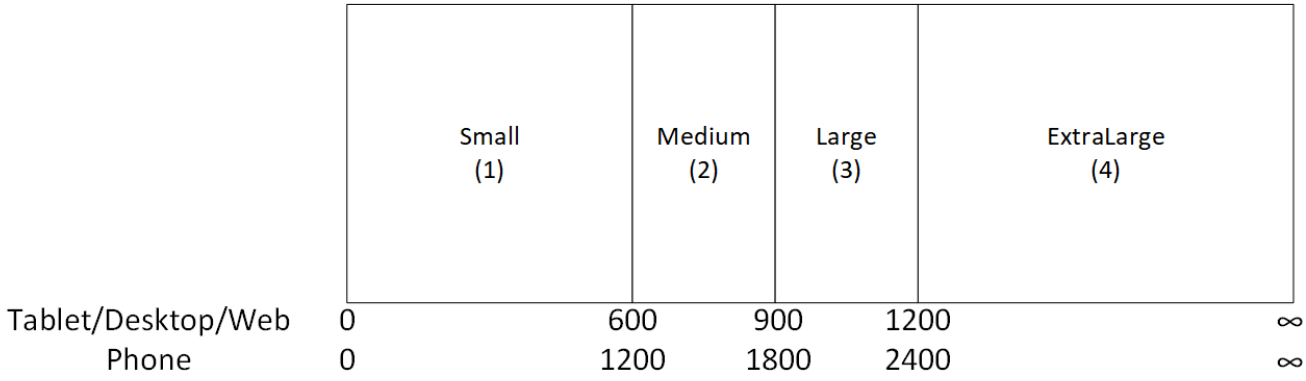
```
Parent.Width *
Switch(
    Parent.Size,
    ScreenSize.Small, 0.5,
    ScreenSize.Medium, 0.3,
    0.25
)
```

This formula sets the control's width to half of the screen width on a small screen, three-tenths of the screen width on a medium screen, and a quarter of the screen width on all other screens.

Custom breakpoints

The screen's **Size** property is calculated by comparing the screen's **Width** property to the values in the app's **SizeBreakpoints** property. This property is a single-column table of numbers that indicate the width breakpoints that separate the named screen sizes:

In an app created for tablet or web, the default value in the app's **SizeBreakpoints** property are **[600, 900, 1200]**. In an app created for phones, the value is **[1200, 1800, 2400]**. (The values for phone apps are doubled because such apps use coordinates that are effectively double the coordinates used in other apps.)



You can customize your app's breakpoints by changing the values in the app's **SizeBreakpoints** property. Select **App** in the tree view, select **SizeBreakpoints** in the property list, and then edit the values in the formula bar. You can create as many breakpoints as your app needs, but only sizes 1 through 4 correspond to named screen sizes. In formulas, you can refer to sizes beyond ExtraLarge by their numeric values (5, 6, and so forth).

You can also specify fewer breakpoints. For example, your app might need only three sizes (two breakpoints), so the possible screen sizes will be Small, Medium, and Large.

Known limitations

The authoring canvas doesn't respond to the sizing formulas created. To test responsive behavior, save and publish your app, and then open it on devices or in browser windows of various sizes and orientations.

If you write expressions or formulas in the **X**, **Y**, **Width**, and **Height** properties of a control, you'll overwrite those expressions or formulas if you later drag the control to a different location or resize the control by dragging its border.

Last updated on 02/28/2026

Get started with formulas in canvas apps

Article • 01/18/2025

Configure your canvas app with formulas that not only calculate values and perform other tasks (as they do in Excel) but also respond to user input (as an app requires).

- In Excel, you build formulas that, for example, populate cells and create tables and charts.
- In Power Apps, you build similar formulas as you configure controls instead of cells. In addition, you build formulas that apply specifically to apps instead of spreadsheets.

For example, you build a formula to determine how your app responds when users select a button, adjust a slider, or provide other input. These formulas might show a different screen, update a data source that's external to the app, or create a table that contains a subset of the data in an existing table.

You can use formulas for a wide variety of scenarios. For example, you can use your device's GPS, a map control, and a formula that uses **Location.Latitude** and **Location.Longitude** to display your current location. As you move, the map automatically tracks your location.

This article provides only an overview of working with formulas. Browse the formula reference for more details and the complete list of functions, operators, and other building blocks you can use.

Prerequisites

1. Sign up for Power Apps and sign in with your credentials.
2. Learn how to configure a control in Power Apps.

Use Power Fx formula bar

The Power Fx formula bar offers a more intuitive and efficient way to write formulas for your apps. Follow these steps to use the formula bar:

1. Open your app for editing in Power Apps Studio.
2. Open the formula bar by selecting it at the top of the screen.

3. Start typing your formula in the bar. As you type, the formula bar provides suggestions for functions that match your input.
4. Continue typing your formula or select the suggestions until you're done.

Show a value

In Excel, you can enter a specific piece of data, such as the number **42** or the phrase **Hello World**, by typing it into a cell. That cell shows the data exactly as you type it. In Power Apps, you can similarly specify a piece of data that doesn't change by setting the **Text** property of a label to the exact sequence of characters that you want, surrounded by double quotation marks.

1. Create a blank canvas app.

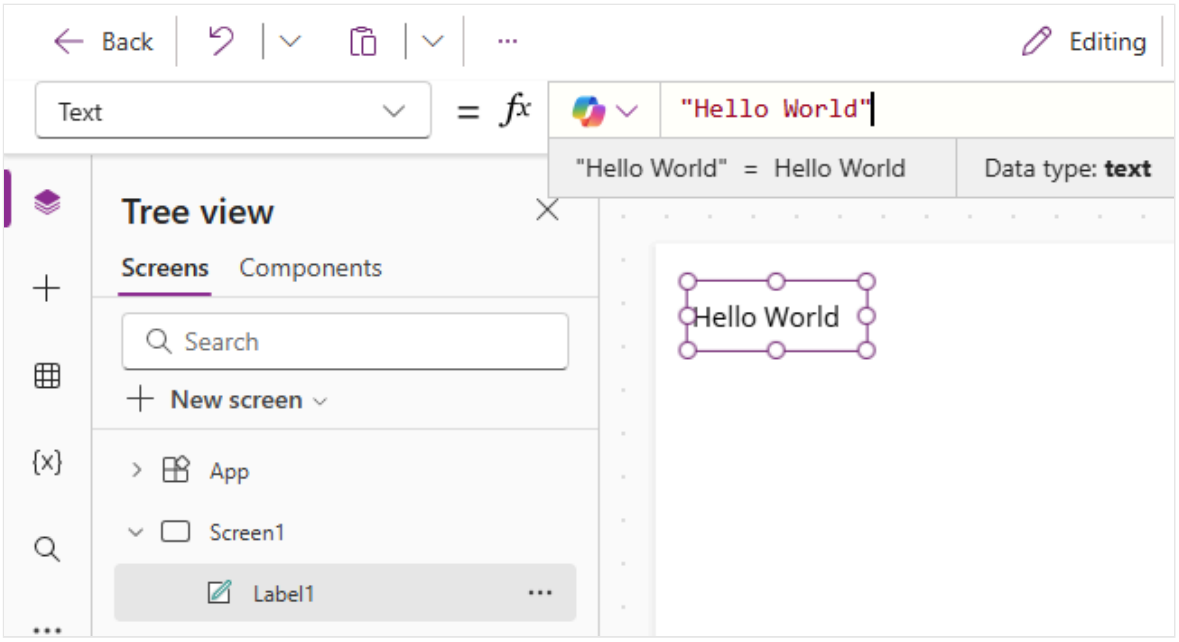
   The formula bar sits at the top of the screen.

   a. *Property list*: Each control and screen has a set of properties. Use this list to select a specific property.
   b. *Formula*: The formula to be calculated for this property, made up of values, operators, and functions. As you type, Intellisense helps you with recommendations for formula, syntax, and errors.
   c. *Selected control*: In the formula bar, you can see and edit properties for the selected control or for the screen if no controls are selected.

2. Add a **Label** control to the screen.

   When you add a label, the property list automatically shows the **Text** property, which drives what the control shows. By default, the value of this property is **"Text"**.

3. Set the value of the **Text** property to **"Hello World"** by typing that string, surrounded by double quotes, into the formula bar:



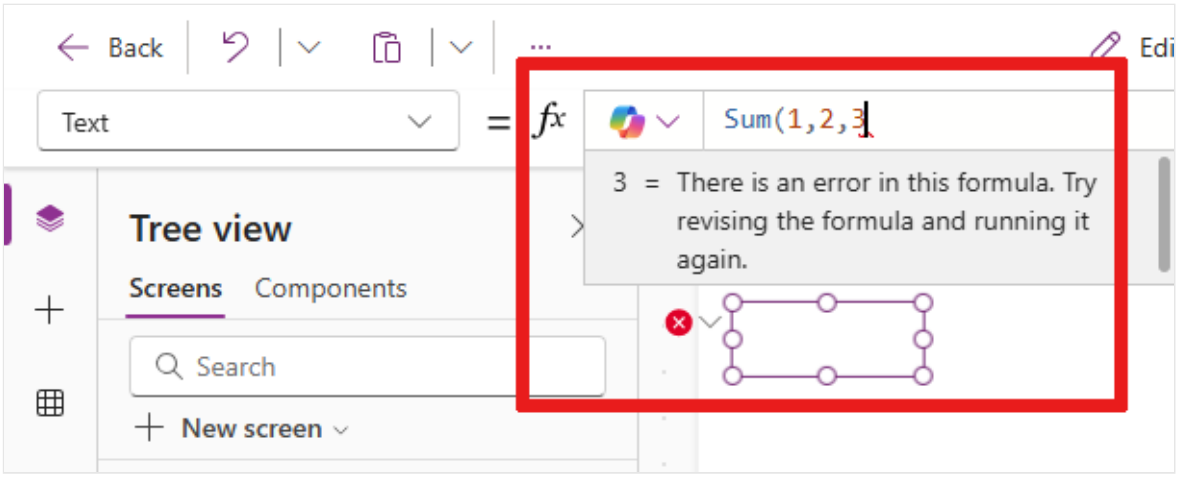
The label reflects this new value as you type it. The screen might show yellow exclamation-point icons while you type. These icons indicate errors, but go away when you finish entering a valid value. For example, a string without double quotation marks on both ends isn't valid.

In Excel, you can show a number, such as **42**, by typing it into a cell or by typing a formula that resolves to that number, such as **=SUM(30,12)**. In Power Apps, you can achieve the same effect by setting the **Text** property of a control, such as a label, to **42** or **Sum(30,12)**. The cell and the label show that number regardless of what else changes in the worksheet or the app.

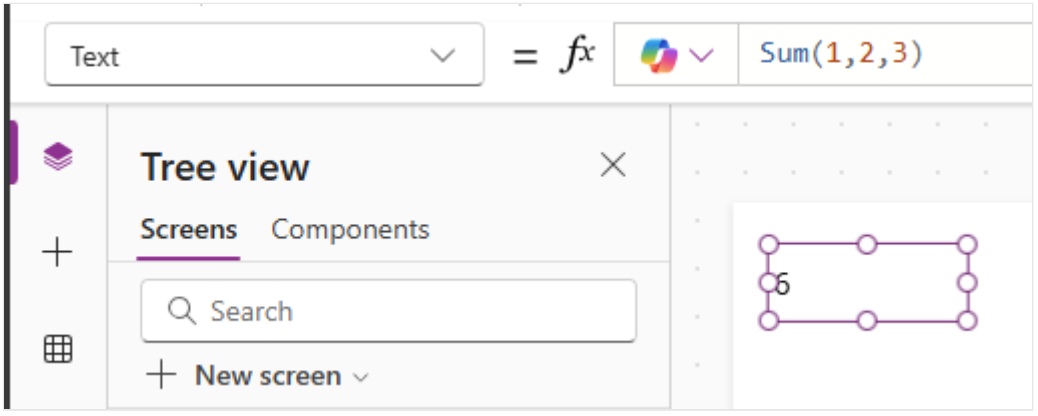
> **Note**
>
> In Power Apps, you don't precede a formula with an equals sign or a plus sign as you do in Excel. The formula bar treats anything you type there as a formula by default. You also don't surround a formula with double quotation marks ("), as you did earlier to specify a string of text.

4. In the Text property of the label, replace **"Hello World"** with **Sum(1,2,3)**.

   While you type, the formula bar helps you by showing the description and the expected arguments for this function. As with the final double quotation mark in **"Hello World"**, the screen shows a red cross, showing an error, until you type the final parenthesis of this formula.

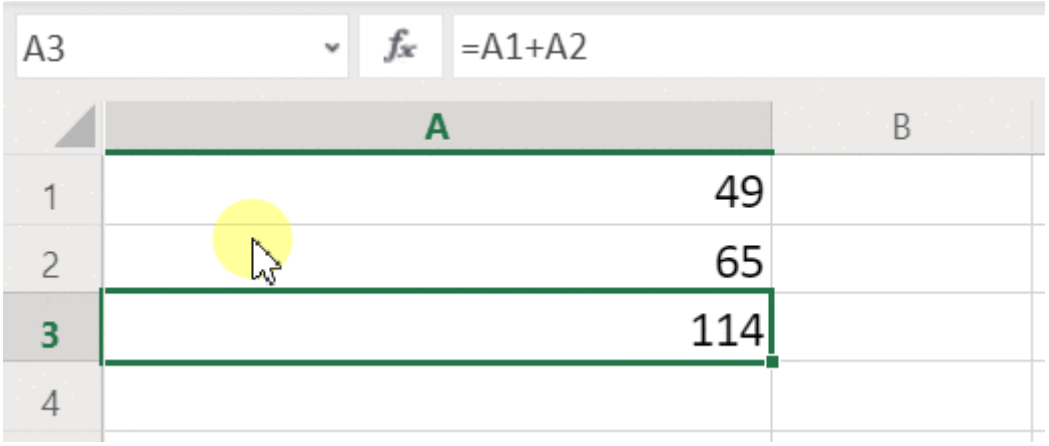


Completed formula with the final parenthesis added:



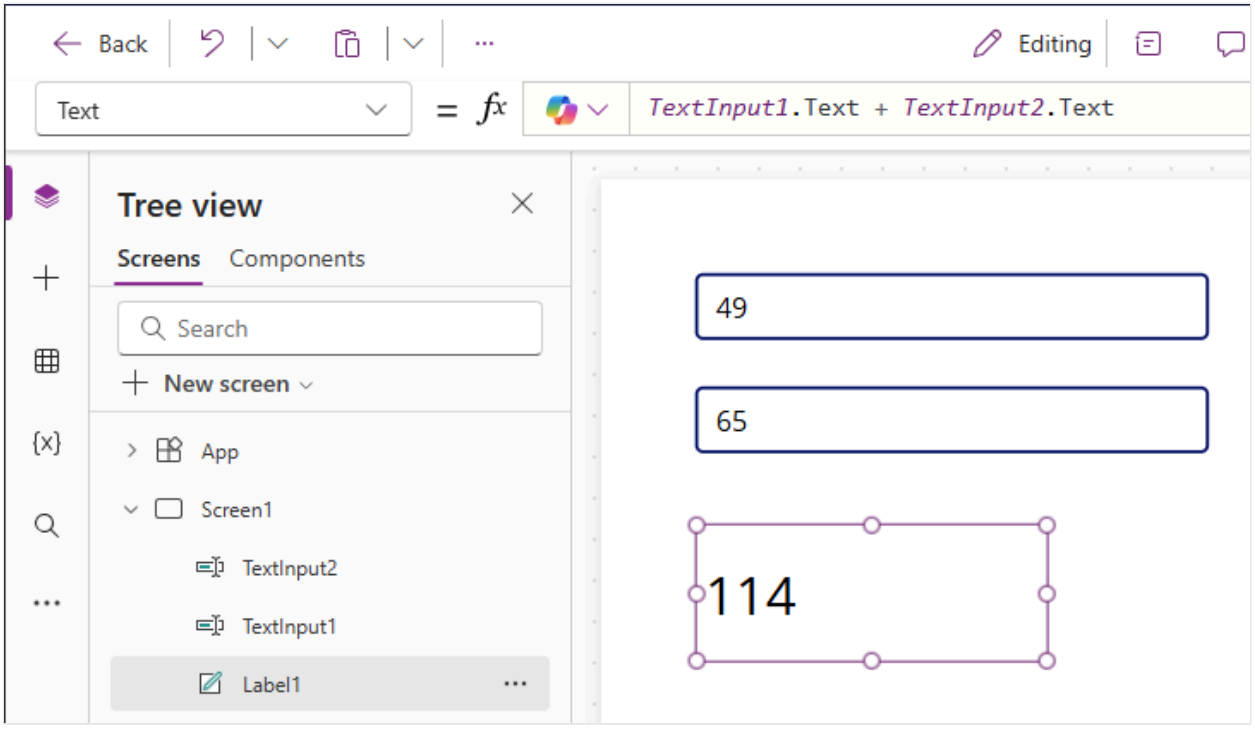
Change a value based on input

In Excel, you type **=A1+A2** into a cell to show the sum of whatever values cells **A1** and **A2** contain. If either or both of those values change, the cell that contains the formula automatically shows the updated result.



In Power Apps, you can achieve a similar result by adding controls to a screen and setting their properties. This example shows a label control named **Label1** and two Text input controls, named **TextInput1** and **TextInput2**. You can add a formula to the **Label1**

control so that when you input a number into **TextInput1** and **TextInput2**, they're added together and display in **Label1**.

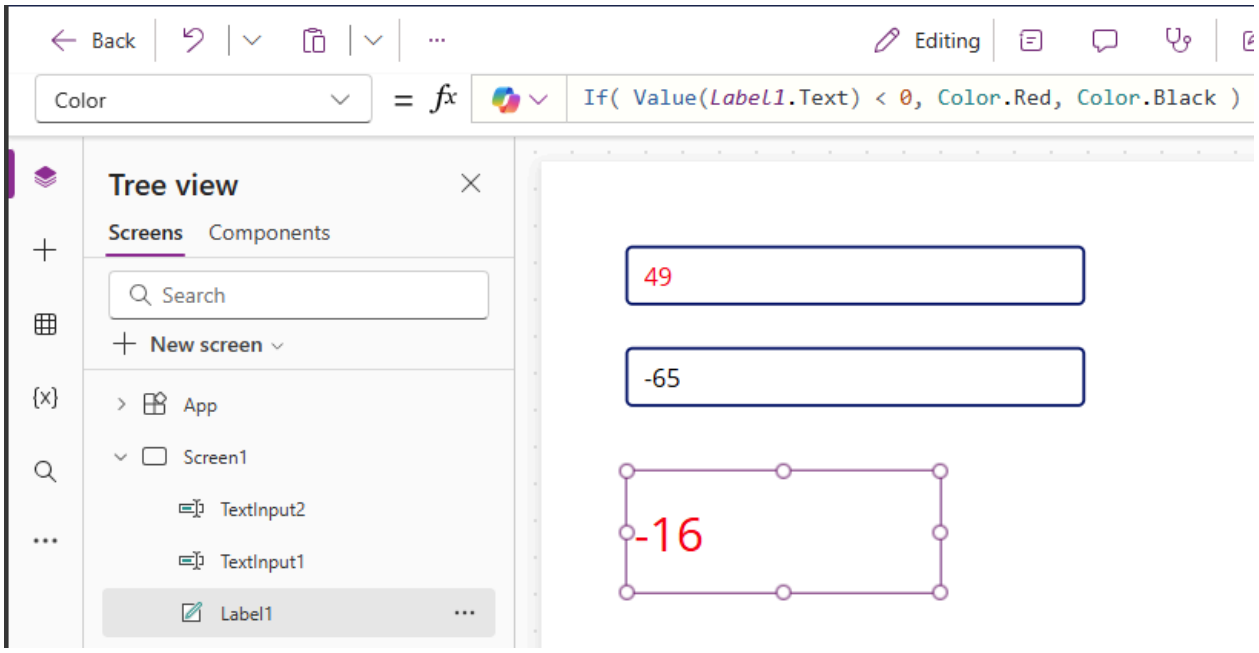


Regardless of what numbers you type in the text-input controls, the label always shows the sum of those numbers because its **Text** property is set to this formula: `TextInput1.Text + TextInput2.Text`.

In Excel, you can use conditional-formatting formulas to show, for example, negative values in red. In Power Apps, you can use formulas to determine not only the primary value of a control but also properties such as color.

In this example, a formula for the **Color** property of the label automatically shows negative values in red. The **If** function should look familiar from Excel:

```
If( Value(Label1.Text) < 0, Color.Red, Color.Black )
```

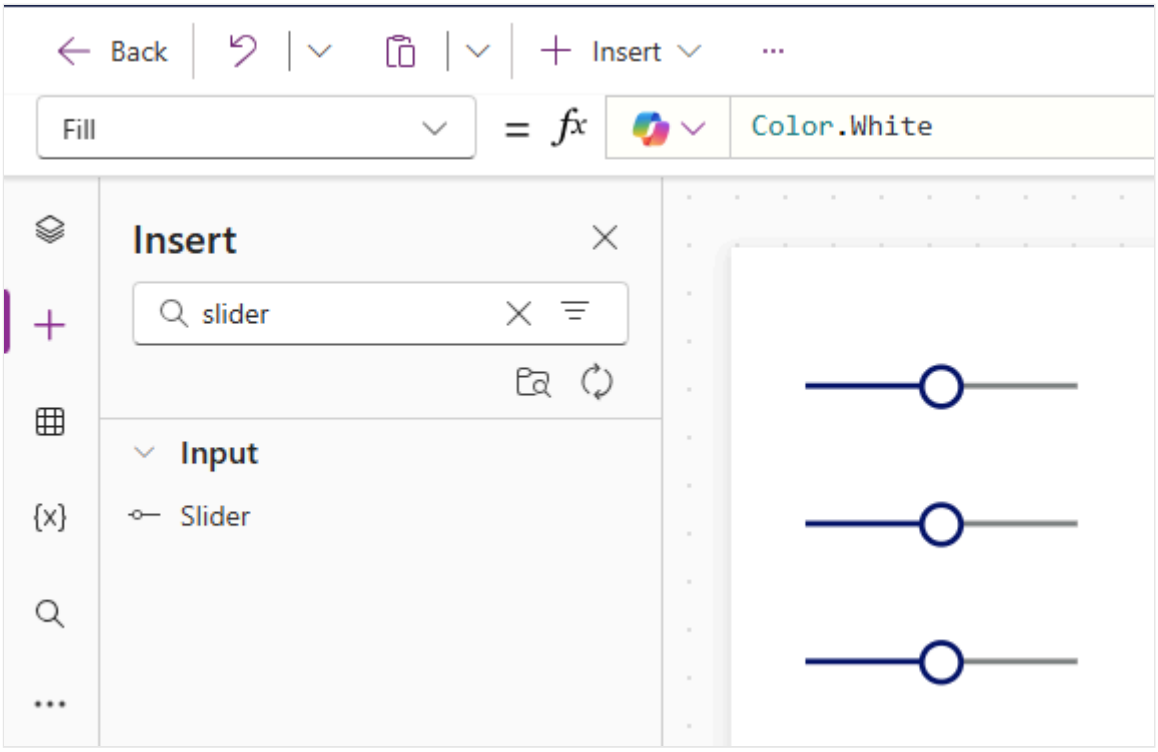


Change a color based on user input

You can configure your app with formulas so that users can change your app's appearance or behavior. For example, you can create a filter to show only data that contains a string of text that the user specifies. You can let users sort a set of data based on a certain column in the data set.

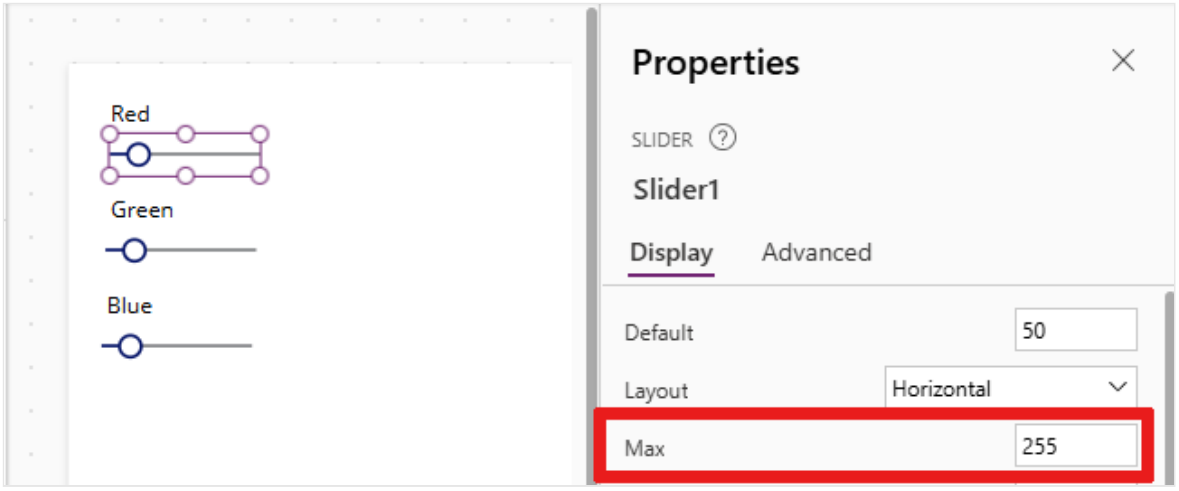
In this example, you can let users change the color of the screen by adjusting one or more sliders.

1. Remove the controls from the previous procedures, or create a blank app as you did previously, and add three slider controls to it. You can search for the slider control in the search box of the **Insert** page to find the control under **Input**. To add the sliders, drag and drop the control to the canvas.



2. Arrange the sliders so they don't overlap, add three labels, and configure the labels to show **Red**, **Green**, and **Blue** text.

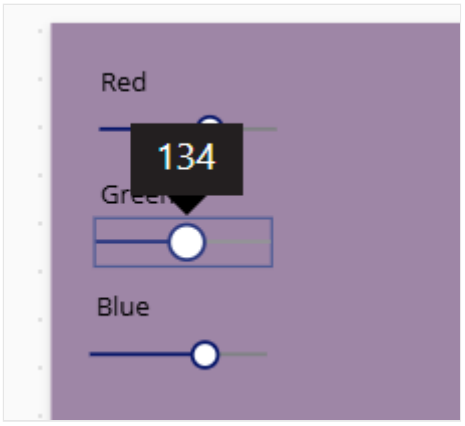
3. Set the **Max** property of each slider to 255 (default is 100), which is the maximum value of a color component for the RGBA function.



4. Select the screen to unselect any control, and then set the screen's **Fill** property to this formula: **RGBA(Slider1.Value, Slider2.Value, Slider3.Value, 1)**. Your screen turns dark gray, which reflects the sliders' current positions.

   In the formula, you can access control properties by using the property selector. For example, **Slider1.Value** refers to the slider's **Value** property, which represents where the user placed the slider between the **Min** and **Max** values.

5. **Preview the app** and adjust the sliders. You see how each control is color coded to change the background color of the screen.



As each slider changes, the formula that contains the **RGBA** function is recalculated, which immediately changes how the screen appears.

Manage app behavior

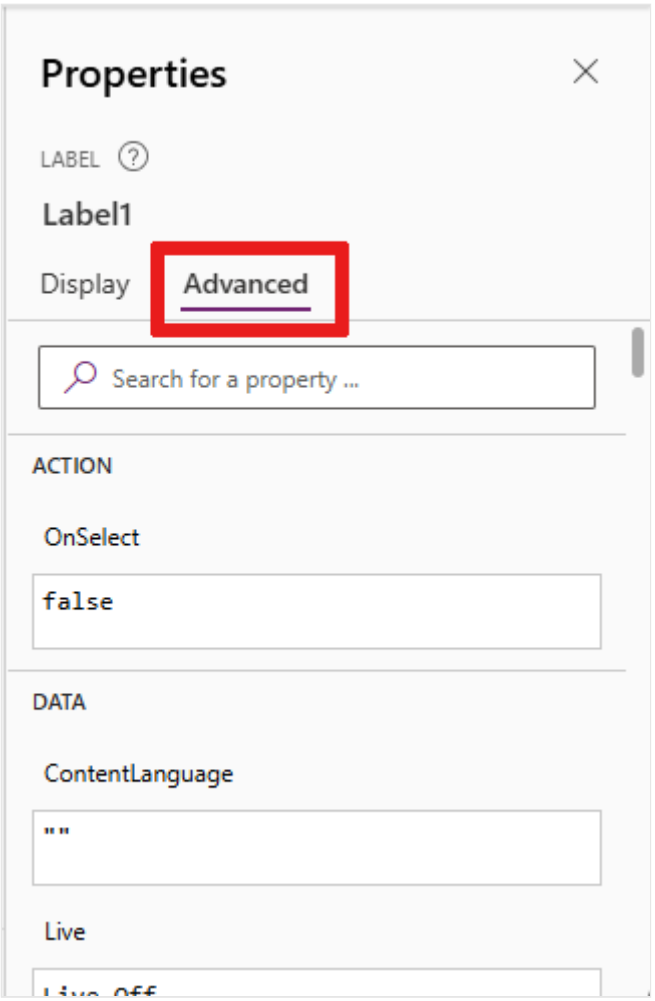
You can use formulas not only to perform calculations and change appearance but also to take action. For example, you can set the **OnSelect** property of a button to a formula that includes the **Navigate** function. When a user selects that button, the screen that you specify in the formula appears.

You can use some functions, such as **Navigate** and **Collect**, only in behavior formulas. The formula reference calls out if you can use a function only in this context.

You can take more than one action in a behavior formula if you separate functions with a semi-colon (;). For example, you might want to update a context variable, push data to a data source, and finally navigate to another screen.

View a list of properties by category

The properties list shows properties alphabetically, but you can also view all the properties of a control, organized by category, if you select a control, for example **Label1**, and then select the **Advanced** tab in the **Properties** pane, you see a long list of properties for that control.



You can edit formulas directly within this view. With the property search, you can quickly find a property of that control and change a control's behavior and appearance.

Formula syntax

As you type a formula in the formula bar, different syntax elements appear in different colors to improve readability and help you understand long formulas. Here's the color code list in Power Apps.

Function	Control	Global data source	Enumerated type
API reference	Keyword “ThisItem”	True, False	Number
String

Build an AI agent to automate your business process

08/14/2025

Agent builder in Power Apps lets organizations transition into the AI-first era by using the knowledge, logic, and actions of an app to create copilot agents. These agents handle daily tasks, streamline processes, enhance productivity, and improve overall business efficiency.

Makers can create agents that automate processes within their existing canvas apps. Agent builder uses the app's metadata and the desired agent goal to generate a comprehensive step-by-step process, extract knowledge, and identify triggers. This process, knowledge, and triggers are then combined with extracted skills from the app, resulting in a fully equipped copilot that offers detailed instructions, knowledge, triggers, and actions.

After creating the agent, makers can edit, test, and publish it in Microsoft Copilot Studio.

Prerequisites

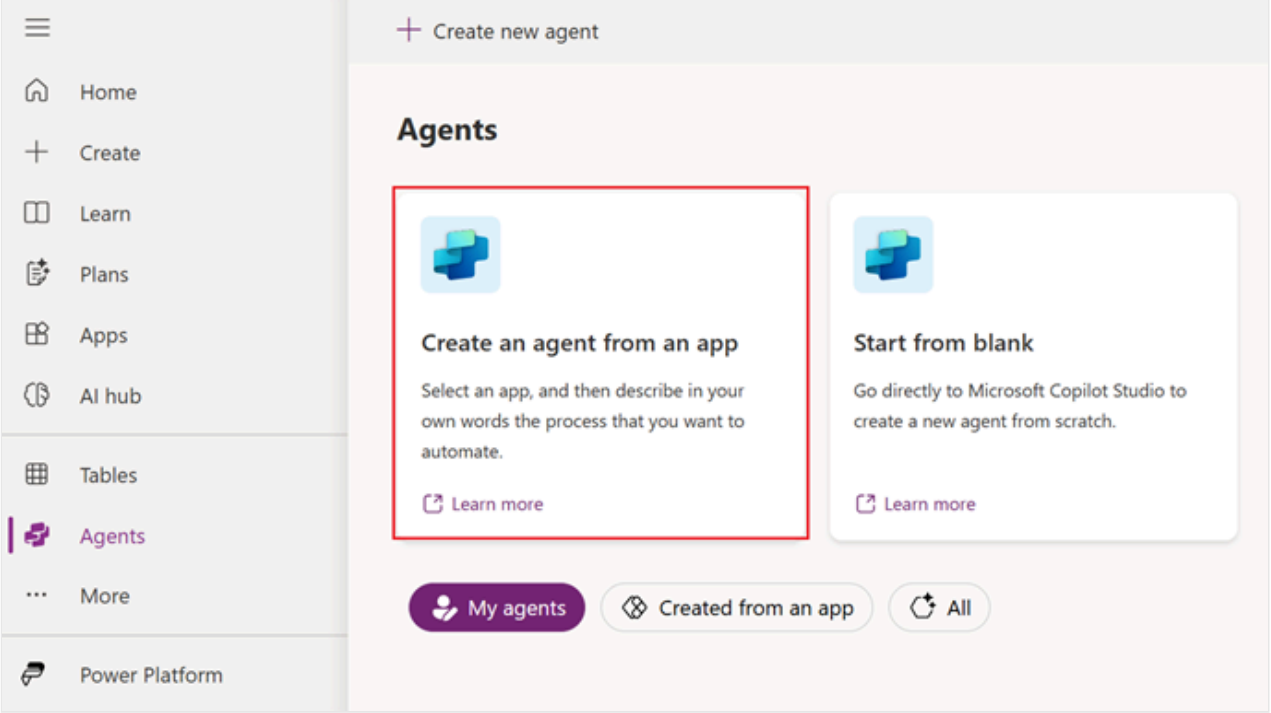
- Your tenant administrator must turn on the Publish Copilots with AI features setting in the Power Platform admin center.
- Include a Dataverse database in your environment. More information: Add a Microsoft Dataverse database.
- Ensure that block unmanaged customizations is disabled. Learn more in Block unmanaged customizations in Dataverse environments.
- Current environment has Power Virtual Agents solution version 2.0.0.649.1 or higher.

Create an agent

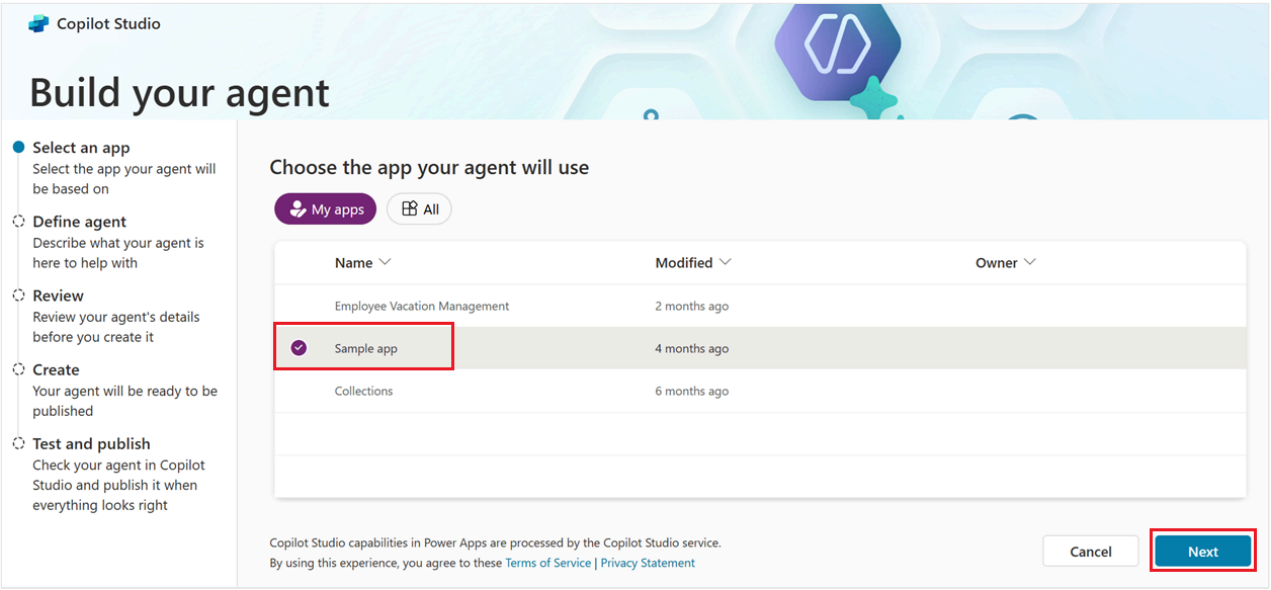
To streamline your manual process, generate an agent that replicates the steps you typically follow to complete tasks.

1. Sign in to Power Apps.
2. Select **Agents** in the left navigation pane. If you don't see **Agents**, select **More**, and then find and select **Agents**.

3. Select **Create an agent from an app**.

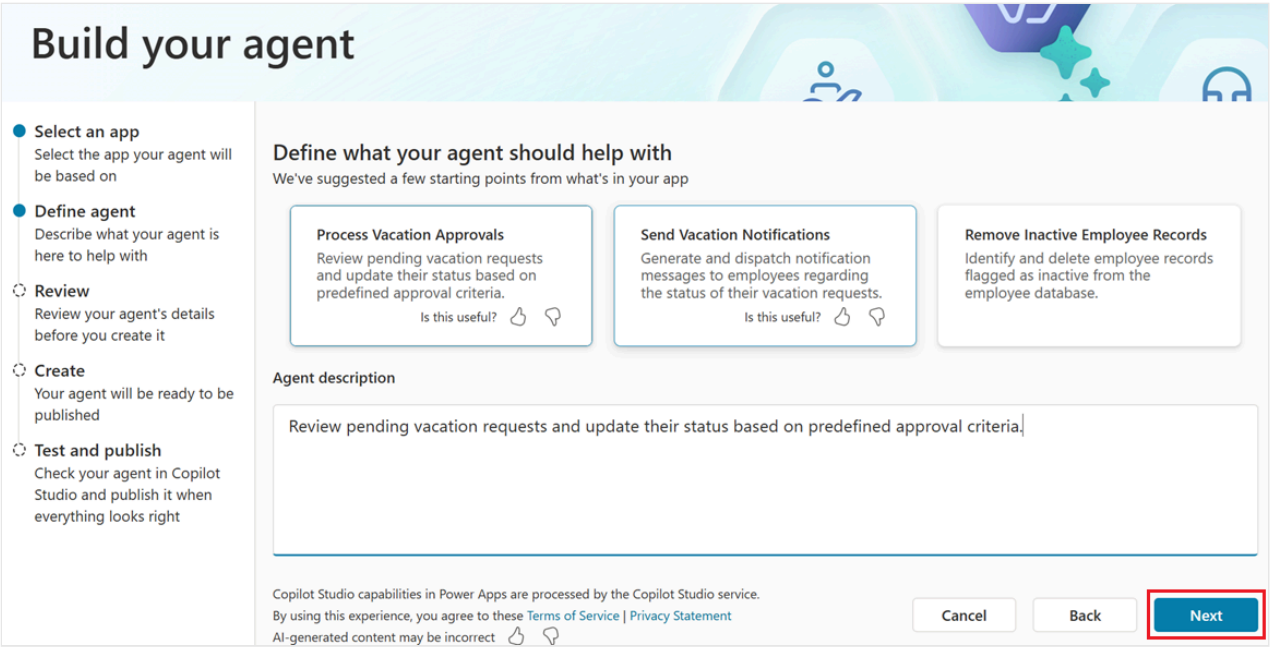


4. Select your app and then select **Next** on the command bar.



Alternatively, you can select **Apps** in the left navigation pane. Select your app, and then select **Create agent from app** on the command bar. You can also select **Commands** (⋮) for the app and then select **Create agent from app**.

5. Select a suggestion, or in the text box, describe the process you want to automate, and then select **Next**.



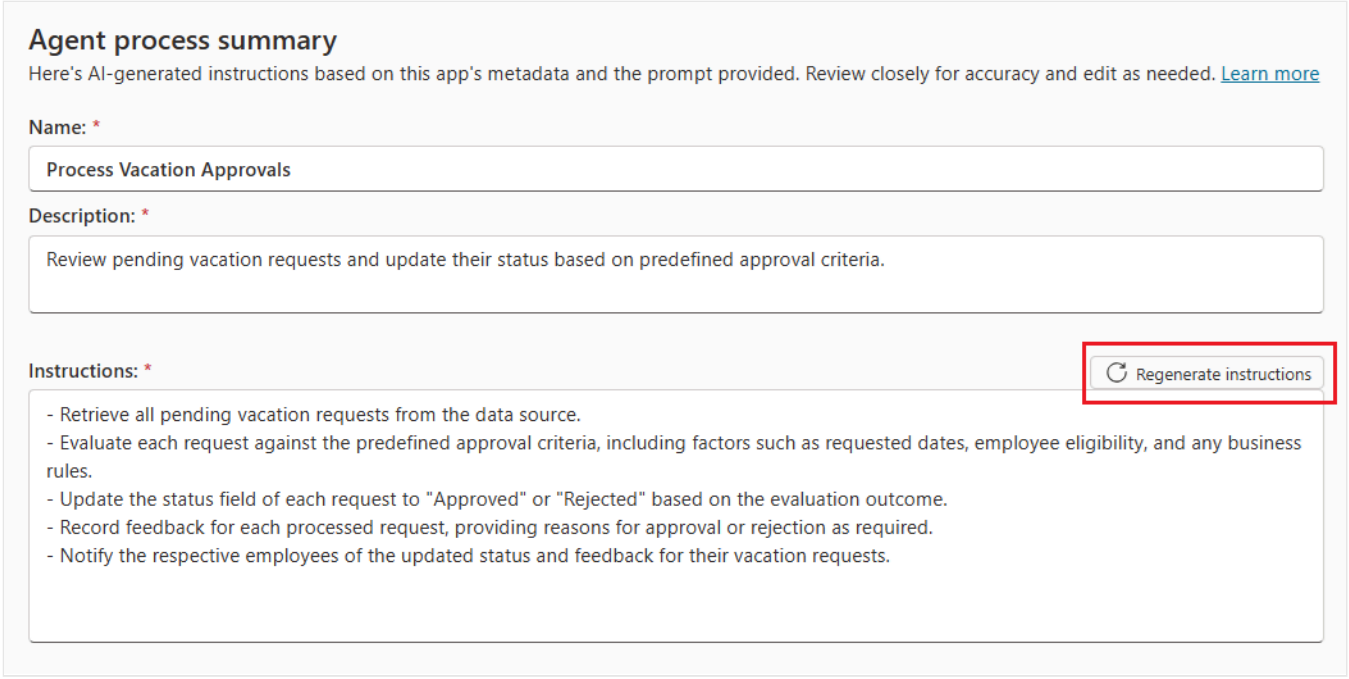
6. When you select a suggestion, the text box is automatically filled. You can edit it and add more details about what you want the agent to do. To improve the agent's accuracy, use simple, everyday language, and be specific, like:

    - Review pending vacation requests and update their status based on predefined approval criteria.
    - Generate and dispatch notification messages to employees regarding the status of their vacation requests.

7. Based on the suggestion or the information that you provide for the agent's goal and the app's metadata, agent builder generates step-by-step instructions to replace your manual process and extracts triggers and knowledge. Review the instructions for accuracy, and make any necessary edits. Then review the extracted knowledge and triggers for accuracy, and make any necessary edits. When you're done, select **Create**.

Regenerate instructions to improve the response

You can also revise the description to better represent the process you want to automate. When you're done, select the **Regenerate instructions** to receive updated instructions that match the new goal of the agent.



Best practices

When you edit the instructions, follow these suggestions:

- Use clear and specific wording in the instructions. For example, "Filter the claims data using the approval status" rather than "Filter the data."
- Verify the instructions to ensure they meet their goal.
- Keep each of the sentences for the instructions relatively simple. If there are too many details and conditions in one of the sentences, it might not work as intended.
- Ensure the logical flow of the instructions is easy to follow. Avoid adding new instructions at the end of the instruction set. Instead, move instructions in line to maintain a logical sequence.

  Here are example instructions:

  1. Read the data from the table.
  2. Process the data with pending status.
  3. If amount is less than $50 auto approve it and mark it as approved.
  4. Update the table with new status.
  5. And if the amount is more than $50 but less than $500 check to see if it's an approved item.
  6. Additionally if the amount is more than $500 update the status to manual review.

To improve the logical flow in this example, move steps 5 and 6 after step 3.

Limitations

- If a data source connection isn't found, you can't extract actions for the app. In such cases, the agent builder generates an agent with the actions that can be converted, or none if no actions can be converted.
- Deprecated Excel connectors aren't supported. However, the following Excel connectors are supported:
  - Excel Online (Business)
  - Excel Online
- Agent builder is available only in regions where Microsoft Copilot Studio generative agents are available.
- This feature is available only for canvas apps.

Provide feedback

Unless feedback is disabled by your admin, each step in the agent builder includes a **Like** (thumbs up) and **Dislike** button (thumbs down).

After reviewing the agent's responses, you can provide feedback in your own words. When you're done, select **Submit**.

FAQ for agent builder in canvas apps

Use Copilot to create and edit Power Fx formulas

Copilot is an AI feature in Power Apps Studio that helps you create and change Power Fx formulas quickly. Use Copilot in the formula bar to explain Power Fx formulas in everyday language or generate Power Fx formulas from natural language or code comments.

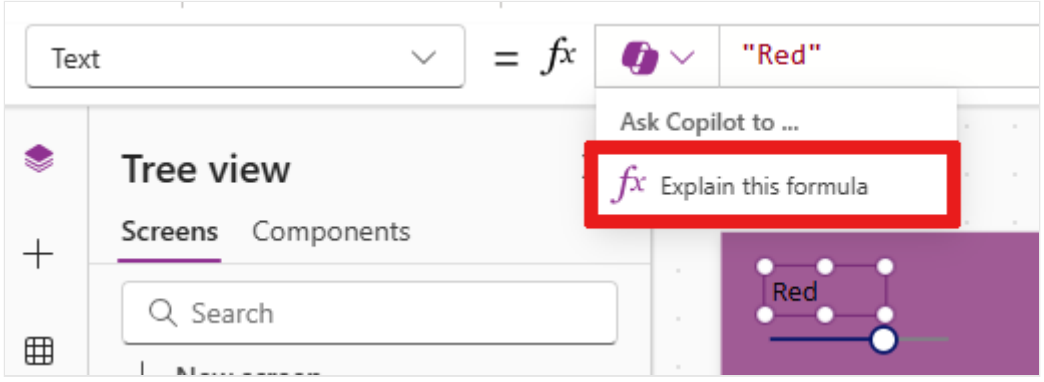
Prerequisites

An admin must enable Copilot for your environment and tenant. For more information, see Copilot in Power Apps overview.

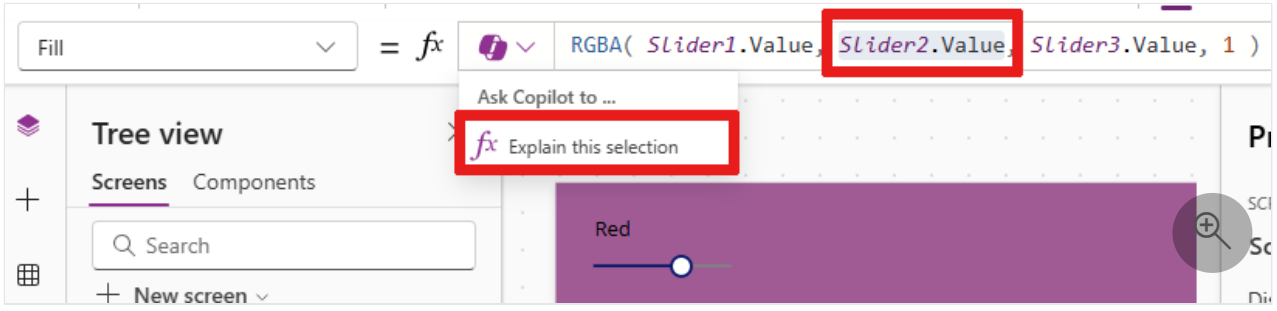
Explain a formula

Use Copilot in the formula bar to learn what a formula does in plain language.

1. Select a control and its property. For example, select a label control with its **Text** property.
2. On the formula bar, select the dropdown near the **fx** field label, and then select **Explain this formula**.

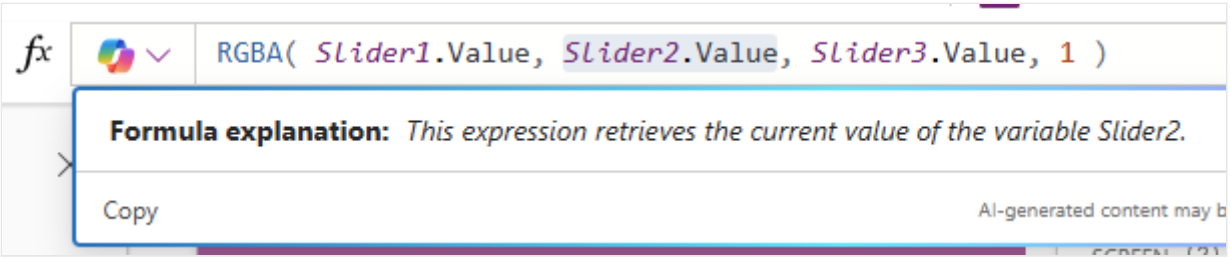


Alternatively, select part of a formula, select the dropdown near the **fx** field label, and then select **Explain this selection** to explain only that part.



Copilot gives you an explanation of the formula that you can copy and insert as a code comment, or share with other makers working on the same app. When Copilot explains a

selection, it can add context if that's important for the explanation.



Known limitations of explaining formulas

- The maximum length for a formula explanation is 5,000 characters. If the formula is longer, use a partial explanation to make sure it works.
- Copilot recognizes only default properties in Power Apps.
- Copilot doesn't recognize user-defined functions.

> **Note**
>
> AI-generated content can be inaccurate, so check it for accuracy.

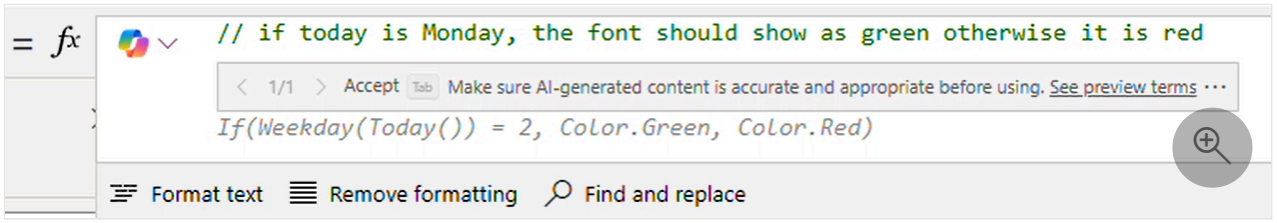
Generate formulas from code comments

Copilot can generate Power Fx formulas from code comments in the formula bar. You can accept the suggestion or type the formula yourself. Formula code comments can also serve as documentation for your formulas, just like regular code comments.

1. With your canvas app open for editing, type a code comment using `//` or `/*` in the formula bar.

   Wait a few seconds for Copilot to generate a formula suggestion or press `Enter` to generate it immediately.

2. Press `Tab` on the keyboard to accept and use the suggested formula. You can also type through the suggestion.



The suggestion remains until you select elsewhere or type a character that doesn't match the suggestion.

You can keep the comments used for generating Power Fx formulas in the formula bar as documentation, similar to traditional code comments.

> **Note**
>
> - If Copilot doesn't provide a suggestion, then it couldn't generate a formula based on your comment. Try rephrasing the comment.
> - We recommend enclosing in quotes the elements that you want to include in your formula, such as `"Button1.text"`.

Known limitations of generating formulas from code comments

- Copilot works on a singular control and property, and it doesn't make changes to other controls or properties to achieve the desired outcome.
- Copilot doesn't take existing formula text into account.
- Copilot only recognizes default properties in Power Apps.
- Copilot doesn't recognize user-defined functions.
- Code comments only work with general Power Fx functions, and not Power Apps-specific functions such as `Navigate()`.
- The advanced panel doesn't trigger suggestions.
- Existing formulas for the property aren't included in the suggestion.

Create a formula (preview)

[This section is prerelease documentation and is subject to change.]

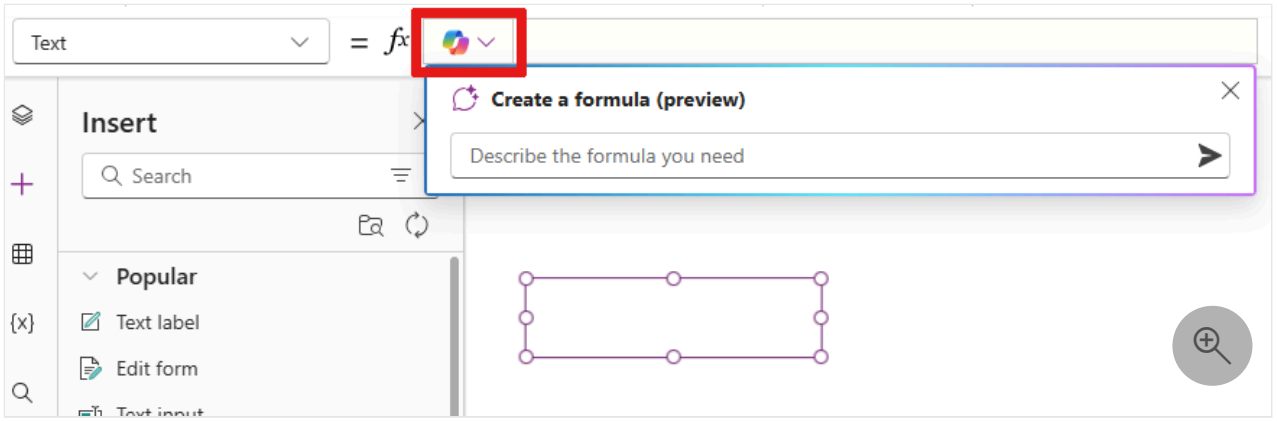
From the Copilot dropdown menu in the formula bar, you can now generate a formula by using natural language to make a discrete request.

> **Note**

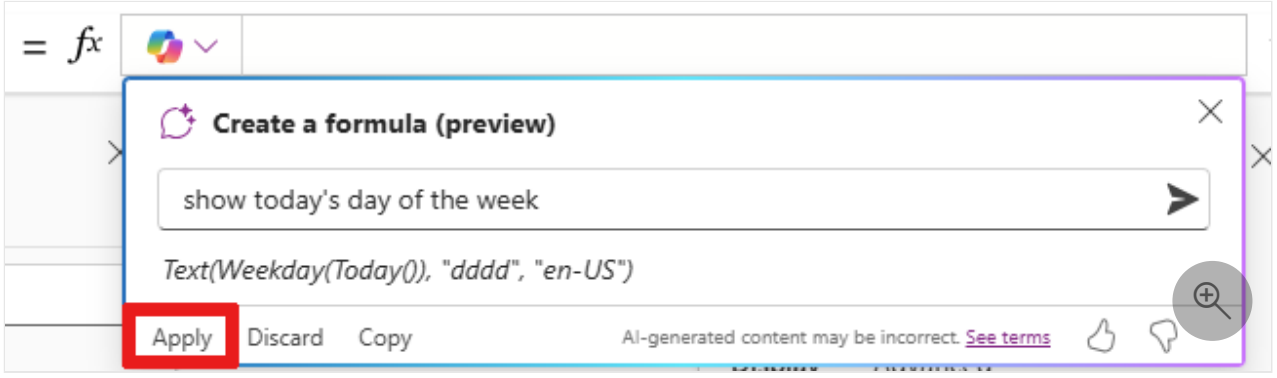
The **Copilot for formulas** feature is on by default. To turn it off, open your app, go to **Settings** > **Updates** > **Preview**, and find the **Copilot for formulas** toggle. If you turn off the setting, the **Create a formula (preview)** menu option disappears from the Copilot dropdown menu in the formula bar.

Use Copilot to create a formula from a discrete request

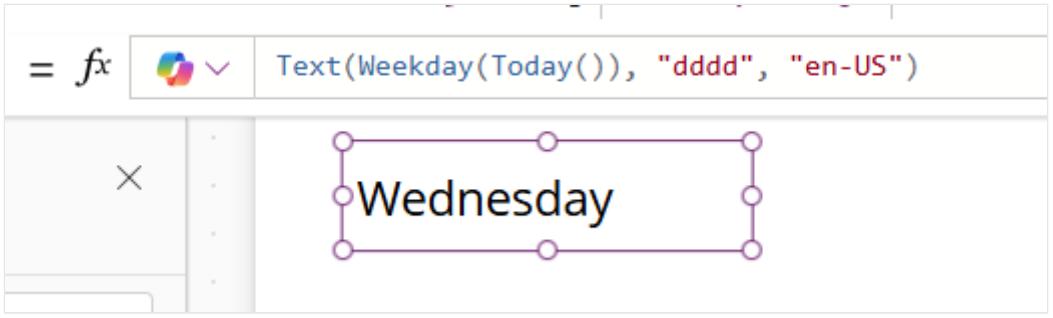
1. Select a control, like a **Text label**, and its corresponding property, such as **Text**.
2. On the formula bar, select the **Copilot functionality menu** > **Create a formula**.



3. In the Copilot text box, type your request, such as *show today's day of the week*.
4. Select the **Create** arrow to submit your request.
5. Copilot attempts to create a formula. Select **Apply** to insert the formula in the same position as the Copilot interface, or update and resubmit your request.



You see the result after you apply the formula.



> [!NOTE]
> The same limitations apply for creating formulas from a discrete request as generating formulas from code comments.

Responsible AI

Understand the choices you have when working with AI. Learn more in FAQ about using AI responsibly in Power Apps. Review the Power Fx Copilot FAQ for questions about this feature specifically.

Language support

The following table lists the languages available for the formula bar copilot features. The list is based on the settings in your Power Platform environment and browser.

Expand table

Name	Language Code	Functionality Supported
English	en-US	Explain a formula, Comment generated formulas, Create a formula
Chinese (simplified) - China	zh-Hans	Explain a formula, Comment generated formulas
Czech - Czech Republic	cs-CZ	Explain a formula, Comment generated formulas
Danish - Denmark	da-DK	Explain a formula, Comment generated formulas
Dutch - Netherlands	nl-NL	Explain a formula, Comment generated formulas
Finnish - Finland	fi-FI	Explain a formula, Comment generated formulas
French - France	fr-FR	Explain a formula, Comment generated formulas

Name	Language Code	Functionality Supported
German - Germany	de-DE	Explain a formula, Comment generated formulas
Greek - Greece	el-GR	Explain a formula, Comment generated formulas
Italian - Italy	it-IT	Explain a formula, Comment generated formulas
Japanese - Japan	ja-JP	Explain a formula, Comment generated formulas
Korean - Korea	ko-KR	Explain a formula, Comment generated formulas
Norwegian (Bokmål) - Norway	nb-NO	Explain a formula, Comment generated formulas
Polish - Poland	pl-PL	Explain a formula, Comment generated formulas
Portuguese - Brazil	pt-BR	Explain a formula, Comment generated formulas
Russian - Russia	ru-RU	Explain a formula, Comment generated formulas
Spanish (Traditional Sort) - Spain	es-ES	Explain a formula, Comment generated formulas
Swedish - Sweden	sv-SE	Explain a formula, Comment generated formulas

Understand variables in canvas apps

08/27/2025

If you've used another programming tool, like Visual Basic or JavaScript, you might ask: **Where are the variables?** Power Apps works differently and needs a different approach. Instead of reaching for a variable when you build a canvas app, ask yourself: **What would I do in Excel?**

In other tools, you might explicitly perform a calculation and store the result in a variable. But Power Apps and Excel automatically recalculate formulas as the input data changes, so you usually don't need to create or update variables. By using this approach, you more easily create, understand, and maintain your app.

Sometimes, you need to use variables in Power Apps, which extends Excel's model by adding behavior formulas. These formulas run when, for example, a user selects a button. Within a behavior formula, it's often helpful to set a variable for use in other formulas.

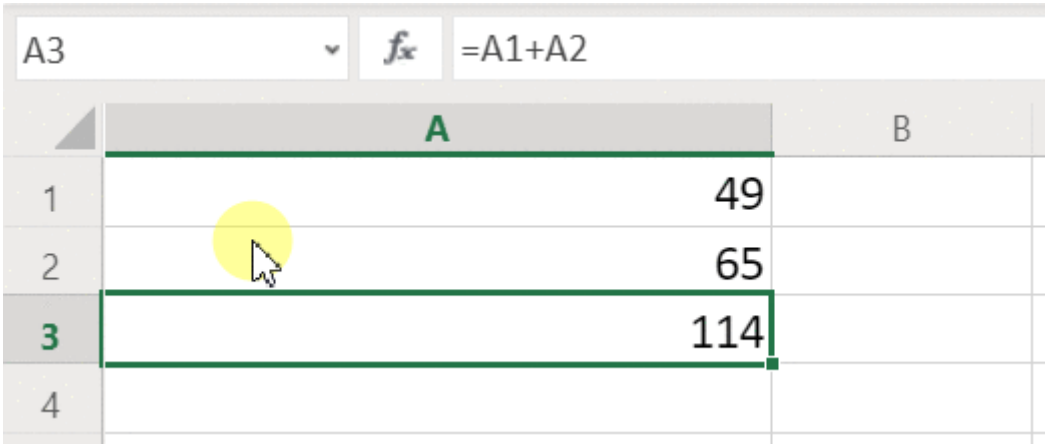
In general, avoid using variables. But sometimes only a variable lets you create the experience you want. Variables are implicitly created and typed when they appear in functions that set their values.

Translate Excel into Power Apps

Excel

Let's review how Excel works. A cell can have a value, like a number or a string, or a formula that's based on the values of other cells. When you enter a different value into a cell, Excel automatically recalculates any formulas that depend on the new value. You don't need to do any programming to enable this behavior.

In the following example, cell **A3** uses the formula **A1+A2**. If **A1** or **A2** changes, **A3** automatically recalculates to show the change. This behavior doesn't require any coding outside of the formula itself.

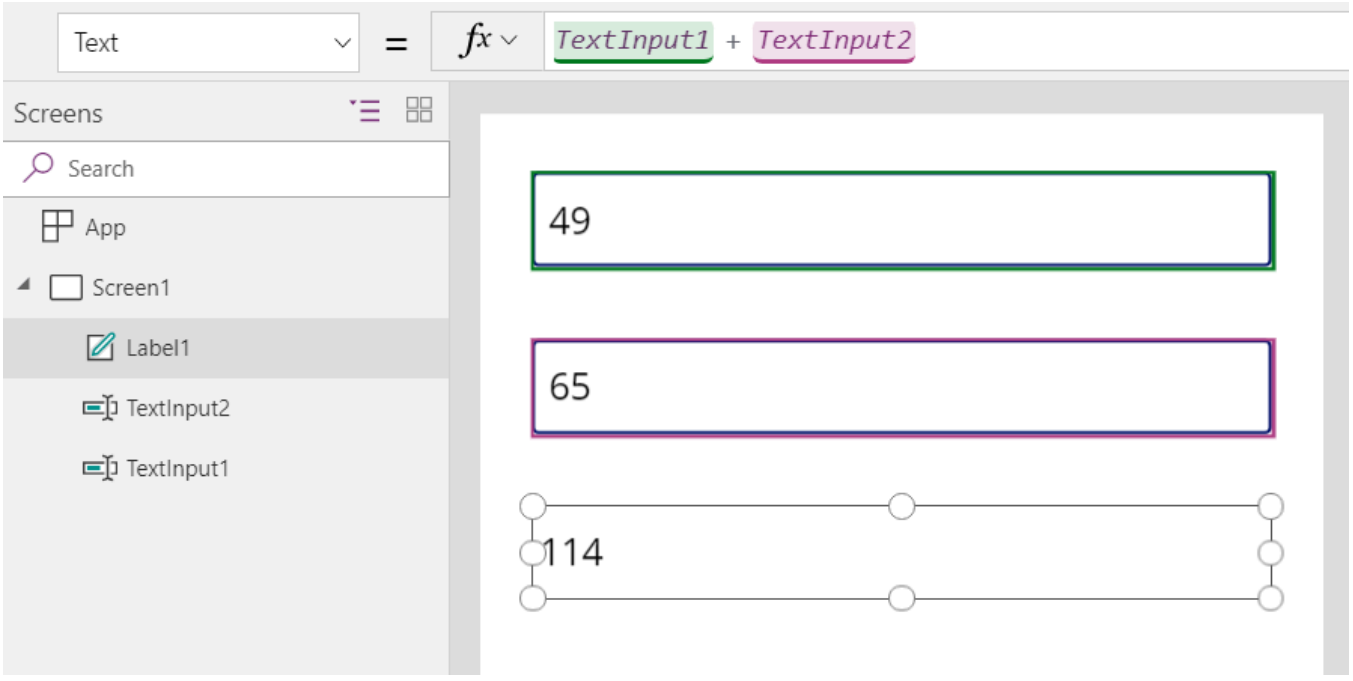


Excel doesn't have variables. The value of a cell with a formula changes based on its input, but there's no way to remember the result of a formula and store it in a cell or anywhere else. If you change a cell's value, the entire spreadsheet can change, and any previously calculated values are lost. You can copy and paste cells, but that's manual and isn't possible with formulas.

Power Apps

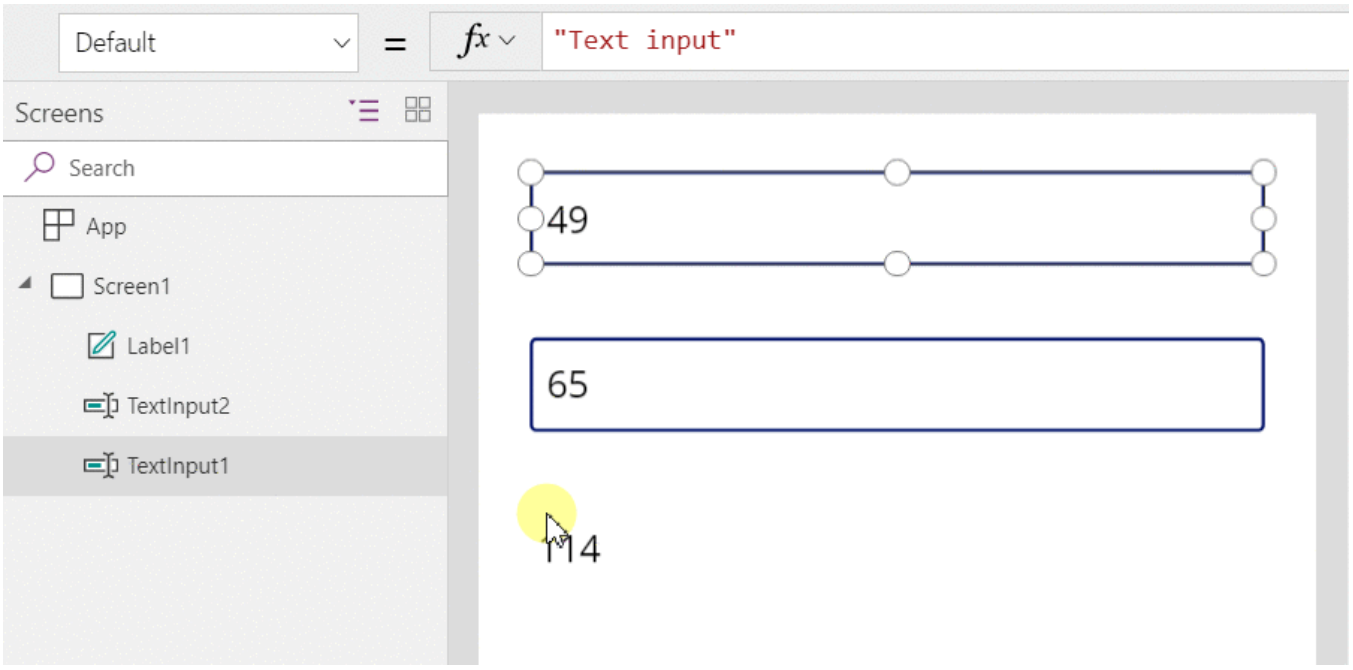
Apps you create in Power Apps work a lot like Excel. Instead of updating cells, you add controls anywhere on a screen and name them for use in formulas.

For example, you can copy the Excel behavior in an app by adding a **Label** control named **Label1**, and two **Text input** controls named **TextInput1** and **TextInput2**. If you set the **Text** property of **Label1** to **TextInput1** + **TextInput2**, it always shows the sum of the numbers in **TextInput1** and **TextInput2** automatically.



Notice that the **Label1** control is selected, showing its **Text** formula in the formula bar at the top of the screen. The formula **TextInput1** + **TextInput2** creates a dependency between these

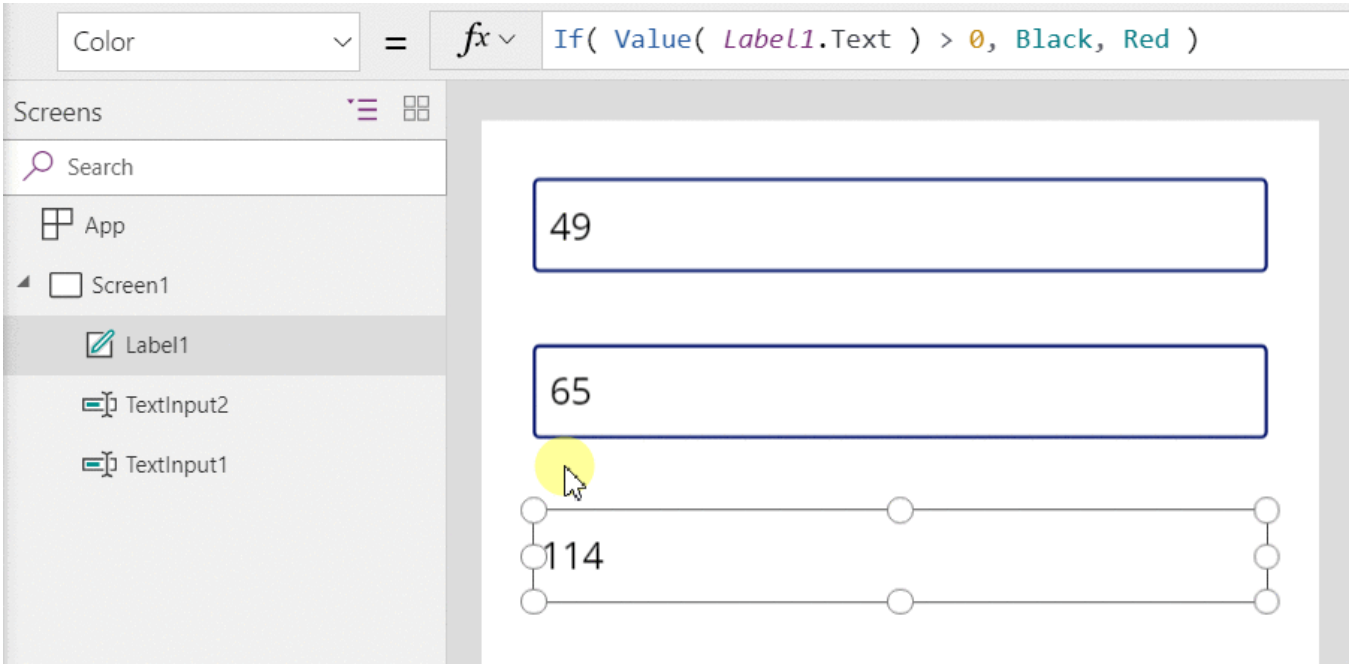
controls, just like dependencies between cells in an Excel workbook. Let's change the value of **TextInput1**:



The formula for **Label1** automatically recalculates and shows the new value.

In Power Apps, you use formulas to set not only the main value of a control but also properties like formatting. In the next example, a formula for the **Color** property of the label automatically shows negative values in red. The **If** function looks familiar from Excel:

```
If( Value(Label1.Text) < 0, Red, Black )
```



You use formulas for many scenarios:

- When your device's GPS is on, a map control shows your current location with a formula that uses **Location.Latitude** and **Location.Longitude**. As you move, the map automatically

tracks your location.
- Other users update data sources. For example, others on your team might update items in a list. When you refresh a data source, any dependent formulas automatically recalculate to show the updated data. For example, you might set a gallery's **Items** property to the formula **Filter(SharePointList)**, which automatically shows the newly filtered set of records.

Benefits

Using formulas to build apps has many advantages:

- If you know Excel, you know Power Apps. The model and formula language are the same.
- If you've used other programming tools, think about how much code you'd need to do these examples. In Visual Basic, you'd write an event handler for the change event on each text-input control. The code to do the calculation in each is redundant and can get out of sync, or you'd need to write a common subroutine. In Power Apps, you do all of that with a single, one-line formula.
- To see where **Label1**'s text comes from, you know exactly where to look: the formula in the **Text** property. There's no other way to change the text of this control. In a traditional programming tool, any event handler or subroutine can change the value of the label, from anywhere in the program. This makes it hard to track down when and where a variable changed.
- If you change a slider control and then change your mind, you can change the slider back to its original value. It's as if nothing ever changed: the app shows the same control values as before. There are no consequences for experimenting and asking "what if," just like in Excel.

In general, if you can do something with a formula, you're better off. Let the formula engine in Power Apps work for you.

Know when to use variables

Let's change our simple adder to act like an old-fashioned adding machine with a running total. When you select the **Add** button, you add a number to the running total. When you select the **Clear** button, you reset the running total to zero.

Expand table

Display	Description
	When the app starts, the running total is 0. The red dot represents the user's finger in the text-input box, where the user enters **77**.
	The user selects the **Add** button.
	77 is added to the running total. The user selects the **Add** button again.
	77 is again added to the running total, resulting in 154. The user selects the **Clear** button.
	The running total is reset to 0.

Our adding machine uses something that doesn't exist in Excel: a button. In this app, you can't use only formulas to calculate the running total because its value depends on a series of actions that the user takes. Instead, you record and update the running total manually. Most programming tools store this information in a *variable*.

Sometimes you need a variable for your app to behave the way you want, but this approach comes with caveats:

- You manually update the running total. Automatic recalculation doesn't do it for you.
- The running total isn't calculated based on the values of other controls. It depends on how many times the user selects the **Add** button and what value is in the text-input control each time. Did the user enter 77 and select **Add** twice, or did they enter 24 and 130 for each addition? You can't tell the difference after the total reaches 154.

- Changes to the total can come from different actions. In this example, both the **Add** and **Clear** buttons update the total. If the app doesn't behave the way you expect, which button causes the problem?

Use a global variable

To create an adding machine, you need a variable to hold the running total. The simplest variables to use in Power Apps are *global variables*.

How global variables work:

- Set the value of a global variable with the Set function. **Set(MyVar, 1)** sets the global variable **MyVar** to a value of **1**.
- Use the global variable by referencing the name used with the **Set** function. In this case, **MyVar** returns **1**.
- Global variables can hold any value, including strings, numbers, records, and tables.

Rebuild the adding machine by using a global variable:

1. Add a text-input control named **TextInput1**, and two buttons named **Button1** and **Button2**.

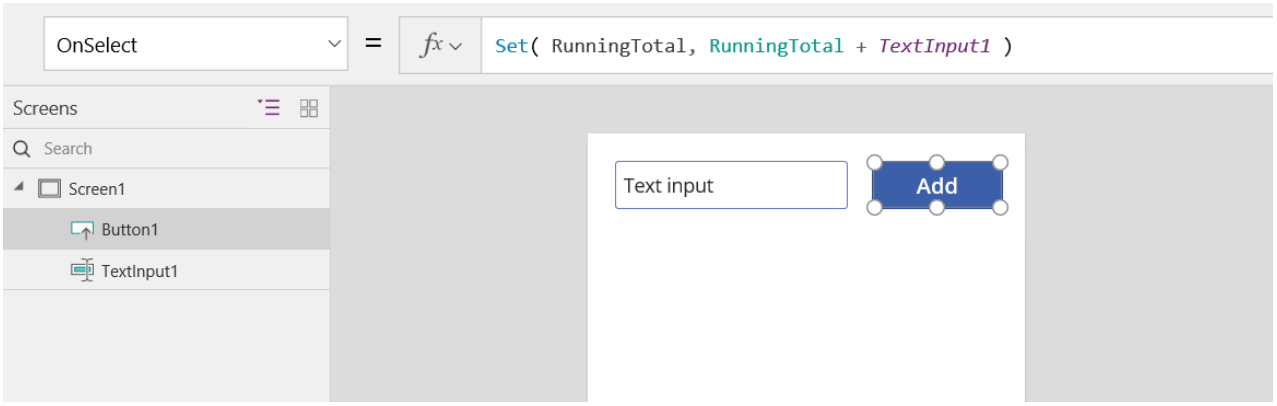
2. Set the Text property of **Button1** to **"Add"**, and set the **Text** property of **Button2** to **"Clear"**.

3. To update the running total when a user selects the **Add** button, set its OnSelect property to this formula:

   Set(RunningTotal, RunningTotal + TextInput1)

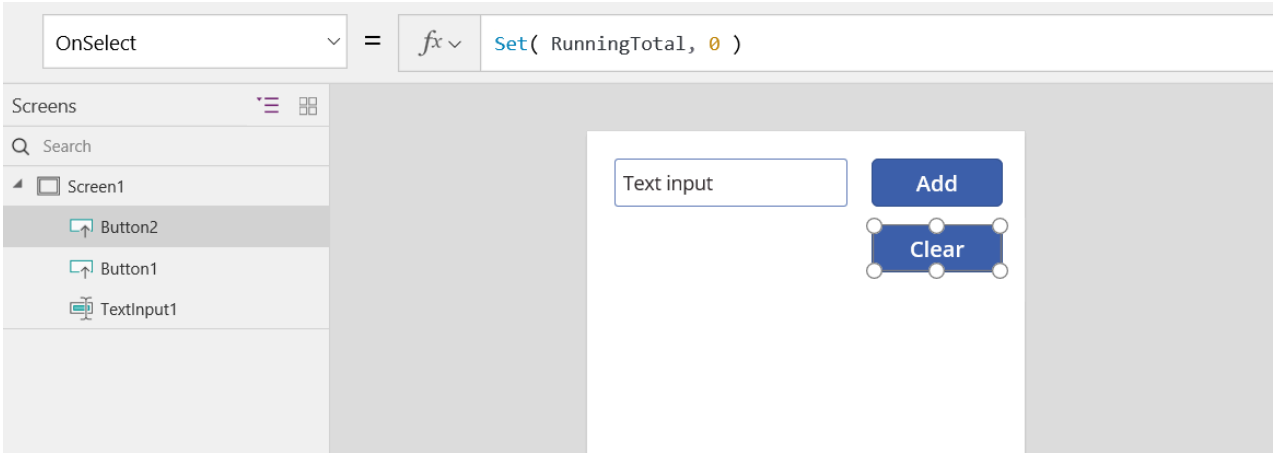
   This formula creates **RunningTotal** as a global variable that holds a number because of the + operator. Reference **RunningTotal** anywhere in the app. When the user opens the app, **RunningTotal** has an initial value of *blank*.

   The first time a user selects the **Add** button and Set runs, **RunningTotal** is set to the value **RunningTotal** + **TextInput1**.



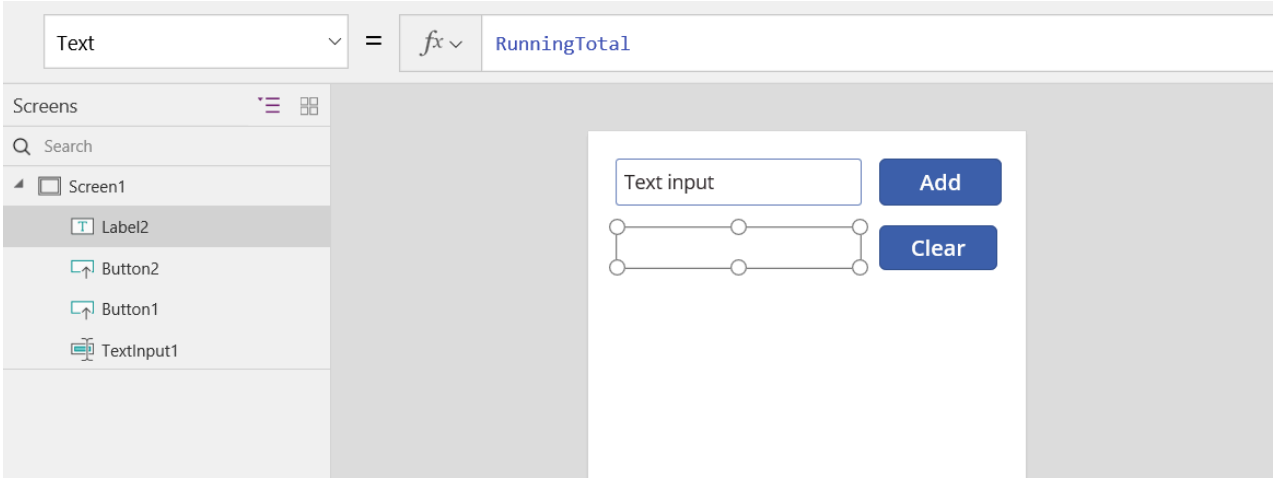
4. To set the running total to **0** when the user selects the **Clear** button, set its **OnSelect** property to this formula:

   Set(RunningTotal, 0)

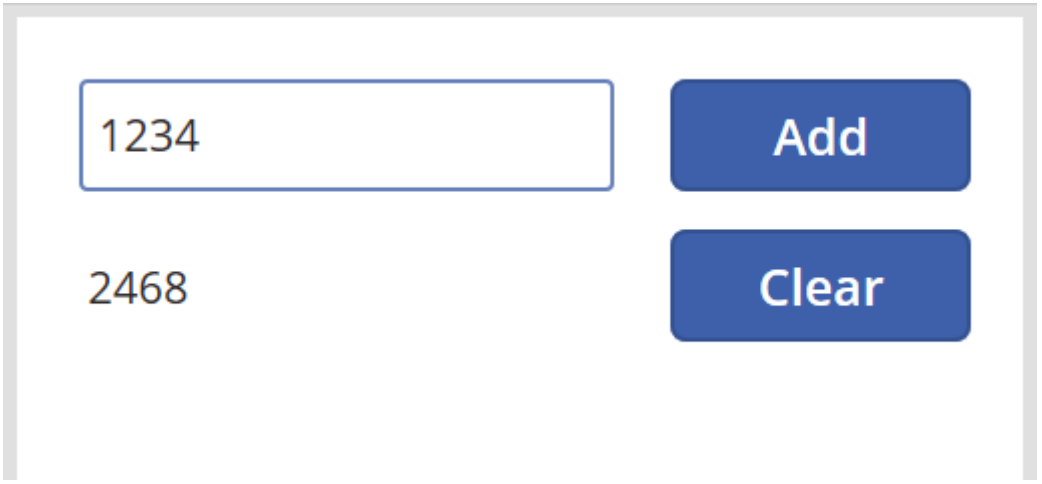


5. Add a **Label** control, and set its **Text** property to **RunningTotal**.

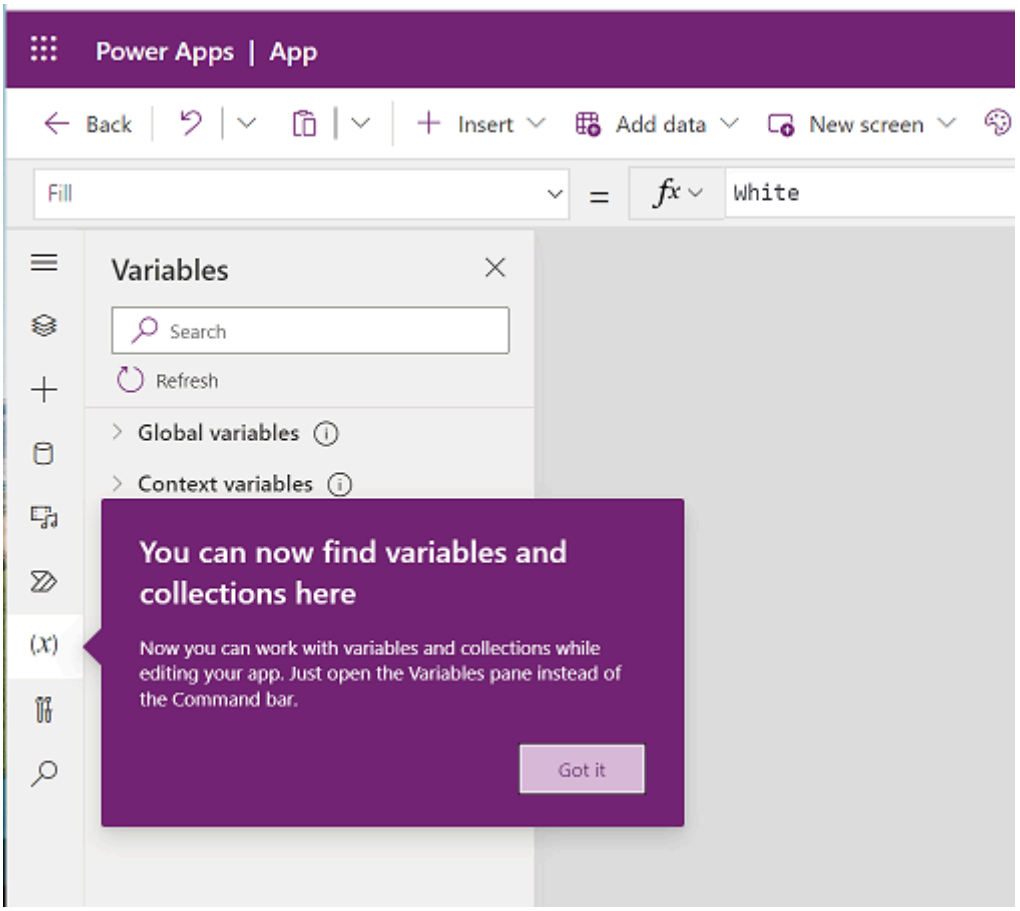
   This formula automatically recalculates and shows the user the value of **RunningTotal** as it changes based on the buttons the user selects.



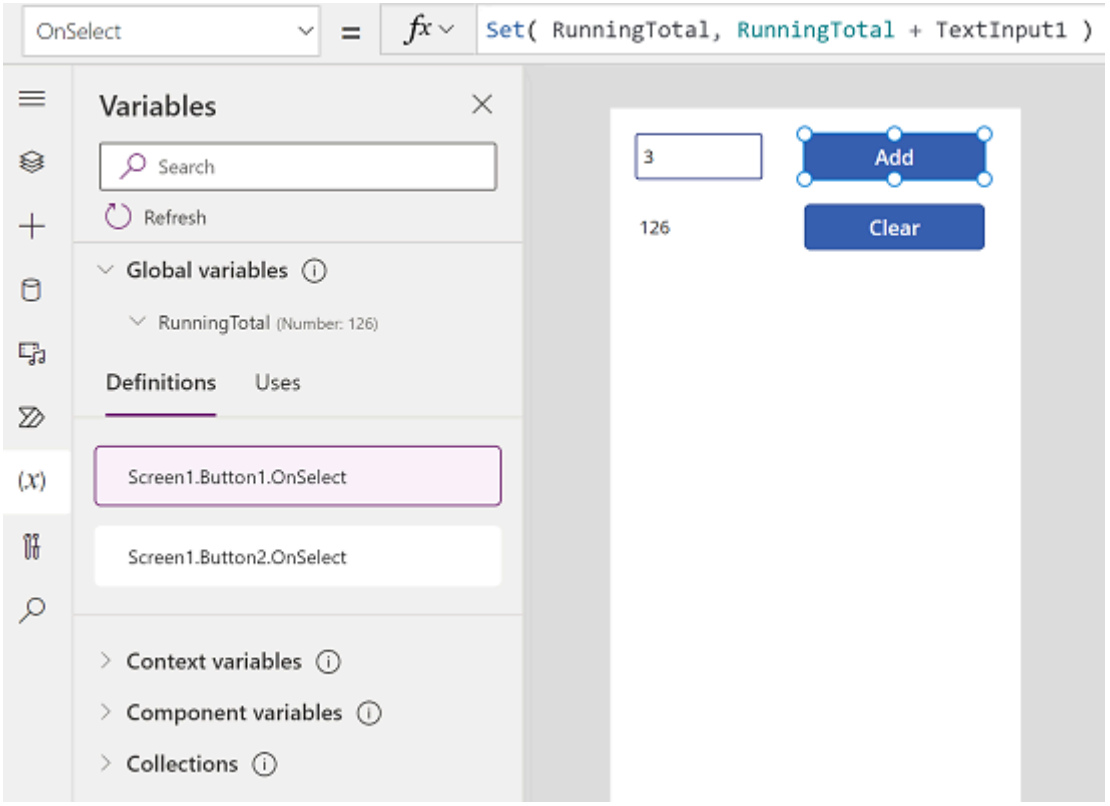
6. Preview the app. Enter a number in the text box and select the **Add** button a few times. When ready, return to the authoring experience using the `Esc` key.



7. To show the global variable's value, select **Variables** on the app authoring menu.



8. To show all the places where the variable is defined and used, select it under **Global variables**.



Types of variables

Power Apps has three types of variables:

Expand table

Variable type	Scope	Description	Functions that establish
Global variables	App	Use global variables to hold a number, text string, Boolean, record, table, or other value that you reference anywhere in the app.	Set
Context variables	Screen	Use context variables to pass values to a screen, like parameters in other languages. You reference them from only one screen.	UpdateContext Navigate
Collections	App	Use collections to hold a table that you reference anywhere in the app. You can change the contents of the table, and save it to the local device for later use.	Collect ClearCollect

Create and remove variables

Variables are created implicitly when they appear in a **Set**, **UpdateContext**, **Navigate**, **Collect**, or **ClearCollect** function. To declare a variable and its type, just include it in any of these functions anywhere in your app. These functions don't create variables; they only fill variables

with values. You never declare variables explicitly like you might in another programming tool, and all typing is implicit from usage.

For example, you might have a button control with an **OnSelect** formula equal to **Set(X, 1)**. This formula establishes **X** as a variable with a type of number. You use **X** in formulas as a number, and that variable has a value of *blank* after you open the app but before you select the button. When you select the button, you give **X** the value of **1**.

If you add another button and set its **OnSelect** property to **Set(X, "Hello")**, an error occurs because the type (text string) doesn't match the type in the previous **Set** (number). All implicit definitions of the variable must agree on type. Again, all this happens because you mention **X** in formulas, not because any of those formulas actually run.

Remove a variable by removing all the **Set**, **UpdateContext**, **Navigate**, **Collect**, or **ClearCollect** functions that implicitly establish the variable. Without these functions, the variable doesn't exist. Also remove any references to the variable because they cause an error.

Variable lifetime and initial value

Variables stay in memory while the app runs. When the app closes, the values in variables are lost.

Store the contents of a variable in a data source by using the **Patch** or **Collect** functions. Store values in collections on the local device by using the SaveData function.

When the user opens the app, all variables start with an initial value of *blank*.

Reading variables

Use the variable's name to read its value. For example, define a variable with this formula:

```
Set( Radius, 12 )
```

Then use **Radius** anywhere you use a number, and it's replaced with **12**:

```
Pi() * Power( Radius, 2 )
```

If you give a context variable the same name as a global variable or a collection, the context variable takes precedence. You can reference the global variable or collection by using the disambiguation operator **[@Radius]**.

Reserved variable names

Don't use any of the following variable names. These names are app properties, and using them can cause variable name collisions that result in unexpected app behavior.

- ActiveScreen
- DesignHeight
- DesignWidth
- Height
- MinScreenHeight
- MinScreenWidth
- SizeBreakpoints
- StudioVersion
- TestCaseId
- Testing
- TestSuiteId
- Theme
- Width

Use a context variable

Let's look at how you create an adding machine by using a context variable instead of a global variable.

How context variables work

- You implicitly establish and set context variables by using the **UpdateContext** or **Navigate** function. When the app starts, the initial value of each context variable is *blank*.
- You update context variables with records. In other programming tools, you usually use "=" for assignment, like "x = 1". For context variables, use **{ x: 1 }** instead. When you use a context variable, use its name directly without the record syntax.
- You can also set a context variable when you use the **Navigate** function to show a screen. If you think of a screen as a kind of procedure or subroutine, this approach is like parameter passing in other programming tools.
- Except for **Navigate**, context variables are limited to the context of a single screen, which is where they get their name. You can't use or set them outside this context.
- Context variables can hold any value, including strings, numbers, records, and tables.

Rebuild the adding machine by using a context variable:

1. Add a text-input control, named **TextInput1**, and two buttons, named **Button1** and **Button2**.

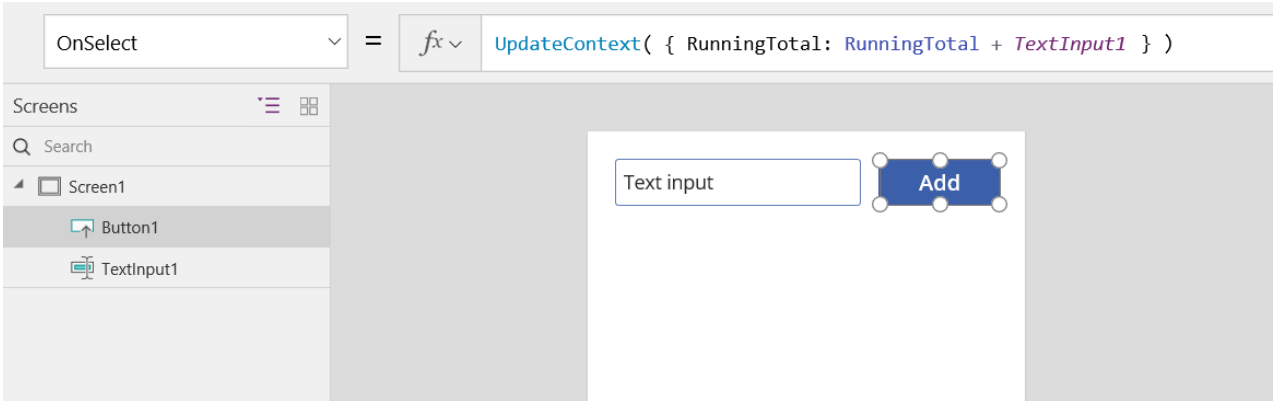
2. Set the Text property of **Button1** to "**Add**", and set the **Text** property of **Button2** to "**Clear**".

3. To update the running total whenever a user selects the **Add** button, set its OnSelect property to this formula:

   UpdateContext({ RunningTotal: RunningTotal + TextInput1 })

   This formula establishes **RunningTotal** as a context variable that holds a number because of the + operator. You reference **RunningTotal** anywhere in this screen. When the user opens the app, **RunningTotal** has an initial value of *blank*.

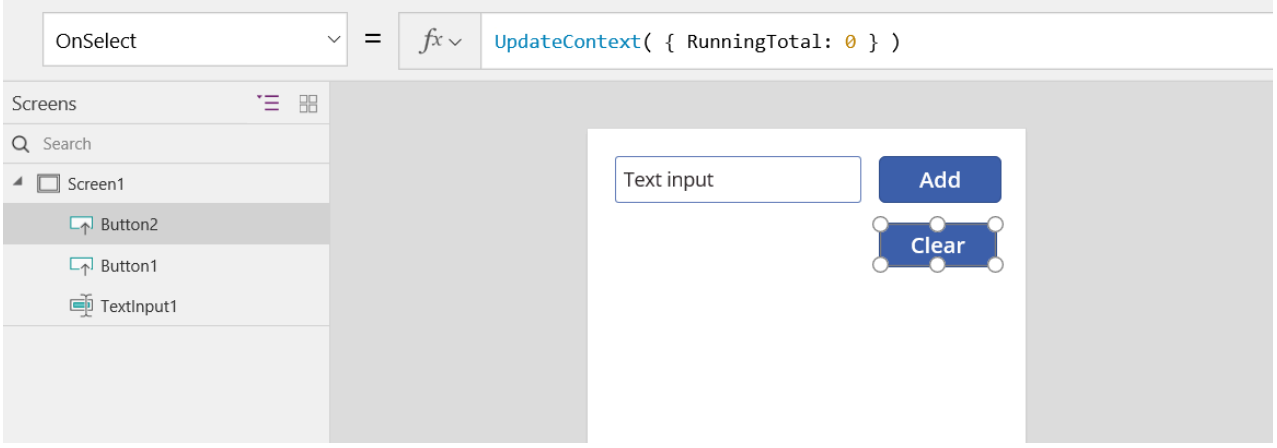
   The first time the user selects the **Add** button and UpdateContext runs, **RunningTotal** is set to the value **RunningTotal + TextInput1**.



4. To set the running total to **0** whenever the user selects the **Clear** button, set its OnSelect property to this formula:

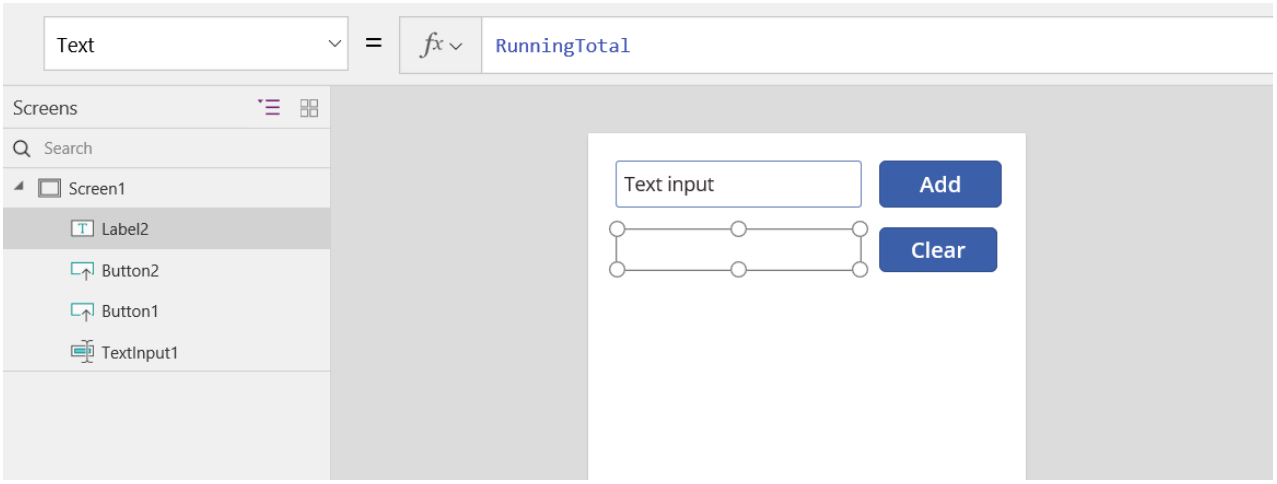
   UpdateContext({ RunningTotal: 0 })

   Again, use UpdateContext with the formula **UpdateContext({ RunningTotal: 0 })**.

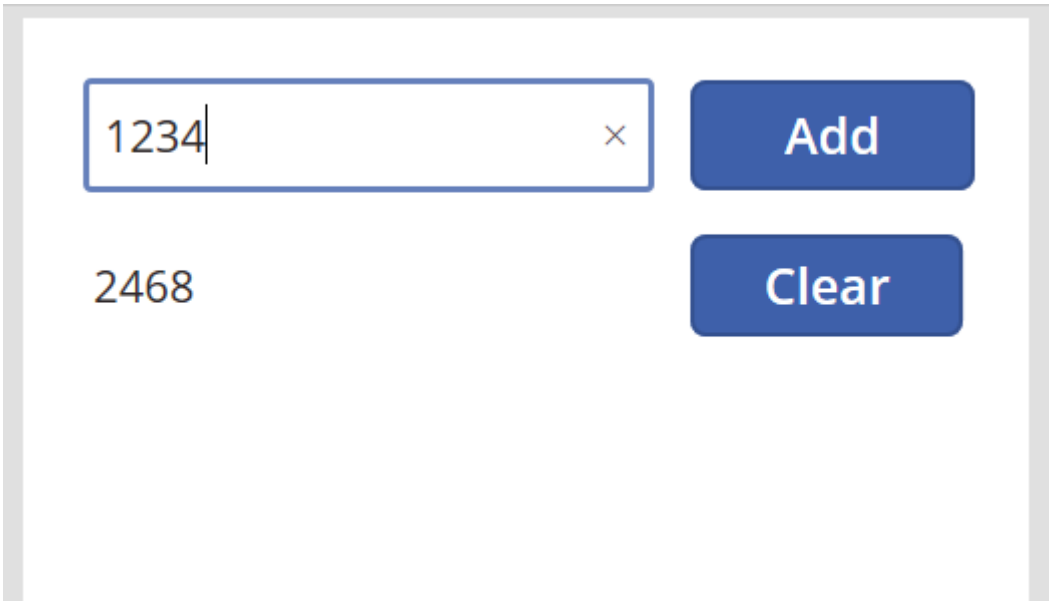


5. Add a Label control, and set its Text property to **RunningTotal**.

   This formula will automatically be recalculated and show the user the value of **RunningTotal** as it changes based on the buttons that the user selects.

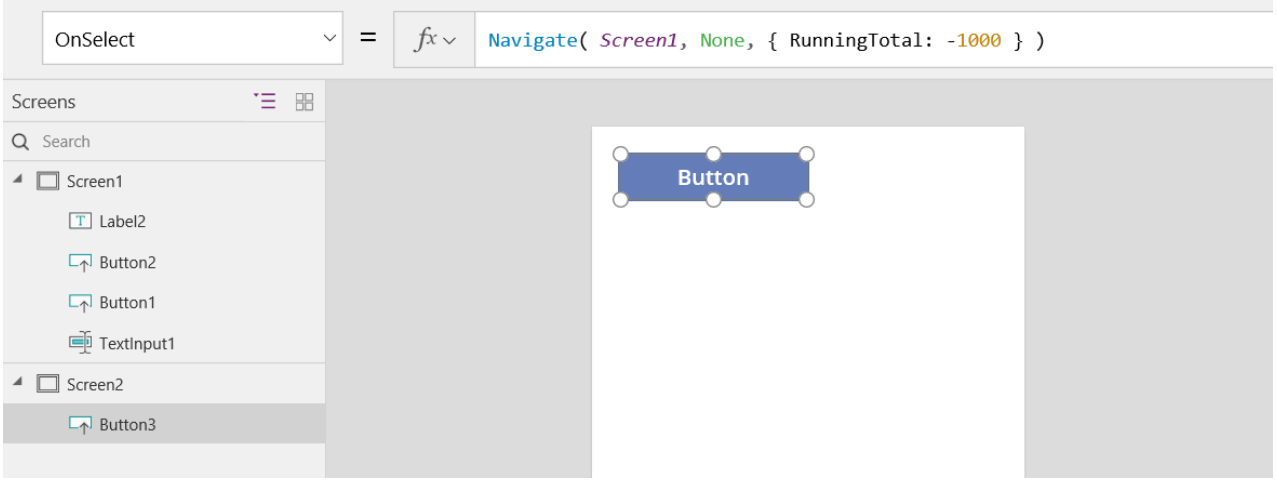


6. Preview the app. Enter a number in the text box and select the **Add** button a few times. When you're ready, return to the authoring experience by using the `Esc` key.

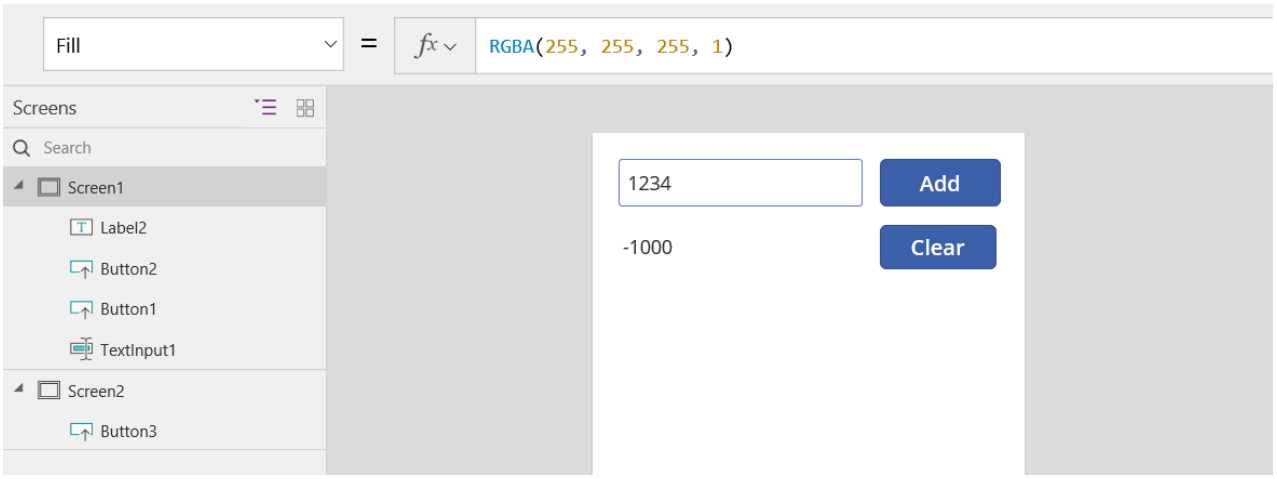


7. Set the value of a context variable while navigating to a screen to pass "context" or "parameters" from one screen to another. To demonstrate this technique, insert a screen, insert a button, and set its **OnSelect** property to this formula:

   Navigate(Screen1, None, { RunningTotal: -1000 })



Hold down the `Alt` key while you select this button to show **Screen1** and set the context variable **RunningTotal** to -1000.



8. To show the value of the context variable, do one of the following:

   - If you're using the preview version of Power Apps Studio, select **Variables** in the app authoring menu.
   - If you're using the classic version of Power Apps Studio, select the **File** menu, and then select **Variables** in the left pane.

9. To show where the context variable is defined and used, select it under **Context variables**.

Use a collection

Let's create an adding machine by using a collection. Because a collection holds a table that's easy to change, this adding machine keeps a "paper tape" of each value as you enter it.

How collections work

- Create and set collections by using the ClearCollect function. You can use the Collect function instead, but it requires another variable instead of replacing the old one.
- A collection is a type of data source and a table. To get a single value in a collection, use the First function, and get one field from the resulting record. If you use a single value with ClearCollect, this is the **Value** field, as in this example:
  First(*VariableName* **).Value**

Create an adding machine by using a collection:

1. Add a Text input control, named **TextInput1**, and two buttons, named **Button1** and **Button2**.

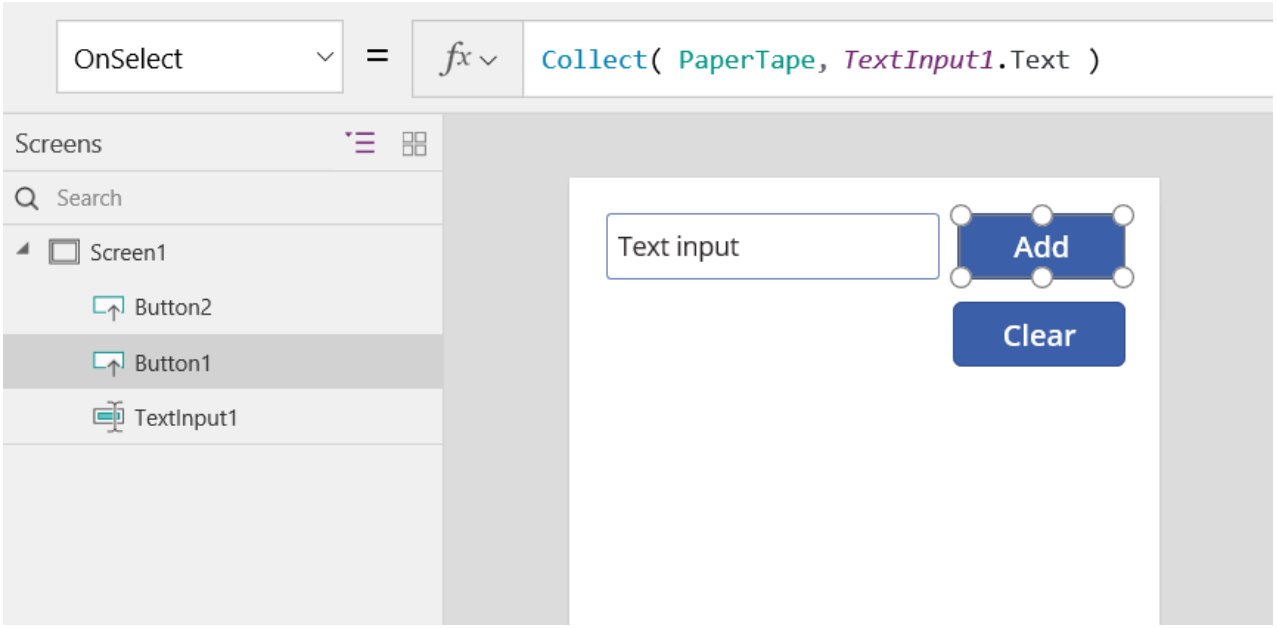
2. Set the Text property of **Button1** to **"Add"**, and set the **Text** property of **Button2** to **"Clear"**.

3. To update the running total whenever a user selects the **Add** button, set its **OnSelect** property to this formula:

   Collect(PaperTape, TextInput1.Text)

   The mere existence of this formula establishes **PaperTape** as a collection that holds a single-column table of text strings. You can reference **PaperTape** anywhere in this app. Whenever a user opens this app, **PaperTape** is an empty table.

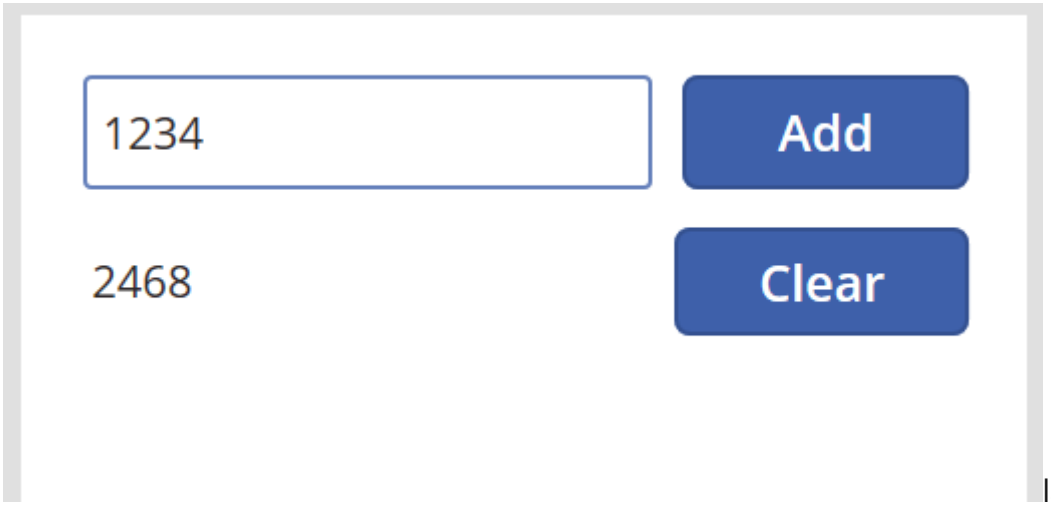
   When this formula runs, it adds the new value to the end of the collection. Because we're adding a single value, **Collect** automatically places it in a single-column table, and the column's name is **Value**, which you'll use later.



4. To clear the paper tape when the user selects the **Clear** button, set its **OnSelect** property to this formula:

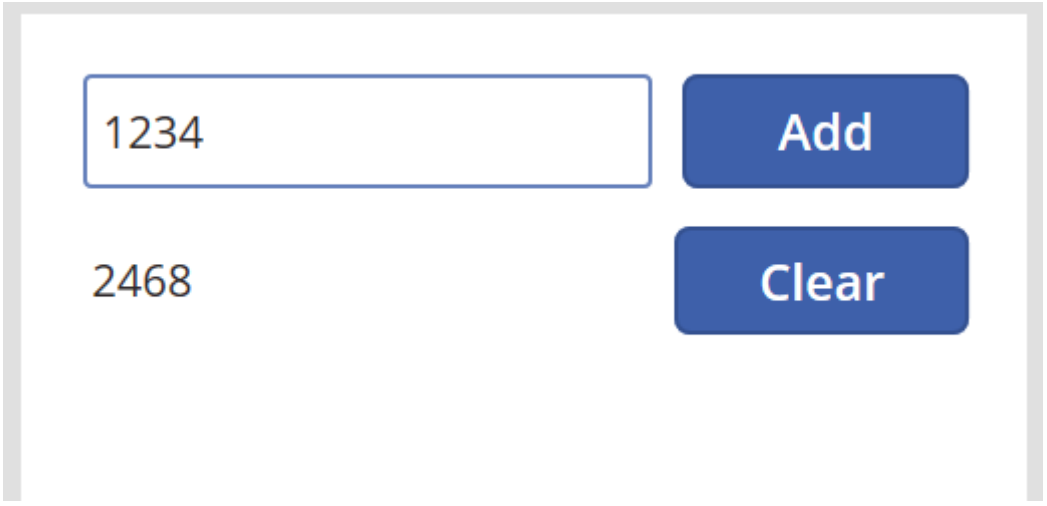
   Clear(PaperTape)

   ![OnSelect property of the Clear but1. To run the adding machine, select F5 to open Preview, enter numbers in the text input control, and select buttons.



label.]
(media/working-with-variables/papertape-3.png)

5. To run the adding machine, press F5 to open Preview, enter numbers in the text-input control, and select buttons.



6. To return to the default workspace, select `Esc`.

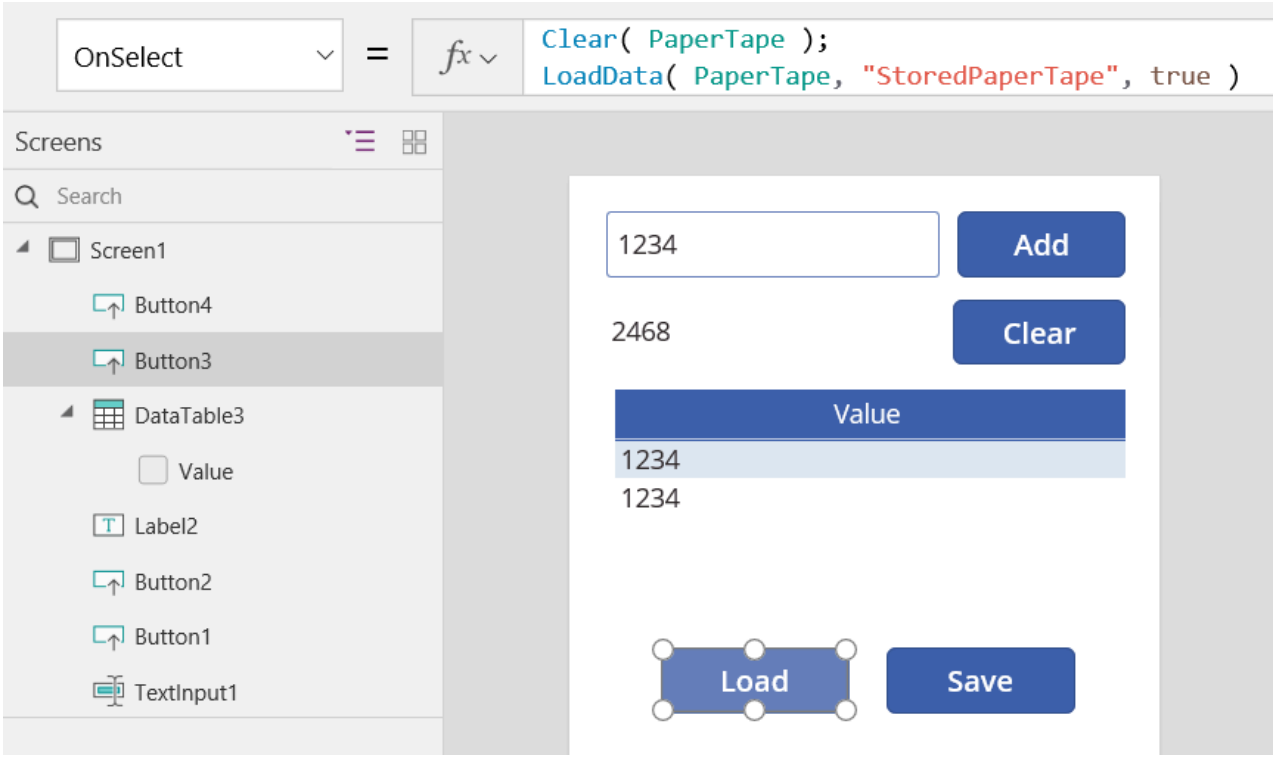
7. To display the paper tape, insert a **Data table** control, and set its **[Items] (controls/properties1. To see the values in your collection, do one of the following:

   - If you're using the preview version of Power Apps Studio, select **Variables** in the app authoring menu, and then select **Collections**.
   - If you're using the classic version of Power Apps Studio, select **Collections** on the **File** menu.. To see the values in your collection, do one of the following:
   - If you're using the preview version of Power Apps Studio, select **Variables** in the app authoring menu and then select **Collections**.
   - If you're using the classic versionof Power Apps Studio, select **Collections** on the **File** menu.

8. To store and get your collection, add two more button controls, and set their **Text** properties to **Load** and **Save**. Set the **OnSelect** property of the **Load** button to this formula:

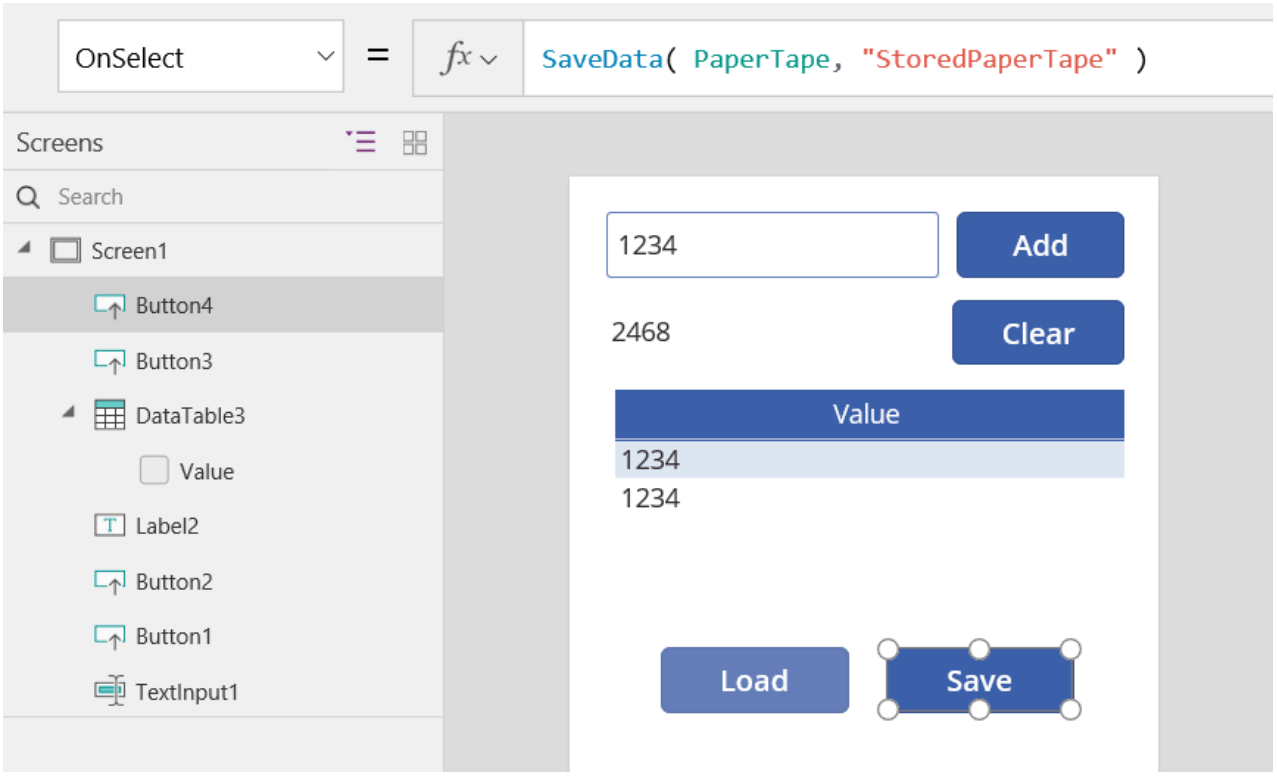
   Clear(PaperTape); LoadData(PaperTape, "StoredPaperTape", true)

   You need to clear the collection first because **LoadData** will append the stored values to the end of the collection.



9. Set the **OnSelect** property of the **Save** button to this formula:

   SaveData(PaperTape, "StoredPaperTape")



10. Preview again by selecting F5, enter numbers in the text input control, and select buttons. Select the **Save** button. Close and reload the app, and select the **Load** button to reload your collection.

> ⓘ **Note**
>
> **SaveData** and **LoadData** functions work in Power Apps Mobile but not Power Apps Studio or the web player for Power Apps.

Understand behavior formulas for canvas apps

Article • 12/16/2022

Most formulas calculate a value. Like an Excel spreadsheet, recalculation happens automatically as values change. For example, you might want to show the value in a **Label** control in red if the value is less than zero or in black otherwise. So you can set the **Color** property of that control to this formula:

Power Fx

```
If( Value(TextBox1.Text) >= 0, Color.Black, Color.Red )
```

In this context, what does it mean when the user selects a **Button** control? No value has changed, so there is nothing new to calculate. Excel has no equivalent to a **Button** control.

By selecting a **Button** control, the user initiates a sequence of actions, or behaviors, that will change the state of the app:

- Change the screen that's displayed: **Back** and **Navigate** functions.
- Control a signal: **Enable** and **Disable** functions.
- Refresh, update, or remove items in a data source: **Refresh**, **Update**, **UpdateIf**, **Patch**, **Remove**, **RemoveIf** functions.
- Update a context variable: **UpdateContext** function.
- Create, update, or remove items in a collection: **Collect**, **Clear**, **ClearCollect** functions.

Because these functions change the state of the app, they can't be automatically recalculated. You can use them in the formulas for the **OnSelect**, **OnVisible**, **OnHidden**, and other **On...** properties, which are called behavior formulas.

More than one action

Use semicolons to create a list of actions to perform. For example, you might want to update a context variable and then return to the previous screen:

Power Fx

```
UpdateContext( { x: 1 } ); Back()
```

Actions are performed in the order in which they appear in the formula. The next function won't start until the current function has completed. If an error occurs, subsequent functions might not start.

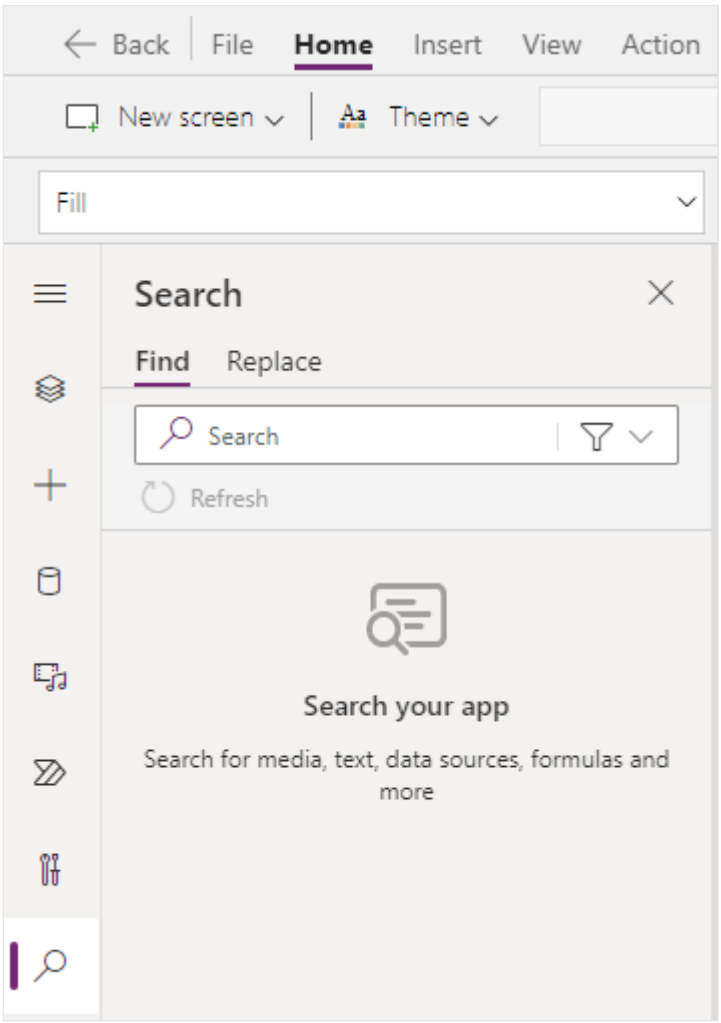
Use the Search pane

Article • 04/24/2023

You can now use the Search pane to locate objects—like media files, variables, collections, and data sources—across your app. You can also use the Search pane to find repeated instances of strings in formulas. For example, using the Search pane, you can look for each instance of `HoverColor` to determine the setting for that property in other areas of your app. You can use the Search pane to learn more about what's being used by your app, where, and you can go right to those results to make any necessary updates. In addition, you can use the replace capability to update one or more instances of text, variables, collections, or formula references.



Prerequisites

- Sign up for Power Apps.
- Create an app from a template, create a new app, or open an existing app in Power Apps.
- Learn how to configure a control.

Open the Search pane

You can open the Search pane by selecting **Search** . You can also use shortcut keys by selecting **Ctrl**+**F** when your cursor is outside the formula bar, or selecting **Ctrl**+**Shift**+**F** when your cursor is inside the formula bar.

You can also open the Search pane directly to the Replace functionality by selecting **Ctrl**+**H** when your cursor is outside the formula bar, or selecting **Ctrl**+**Shift**+**H** when your cursor is inside the formula bar.

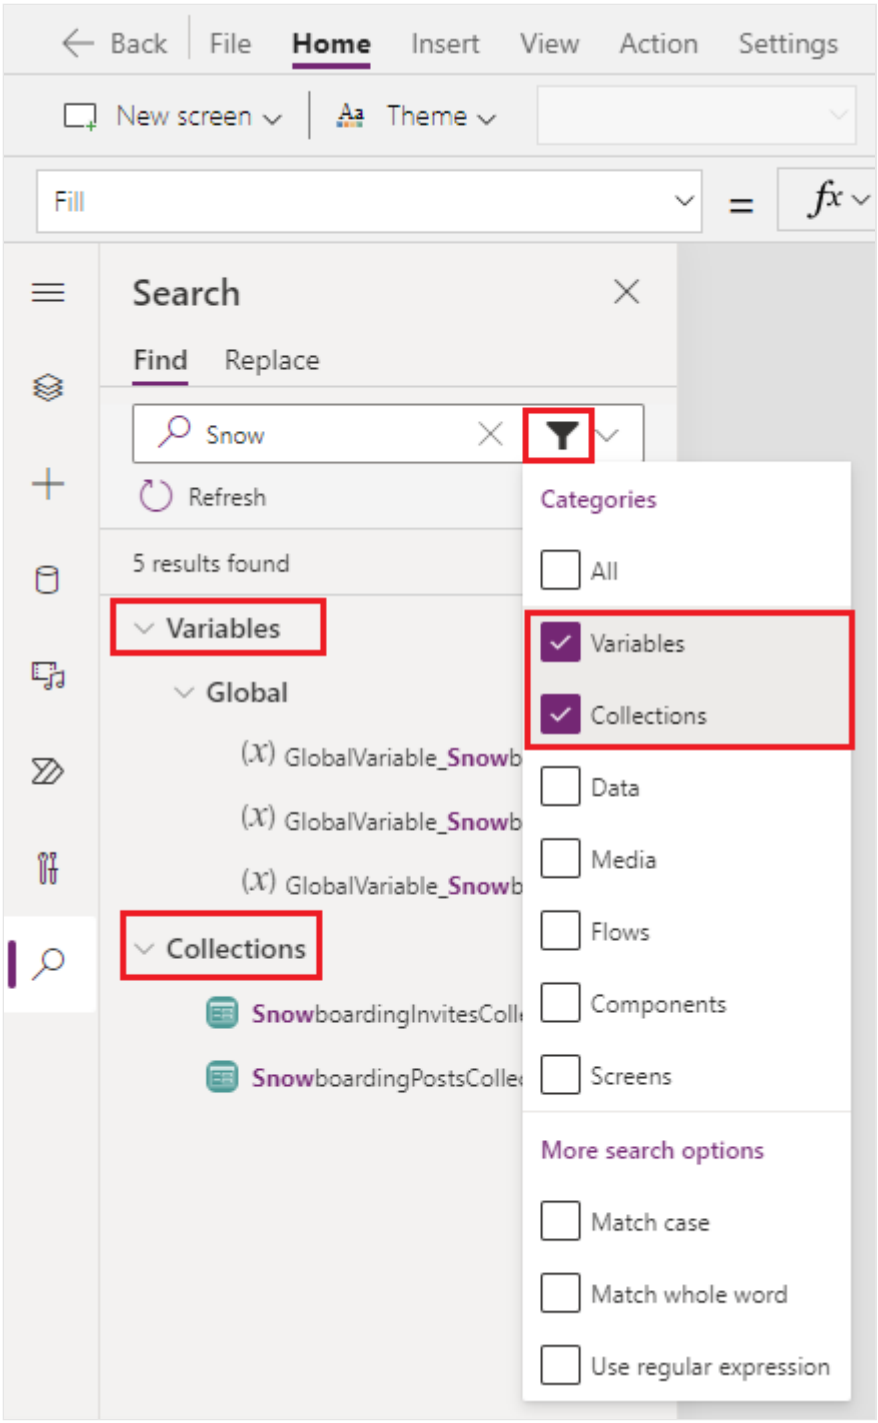
> **Note**
>
> Selecting **Ctrl**+**F** or **Ctrl**+**H** inside the formula bar will open the **Find and Replace** capability inside the formula bar.

Filter search results

You can filter search results by selecting one or more categories. These categories help you focus the search by narrowing down the areas within the app—such as screens, media, and collections.

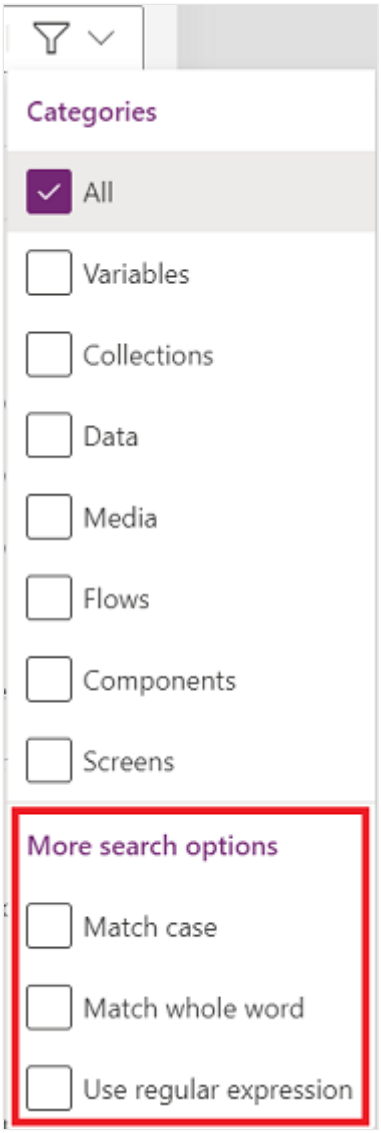
To select the categories you want to search on, use the filter option next to the search box. The default selection is **All**, which searches across all categories within the open app.

The following example shows search results filtered for the search term **Snow** with the selected categories of **Variables** and **Collections**.



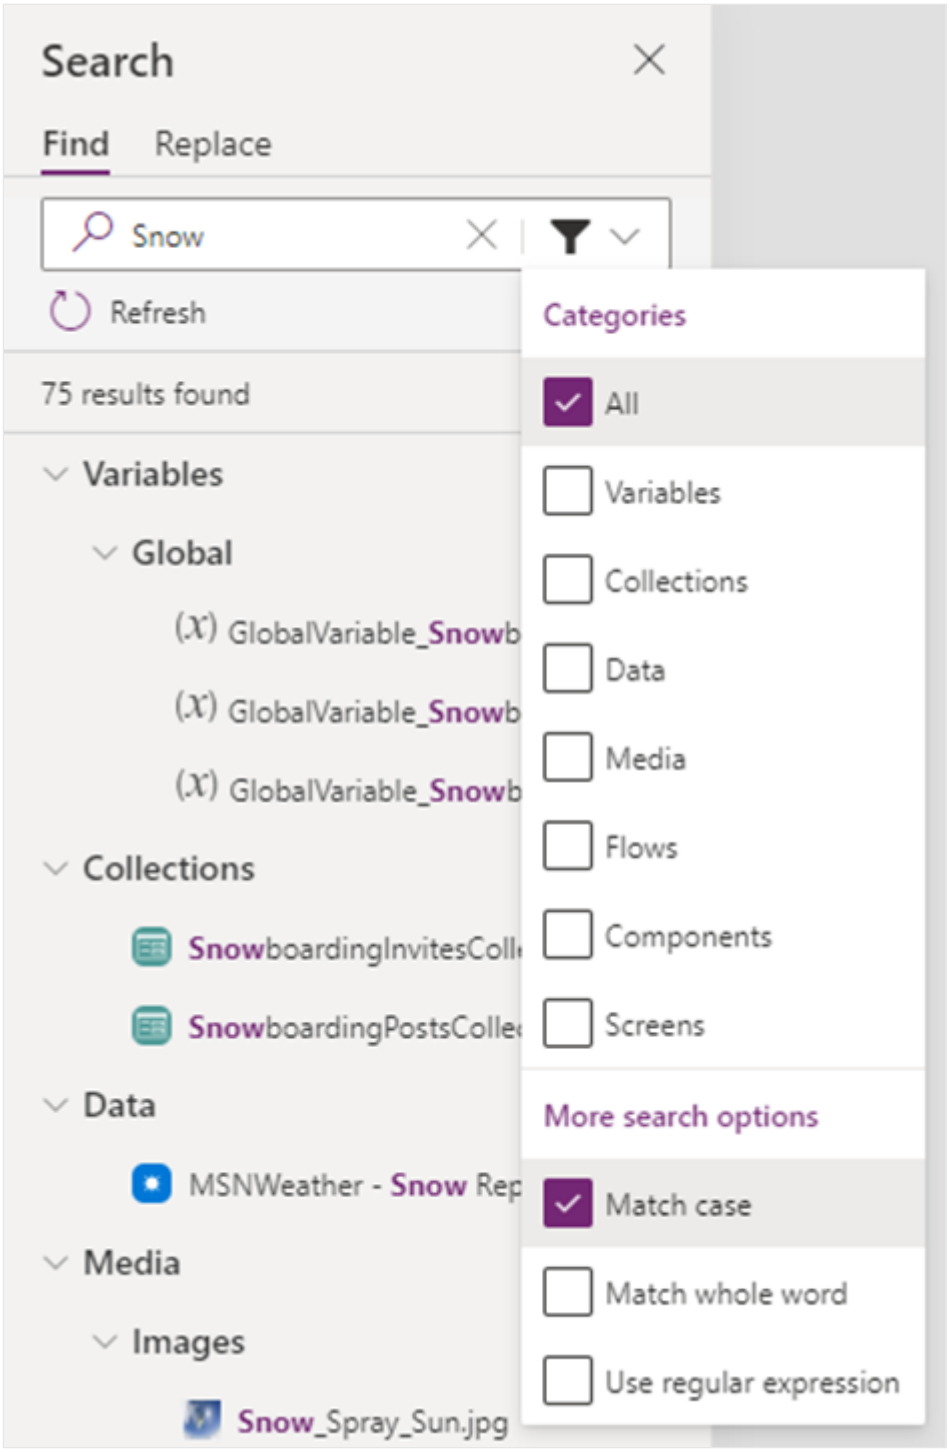
Refine your search

You can use more search options to further refine your search. These options are available inside the filter option named **More search options** (below the **Categories** section).



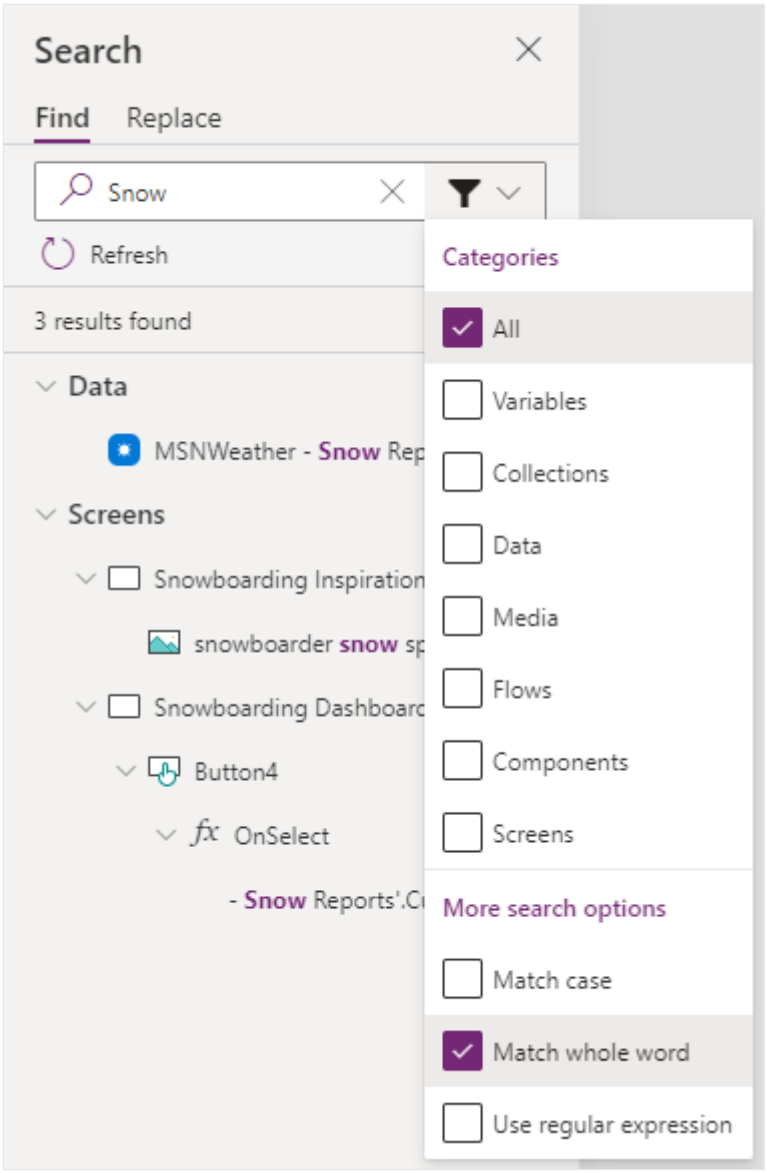
- **Match case** returns search results that only match the specified case.

  In the following example, instances of **Snow** (uppercase S) will appear as a match, but **snow** (lowercase S) won't.



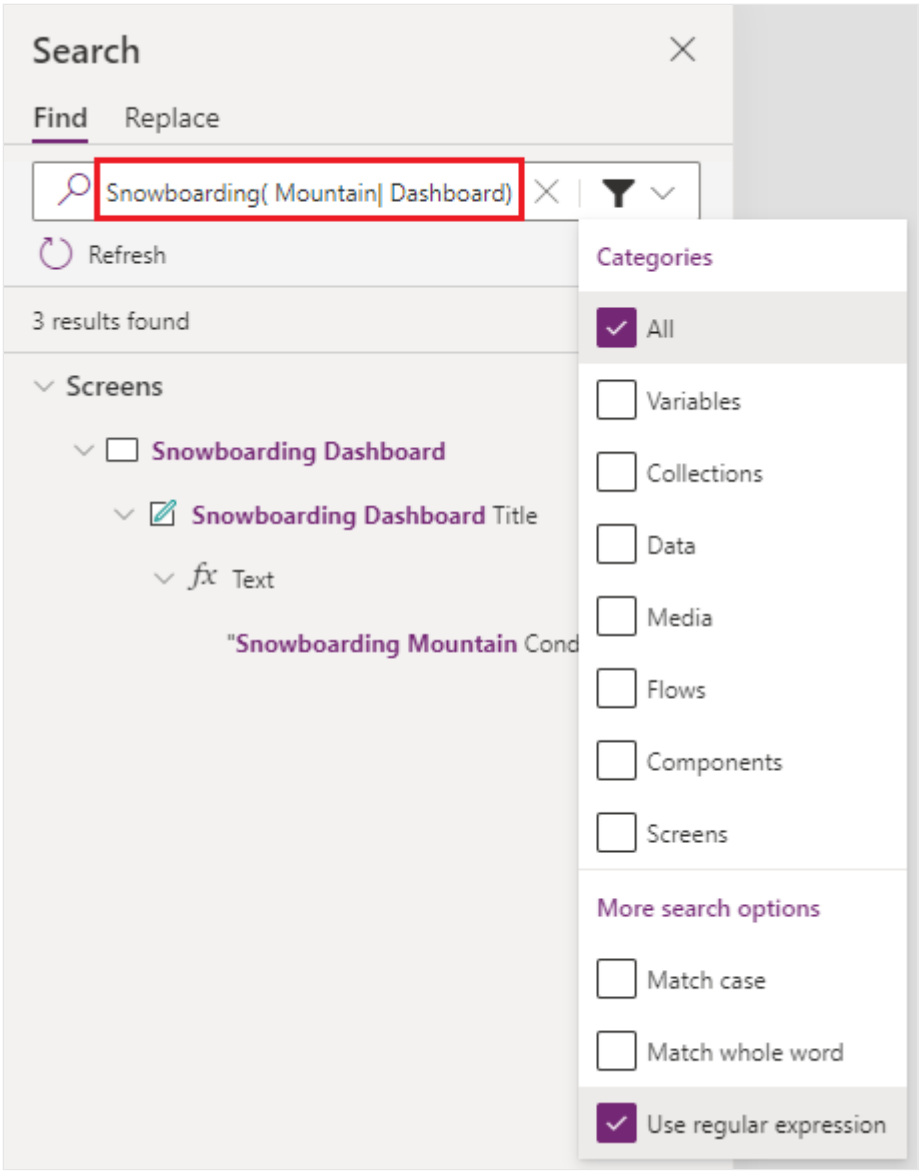
- **Match whole word** returns search results for exact matches of the entire sequence of characters.

  In the following example, **Snow** returns only a few results although **Snow** appears within names many times across all app objects.



- **Use regular expression (RegEx)** returns search results for matches conforming to the regular expression specified within the input area.

  In the following example, using the regular expression search capability with `Snowboarding( Mountain | Dashboard)` formula returns matches for **Snowboarding** when it appears together with either **Mountain** or **Dashboard**.



Work with search results

Selecting search results in different areas of the Search pane will behave differently depending on the context of the result. The search results can be classified under two broad categories—**Definitions** and **Instances**:

- **Definitions** describe the object being referred to in your app, usually in a formula.

  There are several category headers inside the Search pane that you can use to navigate through the results. Categories such as **Variables**, **Collections**, **Data**, **Media**, **Flows**, and **Components** are referred to as **definitions**.

  Selecting the results under such definition category headers takes you to the appropriate information screen such as for Variables and Collections, or to the appropriate pane where that object is available in your app (such as Data, Media, Flows, or Components).

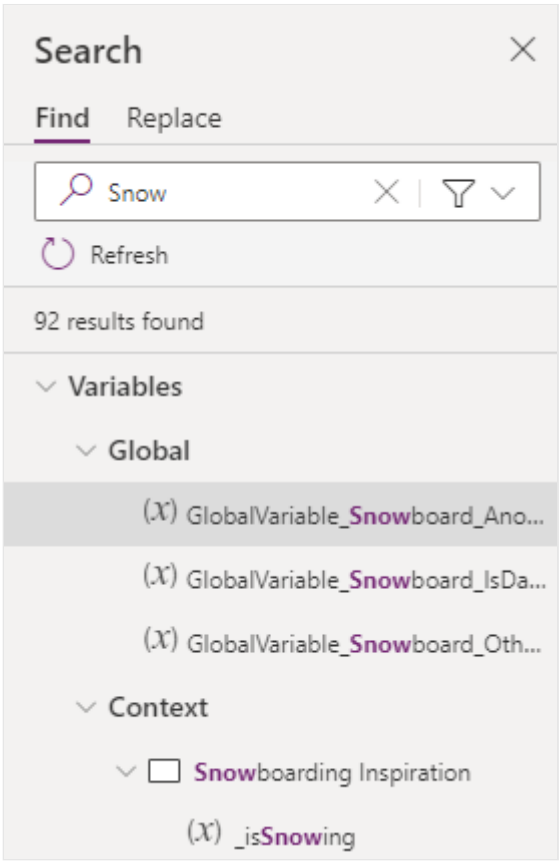
- **Instances** describe the search results that are tied to an individual app, screen, or control property in the formula bar. All these results are tied to the **Screens** category based on the structure found inside the **Tree View**. When you select a result under this **Screens** category, you'll be taken to that specific formula bar reference or the related control, as applicable.

Variables

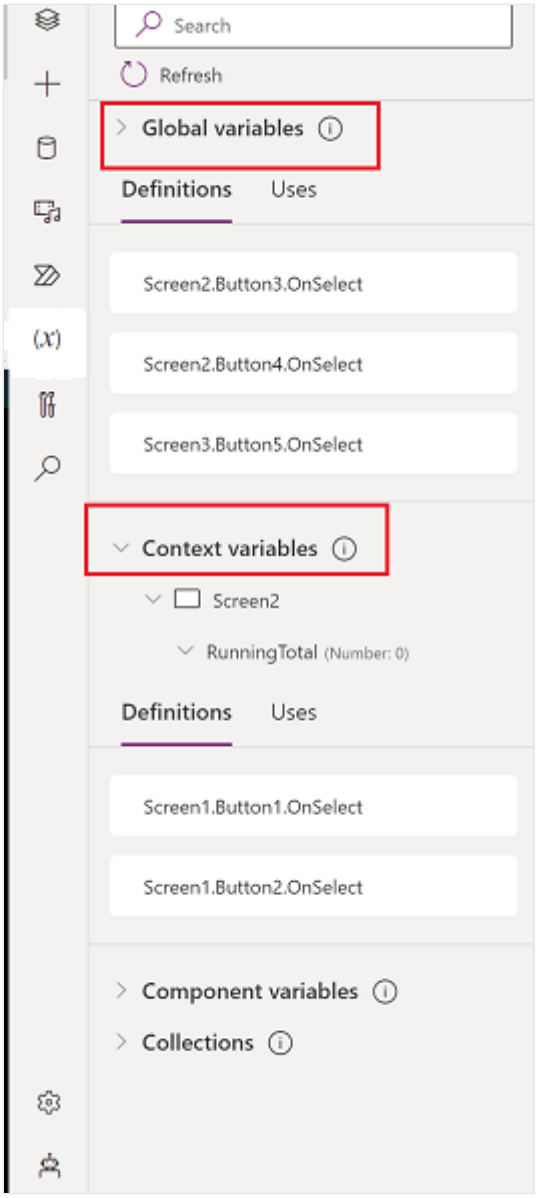
Selecting a global or a context variable under the **Variables** header in the search results will take you to the Variables information screen for the selection.

As shown below, you're taken to the definition of the global or context variable depending on your selection from the search results available.

Search result:

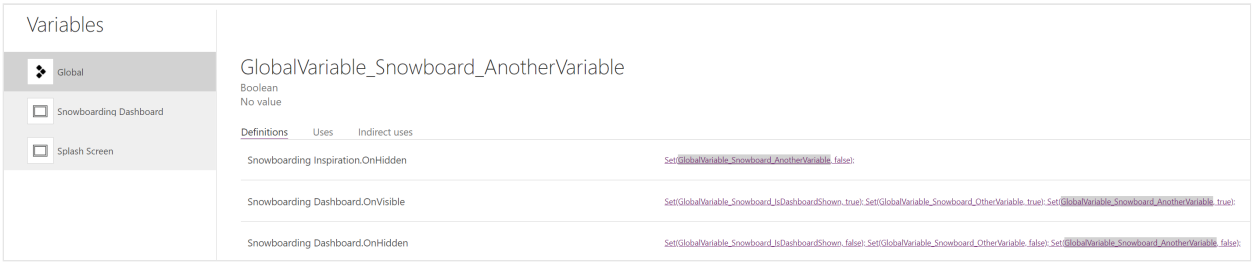


If you're using the preview version of Power Apps Studio, select the **Context variables** or **Global variables** to see more information about the variable.

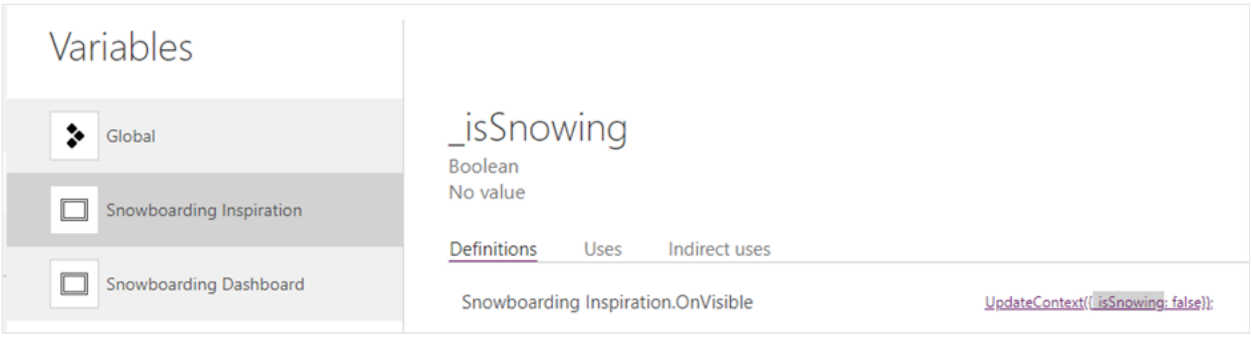


If you're using the classic version of Power Apps Studio, depending on the selected global or context variable, you're taken to the information screen for the selected type of variable.

Global variable selected:

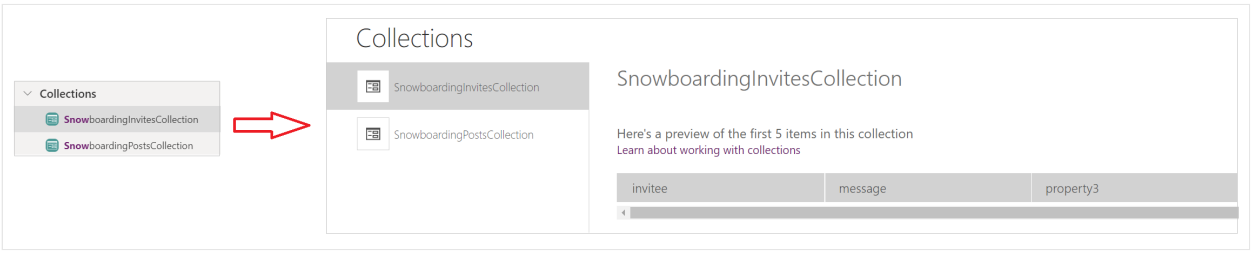


Context variable selected:



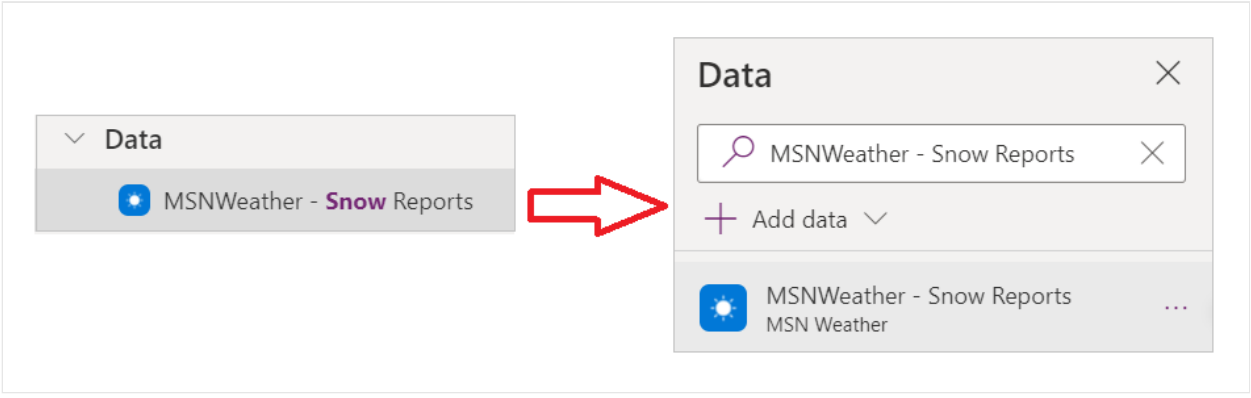
Collections

Selecting a collection under the **Collections** header will take you to the information screen for that collection.



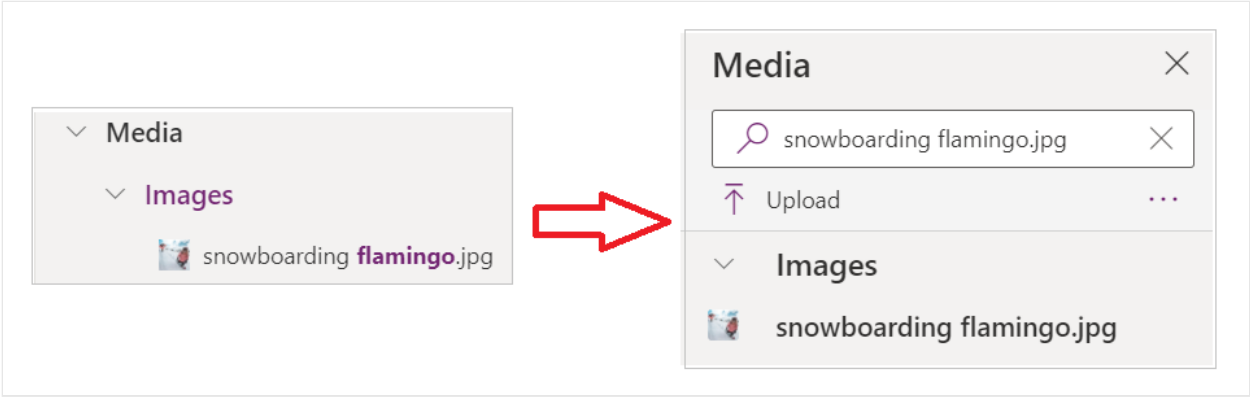
Data

Selecting a result under the **Data** header opens the **Data** pane, and prepopulates the search input for that pane by using the selected result text.



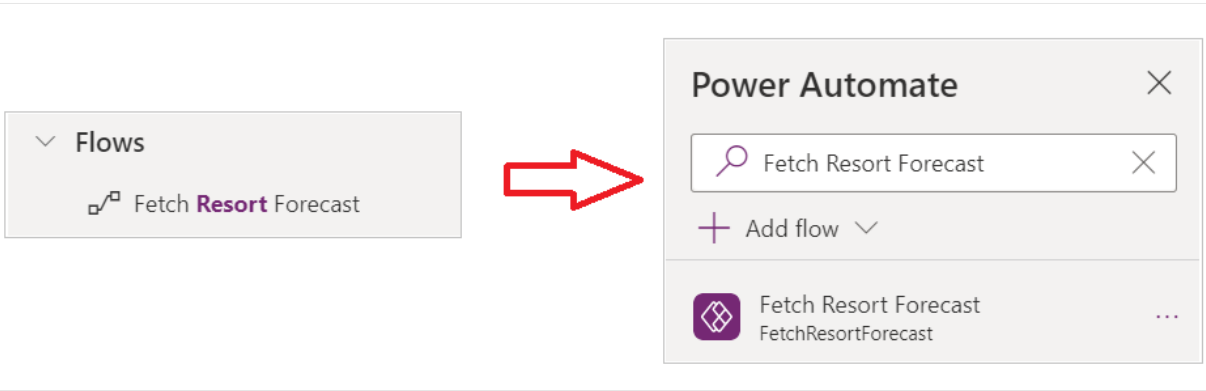
Media

Selecting a result under the **Media** header opens the **Media** pane, and prepopulates the search input for that pane with the selected result text.



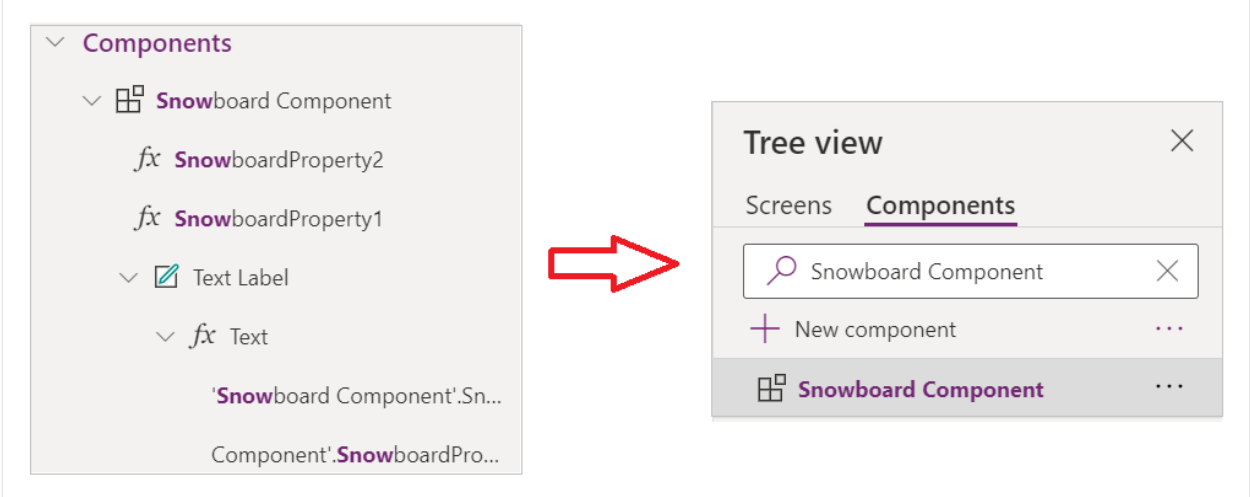
Flows

The **Flows** header only appears if you've enabled the Power Automate pane (preview). Selecting a result here opens the Power Automate pane and prepopulates the search input with the selected result text.



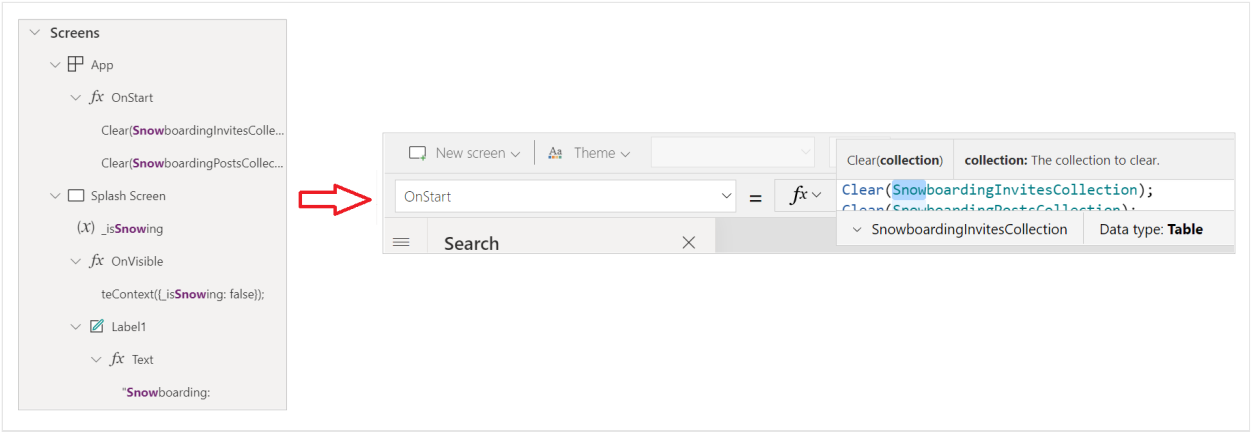
Components

Selecting a result under the **Components** header takes you to the components section in the **Tree view** pane, and prepopulates the search input for that pane with the selected result text.



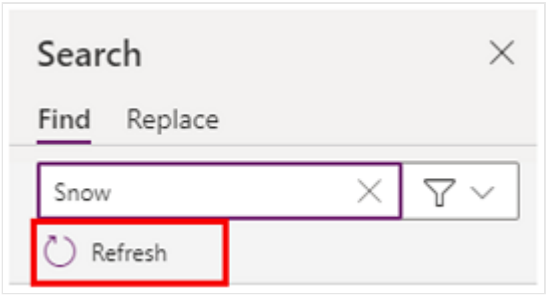
Screens

Selecting a result under the **Screen** header selects the appropriate control or screen on the canvas, and opens the property for the result in the formula bar. The selected result also gets highlighted in the formula bar.



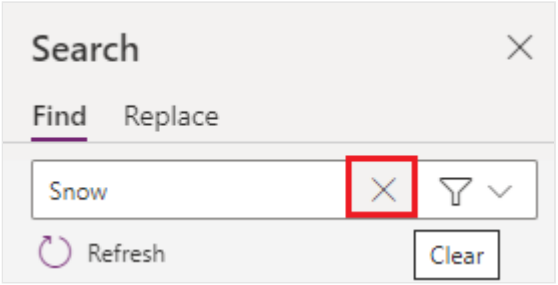
Refreshing the search results

If you make changes within the app, you'll need to refresh the results pane to see the change reflected in your search results.



Clear the search term

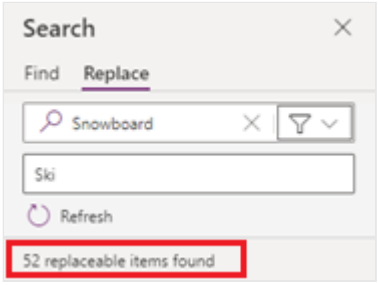
Search terms and results are kept until you no longer need them. To clear the search term and results, select the **X** to the right of the input area.



Replace

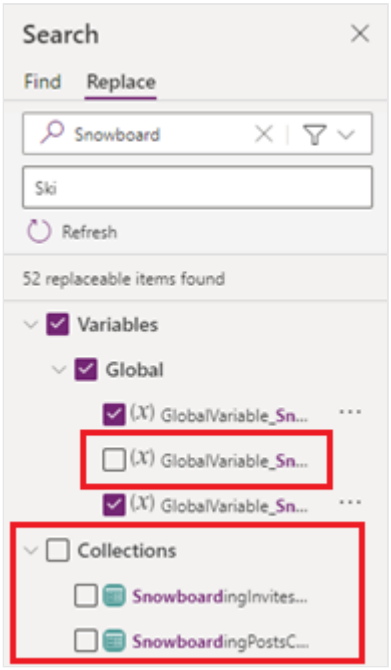
You can replace one or more instances of certain types of search results, including variable names, collection names, any formula text including strings, or other formula references.

After you perform a search, the replace pivot shows the list of search results that can be replaced.

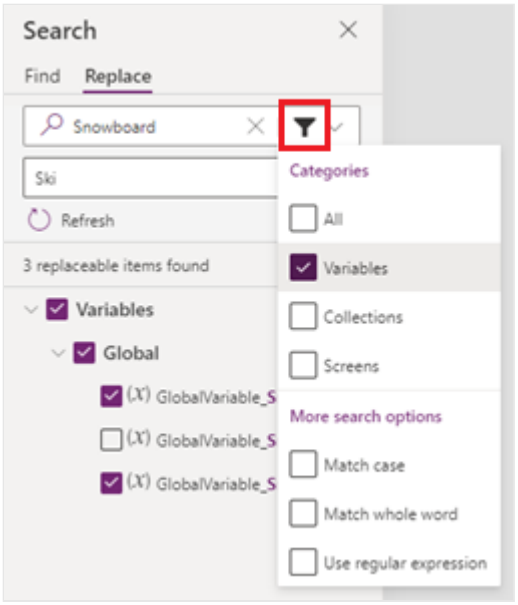


Replace results

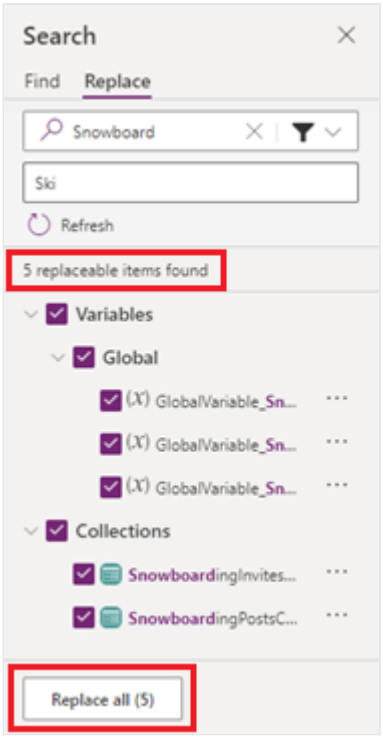
All results that can be replaced are selected by default. You can refine the list of results to replace by deselecting individual results or entire categories by selecting the checkbox next to the result or category heading.



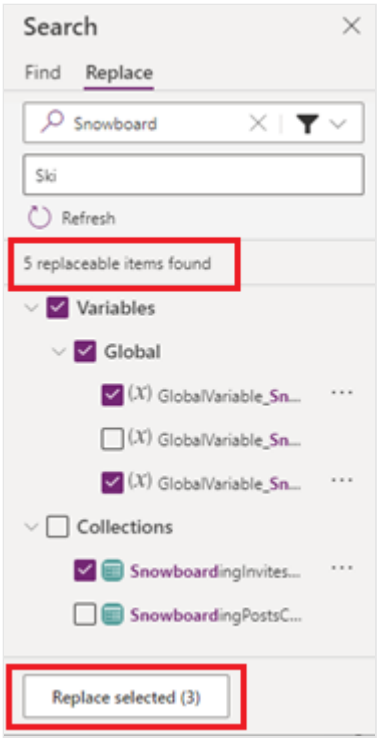
You can also filter the result list to only show selected categories of results.



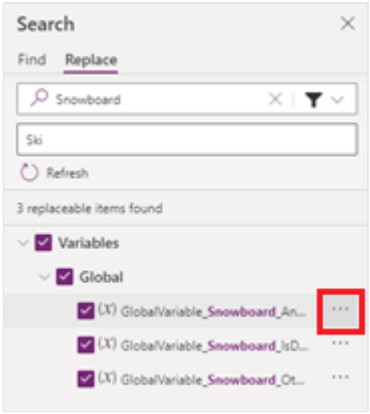
As you refine the list of results to replace, the replace button at the bottom of the panel keeps track of the number of replacements to be made. If all items are selected, the button reads **Replace all** with the total count of all replaceable items.



If you've selected results from the list, the button is updated to read **Replace selected** with the total count of selected items.

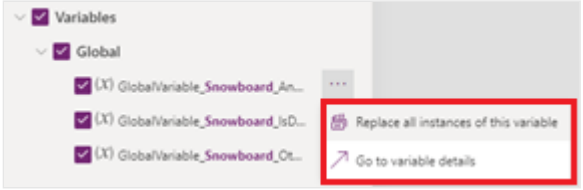


You can also interact with individual results in the results list directly to perform replacements by selecting the ellipsis to the right of each individual result in the result list.



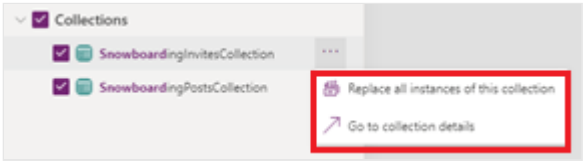
Replacing Variables results

Performing a replacement for results in the Variables category replaces the variable name at the definition level, meaning all instances of the matching variable name will be replaced across the entire app. You can also view the variable details on their information screen to review the usage before making the replacement.



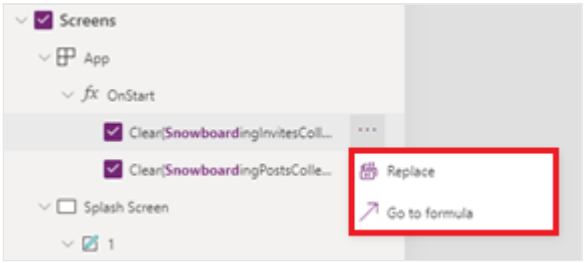
Replacing Collections results

Similar to variables, replacing a result in the Collections category replaces the collection name at the definition level, replacing all matching instances of the collection name across the app. You can view collection details on their information screen prior to making the replacement.



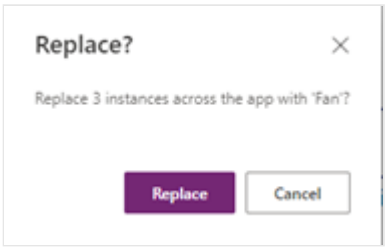
Replacing Screens results

The Screens category shows individual replaceable results following the structure in the tree view, so you can replace text in formulas, formula references, and control names. Replacements made in the Screens category only replace the single instance of the selected matching result, so you can pick and choose what you'd like to replace. You can also review the formula match before making the replacement.



Completing the replacement and undoing replacements

After you've refined your selection to the items you'd like to replace, selecting the button prompts you to confirm the operation.



Confirming the operation performs the replacement, and a notification indicates whether the replacement was successful.

The replacement operation might fail if a control name is already in use or unsupported characters are included.

After the replacement is complete, you can undo the replacement by using the undo button or by selecting **Ctrl**+**Z**.

Limitations

The Search pane is limited to returning a maximum of 2,000 results. A notification appears if you exceed this limit.

Use Find and Replace in the formula bar

Use Find and Replace in the formula bar

Article • 12/11/2023

In complex Power Apps, formulas can get lengthy. Locating and replacing portions of large formulas can become difficult. You can now use the **Find and Replace** capability for the selected control or property to easily find and replace the specified word or sequence of characters.

With **Find and Replace** capability, you can search for combinations of letters, numbers, words, and phrases within a formula in the formula bar. This capability also allows you to use text casing, whole words, and regular expressions to find and replace text inside formulas.

Prerequisites

- Sign up for Power Apps.
- Create an app or open an existing app in Power Apps.
- Learn how to configure a control.

Launch Find and Replace

You can launch the **Find and Replace** control in the formula bar using the **Find and replace** button, or shortcut keys. You can also pre-populate text in the search input.

To get started, create a new app, or edit an existing app in Power Apps Studio. Once open, use any of the following methods to launch the **Find and Replace** control.

Method 1: Use the Find and Replace button

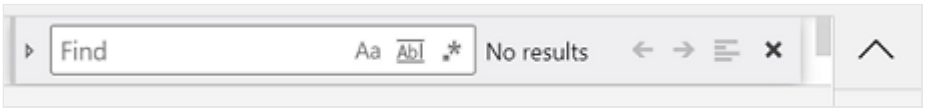
1. Select the control or property that you want to edit.
2. Select the drop-down on the right-side of the formula bar to show the **Find and Replace** control.

> **Tip**

You can also drag the formula bar down to expand the formula bar making it easier to read complex expressions.

3. Select **Find and replace** from the bottom of the formula bar.

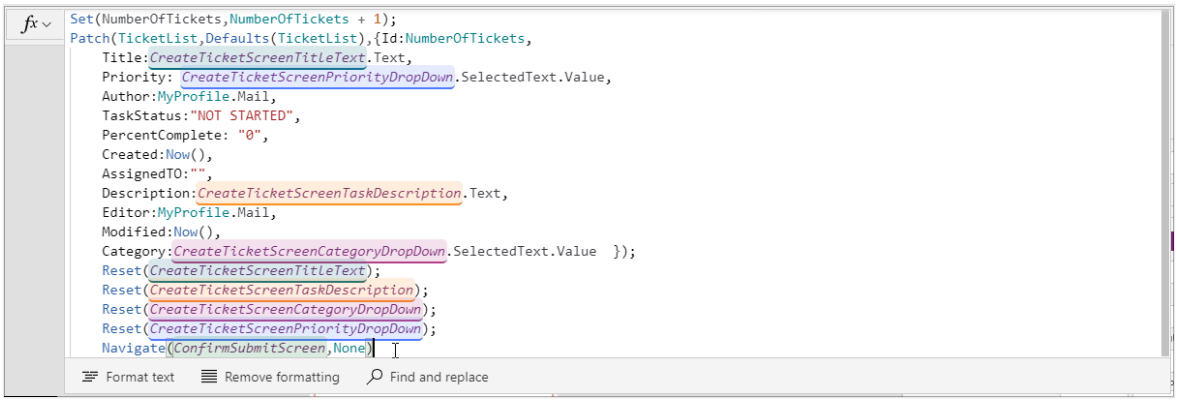
Find and Replace control appears on the upper-right hand side of the formula bar.



Method 2: Use shortcut keys

1. Select the control or property that you want to edit.

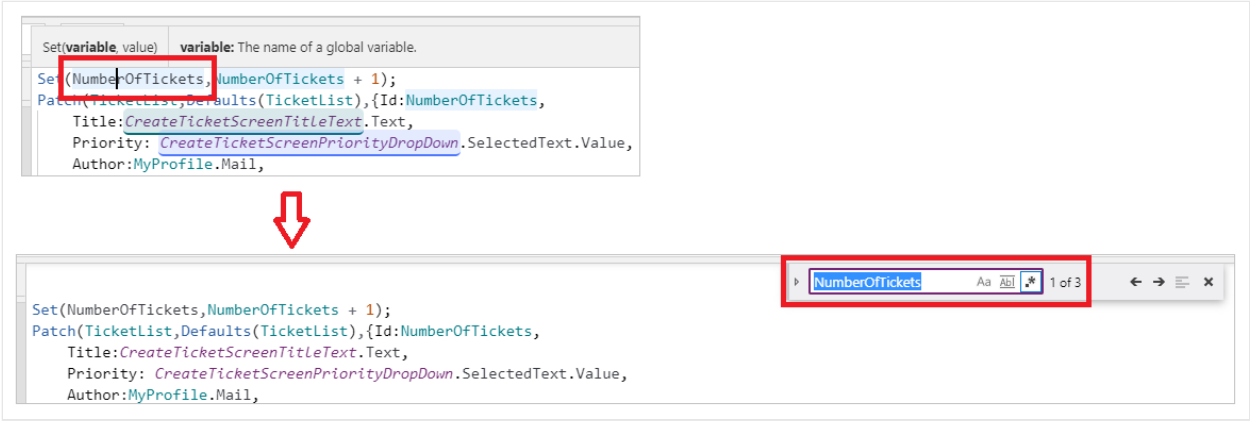
2. While your cursor is within the formula bar, press **Ctrl+F** to find, or **Ctrl+H** to find and replace the specified word or sequence of characters in the formula.



Method 3: Launch Find and Replace with text already selected

You can also launch the control pre-populated with text from your formula that you wish to search for.

To do this, select or keep the cursor inside the formula bar over the section that you want to find or replace. And then, use **Find and replace** button, or the shortcut keys as described earlier to launch **Find and Replace** control.



Working with Find and Replace

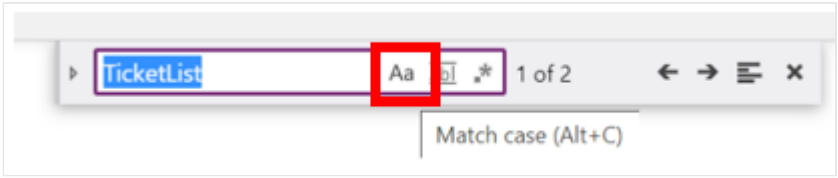
When working with **Find**, you have three options to search the formula. When working with **Replace**, you have two options to choose from. We'll take a look at the options for both **Find** and **Replace**.

Find

Add text or characters to search for into the provided input area. And then, use the icons on the right-hand side of the input area to help refine your search:

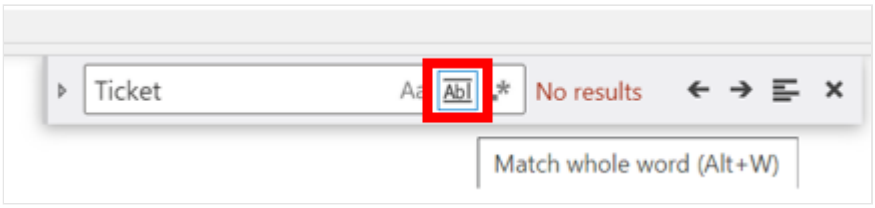
- **Match case** returns only matches with the specified case.

  In the example below, instances of `TicketList` will appear as a match, but `ticketlist` wouldn't.

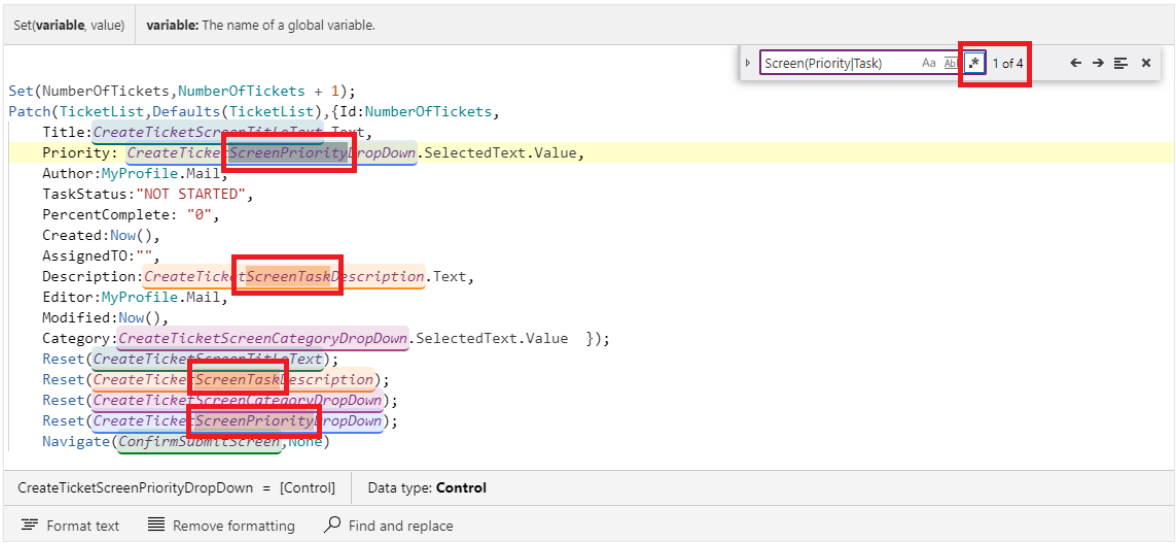
- **Match whole word** returns only exact matches of the entire sequence of characters.

  In the example below, instances of `Ticket` returns no matches although the word `Ticket` appears within the names several times in the formula.

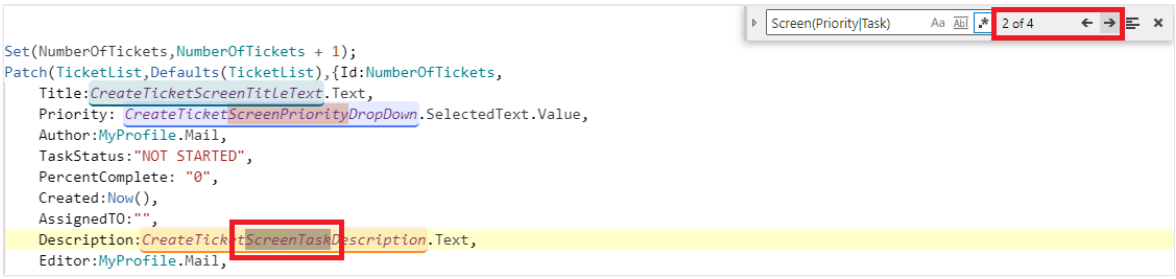
  


- **Use regular expression** (RegEx) returns only matches conforming to the regular expression specified within the input area. More information: Regular expressions

  In the example below, using the Regular Expression search capability with `Screen(Priority|Task)` returns matches for `Screen` when it appears together with either `Priority` or `Task` as shown below.



- **Previous match** or **Next match** arrows allow you to move forward and backward through any matches the search returns. As you move through the matches, the match position updates and the row containing the match is highlighted to let you know which match you're currently working with.



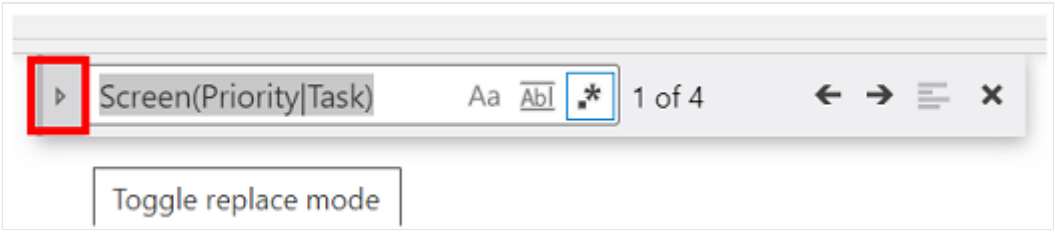
- **Find in selection** limits the search area within a formula to only the selected portion of a formula. To select part of the formula, select and hold at the beginning of the desired searching area and then drag your cursor to highlight the entire desired area. To select using the keyboard, move cursor focus to the beginning of the desired search area, then hold **Shift** key, and use the arrow keys to highlight the desired search area.

  In the example below, the search has been limited to the selected area, so the search now only returns two matches instead of the four matches returned previously.

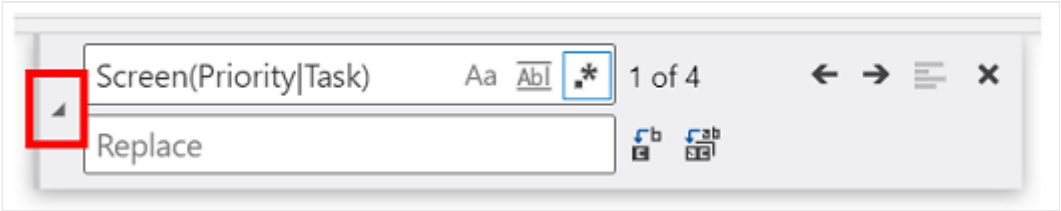
Replace

By default, the **Find and replace** control opens in collapsed format and only displays the Find capability. To expand the control and show the Replace capability, select the icon to the left of the search input box, or press **Ctrl+H** on your keyboard. To collapse again, select the rotated icon.

Collapsed replace mode:



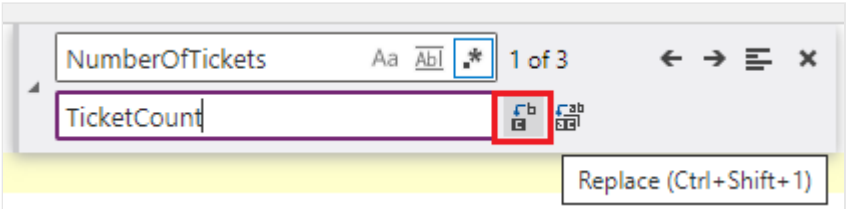
Expanded replace mode:



In the Replace input area, specify the word or sequence of characters you'd like to replace the search text.

Use the **Replace** or **Replace all** icons to update one or all matches returned with the specified word or characters.

Replace



Replace all

Show text, dates, and times in canvas apps

Article • 02/11/2025

In Power Apps, add dates and times to a canvas app, and format them to show the right level of detail or to reflect your locale. Calculate the amount of time between two dates, or calculate a date that's a certain amount of time before or after a date that you specify. Convert dates to or from separate values for days, months, and years, and convert times to or from separate values for hours, minutes, and seconds.

For example, add data from users about stock trades or client meetings, data from an external source, or data from another app created in Power Apps. If that data includes times down to the millisecond, round it to the nearest minute for simplicity. Calculate how many days remain before a major milestone. If you want to schedule client meetings every five days, calculate those dates automatically. If May 10, 1985, is stored in separate fields for the day, the month, and the year, consolidate them into a single value. Conversely, break each date into separate values if your app manages them separately.

Prerequisites

- Sign up for Power Apps, and then sign in by providing the same credentials that you used to sign up.
- Create an app or open an existing app in Power Apps.
- Learn how to configure a control in Power Apps.

Show text in a Label control

Show text in a **Label** control by setting the value of its **Text** property. Set this property by typing directly into the control or by typing an expression in the formula bar.

- If you type directly into the control, it shows exactly what you type.
- If you type an expression in the formula bar, the control shows the result of the expression.

Here are some examples.

1. Add a **Label** control named **ShowText**, and set its **Text** property to this formula:
   Now()

If your computer is set to the "en-us" locale, the current date and time appears in this format:
mm/dd/yyyy hh:mm AM/PM

If your computer is set to a locale such as "fr-fr", the current date and time appears in this format:
dd/mm/yyyy hh:mm AM/PM

2. Set the Text property of **ShowText** to this formula:
   DateDiff(Today(), DateValue("01/01/2025"))

   The control shows the number of days between today and January 1, 2020, by using these functions:

   - **DateDiff**, which calculates the number of days, quarters, or years between two dates.
   - **Today**, which calculates the current day as a value.
   - **DateValue**, which converts a literal string, as shown between double quotation marks, to a value on which calculations can be performed.

3. Add a Text input control named **BirthDate**, and move it under **ShowText**.

4. In **BirthDate**, type the month and the day of your birth (for example, **05/18**).

5. Set the Text property of **ShowText** to this formula:
   DateDiff(Today(), DateValue(BirthDate.Text))

   ShowText shows the number of days between today and whatever date you type into **BirthDate**. If your birthday has already occurred this year, **ShowText** displays a negative value.

Format dates and times by using DateTimeValue

Convert dates and times from strings of text to values, which you can format in a variety of ways and use in calculations. Specify the format by using built-in and custom options.

> ⓘ **Note**
>
> The DateTimeValue and DateValue functions can convert dates in any of these formats into values:
>
> - MM/DD/YYYY

- DD/MM/YYYY
- DD Mon YYYY
- Month DD, YYYY

1. Add a Text input control named **ArrivalDateTime**, and type a date and time in this format:
   5/10/85 6:15 AM

2. Add a Label control named **ShowDate**, and set its Text property to this formula:
   DateTimeValue(ArrivalDateTime.Text)

   ShowDate shows the same information that you typed, but it's been converted from text to a value and formatted differently. For example, the year appears as four digits instead of just two.

3. Change the Text property of **ShowDate** to this formula:
   DateTimeValue(ArrivalDateTime.Text, "fr")

   ShowDate shows the day before the month, as a French user would expect.

   > **Tip**
   >
   > To display a list of other locales in Intellisense, remove the closing quotation mark and **fr** from the formula, but leave the open quotation mark:

4. To use one of several built-in formats, change the Text property of **ShowDate** to this formula:
   Text(DateTimeValue(ArrivalDateTime.Text), DateTimeFormat.LongDateTime)

   ShowDate shows the day of the week, the date, and the time.

   > **Tip**
   >
   > The **DateTimeFormat** parameter supports several other built-in formats. To display that list, remove **LongDateTime** from the formula.

5. To use a custom format, change the Text property of **ShowDate** to this formula:
   Text(DateTimeValue(ArrivalDateTime.Text), "mm/dd/yyyy hh:mm:ss.fff AM/PM")

   ShowDate shows the date/time value in the format that you specified, including milliseconds.

> **Tip**
>
> To round the time to the nearest tenth or hundredth of a second, specify **hh:mm:ss.f** or **hh:mm:ss.ff** in the formula.

Format a date by using DateValue

1. Add a **Text input** control named **ArrivalDate**, and then type a date in it (for example, **5/10/85**).

2. Add a **Label** control named **FormatDate**, and set its **Text** property to this formula:
   DateValue(ArrivalDate.Text)

   FormatDate shows the date that you typed, except the year appears as four digits.

3. Set the **Text** property of **FormatDate** to this formula:
   DateValue(ArrivalDate.Text, "fr")

   FormatDate shows the day before the month, just as a French user would expect.

4. To use one of several built-in formats, set the **Text** property of **FormatDate** to this formula:
   Text(DateValue(ArrivalDate.Text), DateTimeFormat.LongDate)

   FormatDate shows the day of the week, the month, the day, and the year.

5. To use a custom format, set the **Text** property of **FormatDate** to this formula:
   Text(DateValue(ArrivalDate.Text), "yy/mm/dd")

   FormatDate shows the date in the format that you specified.

Format a time using DateTimeValue

1. Add a **Text input** control named **ArrivalTime**, and then type **6:15 AM** in it.

2. Add a **Label** control named **ShowTime**.

3. To use one of several built-in formats, set the **Text** property of **ShowTime** to this formula:
   Text(DateTimeValue(ArrivalTime.Text), DateTimeFormat.LongTime)

   ShowTime shows the time that you specified, including seconds.

4. To use a custom format, set the Text property of **ShowTime** to this formula:
   Text(DateTimeValue(ArrivalTime.Text), "hh:mm:ss.fff AM/PM")

   ShowTime shows the time that you specified, including seconds and milliseconds.

   > **Tip**
   >
   > To round the time to the nearest tenth or hundredth of a second, enter **hh:mm:ss.f** or **hh:mm:ss.ff** in the formula.

Show the time between dates

1. Add two Text input controls named **Start** and **End**.
2. Type **4/1/2015** in **Start**, and type **1/1/2016** in **End**.
3. Add a Label control named **DateDiff**, and set its Text property to this formula:
   DateDiff(DateValue(Start.Text), DateValue(End.Text))

   DateDiff shows **275**, which is the number of days between April 1, 2015, and January 1, 2016.
4. Set the Text property of **DateDiff** to this formula:
   DateDiff(DateValue(Start.Text), DateValue(End.Text), Months)

   DateDiff shows **9**, which is the number of months between April 1, 2015, and January 1, 2016. Replace **Months** with **Quarters** or **Years** to show the time in those units.

Identify a date before or after another date

1. Add a Text input control named **Start**, and type **5/10/1985** in it.
2. Add a Label control named **DateAdd**, and set its Text property to this formula:
   DateAdd(DateValue(Start.Text), 3)

   DateAdd shows **5/13/1985**, which is three days after the date in **Start**.
3. Set the Text property of **DateAdd** to this formula:
   DateAdd(DateValue(Start.Text), -3)

   DateAdd shows **5/7/1985**, which is three days before the date in **Start**.

4. Change the Text property of **DateAdd** to this formula:
   DateAdd(DateValue(Start.Text), 3, Months)

   The label shows **8/10/1985**, which is three months after the date in **Start**. Replace **Months** with **Quarters** or **Years** to identify a date that's the specified number of quarters or years before or after the date in **Start**.

Calculate dates based on years, months, and days

1. Add three Drop down controls named **Year**, **Month**, and **Day**.

2. Set the Items property of **Year** to this formula:
   Table({Year:"2014"}, {Year:"2015"}, {Year:"2016"})

3. Set the Items property of **Month** to this formula:
   Table({Month:"1"}, {Month:"2"}, {Month:"3"}, {Month:"4"}, {Month:"5"}, {Month:"6"}, {Month:"7"}, {Month:"8"}, {Month:"9"}, {Month:"10"}, {Month:"11"}, {Month:"12"})

4. Set the Items property of **Day** to this formula:
   Table({Day:"1"}, {Day:"2"}, {Day:"3"}, {Day:"4"}, {Day:"5"}, {Day:"6"}, {Day:"7"}, {Day:"8"}, {Day:"9"}, {Day:"10"}, {Day:"11"}, {Day:"12"}, {Day:"13"}, {Day:"14"}, {Day:"15"}, {Day:"16"}, {Day:"17"}, {Day:"18"}, {Day:"19"}, {Day:"20"}, {Day:"21"}, {Day:"22"}, {Day:"23"}, {Day:"24"}, {Day:"25"}, {Day:"26"}, {Day:"27"}, {Day:"28"}, {Day:"29"}, {Day:"30"}, {Day:"31"})

5. Add a Label control, and set its Text property to this formula:
   Text(Date(Value(Year.SelectedText.Value), Value(Month.SelectedText.Value), Value(Day.SelectedText.Value)), DateTimeFormat.LongDate)

   Wednesday, January 1, 2014 is listed by default. Select different values in the Drop down controls to change the date in the Label control.

You may need to convert data that you didn't expect. If you add Text input controls instead of Drop down controls, a user may enter an incorrect date, such as May 45. The Date function handles atypical data in the following ways:

- If a year value is between 0 and 1899 (inclusive), the function adds that value to 1900 to calculate the year.
- If a year value is between 1900 and 9999 (inclusive), the function uses that value as the year.

- If a year value is less than 0 or is 10000 or greater, the function returns an error value.
- If a month value is greater than 12, the function adds that number of months to the first month of the specified year.
- If a month value is less than 1, the function subtracts that many months, plus 1, from the first month of the specified year.
- If a day value is greater than the number of days in the specified month, the function adds that many days to the first day of the month and returns the corresponding date from a subsequent month.
- If a day value is less than 1, the function subtracts that many days, plus 1, from the first day of the specified month.

Calculate times based on hours, minutes, and seconds

1. Add two **Drop-down** lists named **Hour** and **Minute**.

2. Set the **Items** property of **Hour** to this formula:
   Table({Hour:"9"}, {Hour:"10"}, {Hour:"11"}, {Hour:"12"}, {Hour:"13"}, {Hour:"14"}, {Hour:"15"}, {Hour:"16"}, {Hour:"17"})

3. Set the **Items** property of **Minute** to this formula:
   Table({Minute:"0"}, {Minute:"15"}, {Minute:"30"}, {Minute:"45"})

4. Add a **Label** control, and set its **Text** property to this formula:

   Text(Time(Value(Hour.SelectedText.Value), Value(Minute.SelectedText.Value),0), DateTimeFormat.ShortTime)

5. Select **15** in **Hour** and **45** in **Minute**.

   The **Label** control shows **3:45 PM**.

   You can add entries to **Hour** and **Minute** so that users can select from a bigger range of hours and a more precise number of minutes. You can also add a third **Drop down** control so that users can specify seconds. If you add a third list, set the **Text** property of the **Label** control to the following expression:
   Text(Time(Value(Hour.Selected.Value), Value(Minute.Selected.Value), Value(Second.Selected.Value)), DateTimeFormat.LongTime)

Provide product feedback

Create and update a collection in a canvas app

Use a collection to store data that users can manage in your app. A collection is a group of items that are similar, such as products in a product list. For more information about different types of variables, including collections, see Understand canvas-app variables.

Prerequisites

- Sign up for Power Apps, and then sign in by providing the same credentials that you used to sign up.
- Create an app or open an existing app in Power Apps.
- Learn how to configure a control in Power Apps.

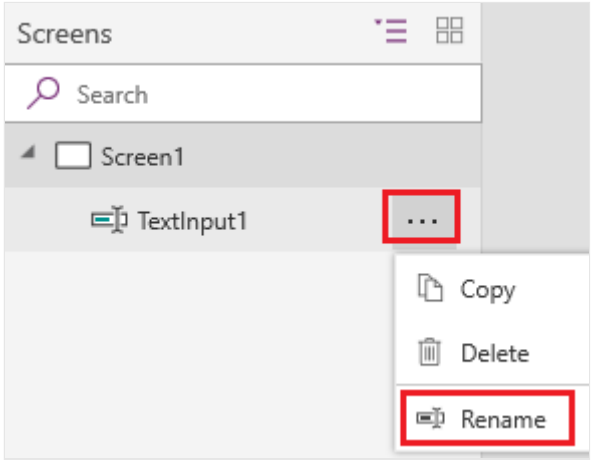
Watch this video to learn how to create and update a collection:

https://learn-video.azurefd.net/vod/player?id=b709db8a-7d9c-4869-b2f7-76027df3bee0&locale=en-us&embedUrl=%2Fpower-apps%2Fmaker%2Fcanvas-apps%2Fcreate-update-collection

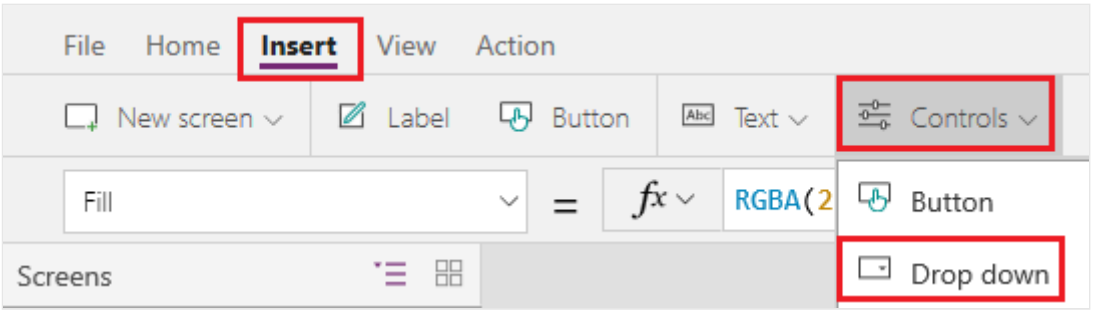
Create a multicolumn collection

1. In Power Apps Studio, add a **Text input** control.

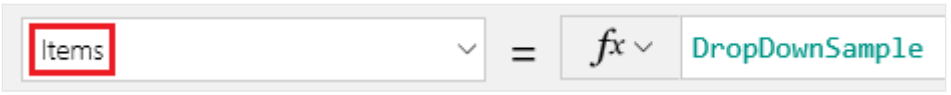
2. Rename the control by selecting its ellipsis in the left navigation pane, selecting **Rename**, and then typing **ProductName**.



3. Add a **Drop down** control.



4. Rename the **Drop down** control **Colors**, and make sure that the **Items** property is selected in the property list.



5. In the formula bar, replace **DropDownSample** with this expression:

   `["Red","Green","Blue"]`

6. Add a **Button** control, set its **Text** property to "**Add**", and set its **OnSelect** property to this formula:

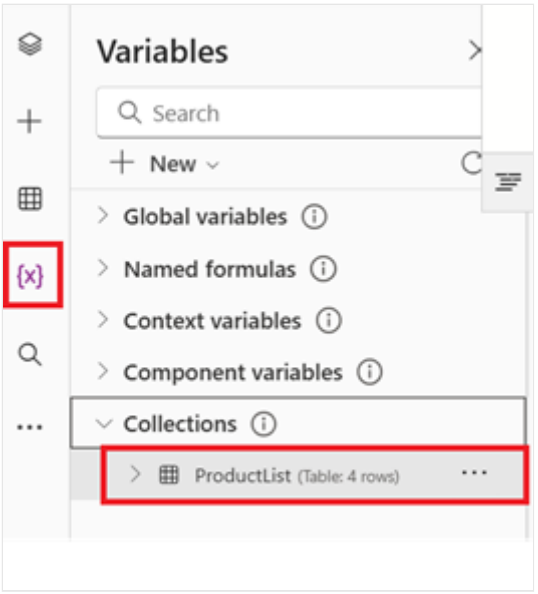
   Power Fx

   ```
   Collect(
       ProductList,
       {
           Product: "ProductName.Text",
           Color: "Colors.Selected.Value"
       }
   )
   ```

7. To preview the app, press `F5` or select the play button. Type some text into **ProductName**, select an option in **Colors**, and then select **Add**.

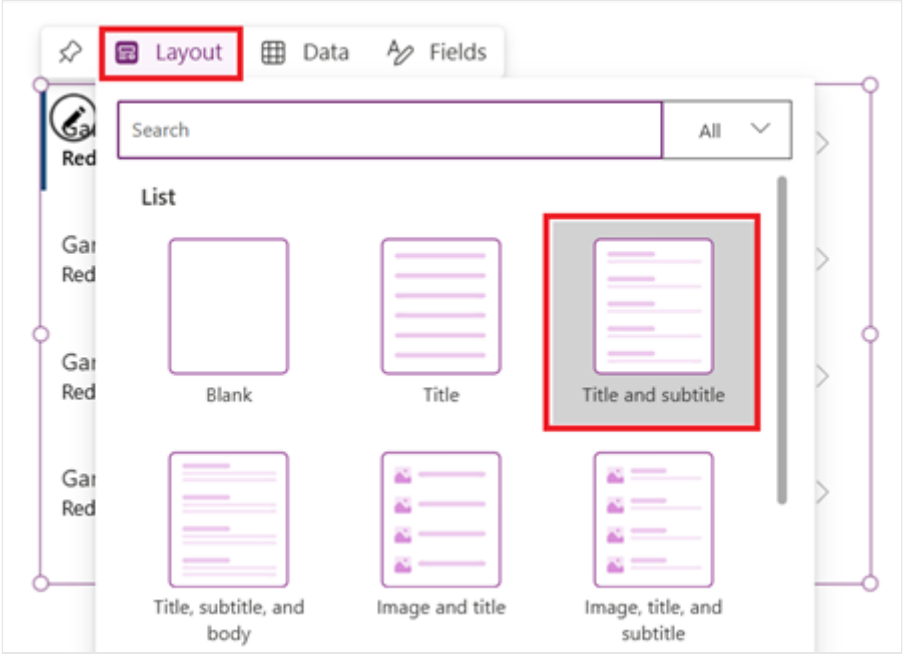
8. Repeat the previous step at least two more times, and then press `Esc`.

9. Select the **Variables** pane and then select **Collections** to see the collections that you created.



Show a collection

1. Select **Insert** > **Vertical gallery** control.
2. Set the gallery's **Items** property to **ProductList**.
3. Select the gallery in the tree view and then select **Fields**.
4. Set the subtitle field to **Color**, and set the title field to **Product**.
5. Select **Layout** > **Title and subtitle**.



Remove one or all items

1. Select the gallery and add a **Trash** icon to the gallery template.

2. Set the icon's **OnSelect** property to this formula:

   ```
   Remove(ProductList, ThisItem)
   ```

3. Outside the gallery, add a button, set its **Text** property to "**Clear**", and set its **OnSelect** property to this formula:

   ```
   Clear(ProductList)
   ```

4. While holding down the Alt key, select the **Trash** icon for an item to remove that item from the collection, or select the **Clear** button to remove all items from the collection.

Put a list into a collection

1. Create a connection to a list created using Microsoft Lists.

2. Add a button, and set its **OnSelect** property to this function, replacing *ListName* with the name of your list:

   ```
   Collect(MySPCollection, ListName)
   ```

   This function creates a collection named **MySPCollection** that contains the same data as your list.

3. Select the button while holding down the `Alt` key.

For information about how to show data in a form (with drop-down lists, date pickers, and people pickers), see Edit form and Display form controls.

Next steps

- Review the reference article for the **Collect** function.
- Learn how to shape data in a collection by using the AddColumns, DropColumns, RenameColumns, and ShowColumns functions.

Show information about a user in a canvas app

Article • 12/16/2022

In Power Apps, show the full name, the email address, and the picture that's associated with the user who's signed in to a canvas app. You can use this information, for example, to automatically fill in a form.

For example, you can use this feature to:

- Create a sign-up "sheet" for users to attend training, volunteer for events, check in at a kiosk, and more.
- Display the full name on a Human Resources app.
- Automatically enter an email address when contacting your helpdesk.

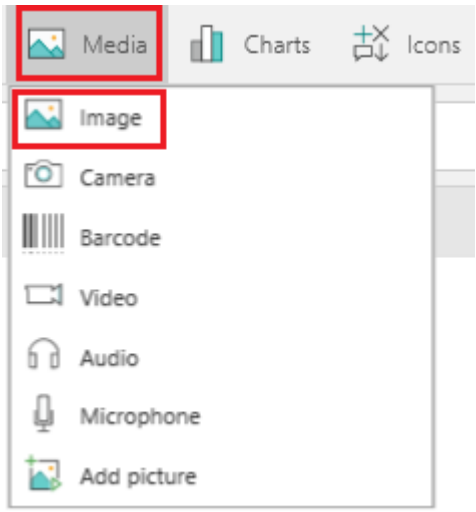
Basically, you can use this anywhere users would benefit from a form or labels that are populated automatically

Prerequisites

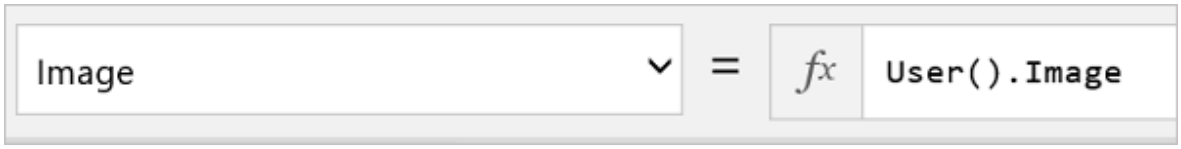
1. Create a blank canvas app.
2. Learn how to add and configure controls.

Show user details

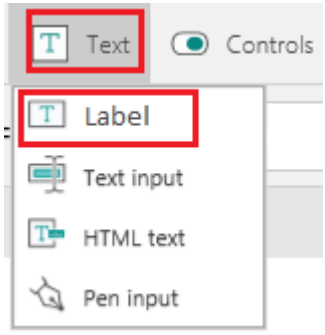
1. On the **Insert** tab, click or tap **Media**, and then click or tap **Image**.



2. Set the Image property to this formula:
   User().Image



3. On the **Insert** tab, click or tap **Text**, and then click or tap **Label**:



4. Set the Text property to this formula:
   User().FullName

   When you do this, the label is automatically populated with your full name. Move the label so it's below the image control, similar to the following:

5. Add another label, and set its Text property to this formula:
   User().Email

   When you do this, the label is automatically populated with your email address. Move the label so it's below the first label, similar to the following:

Your Full Name

Your Email Address

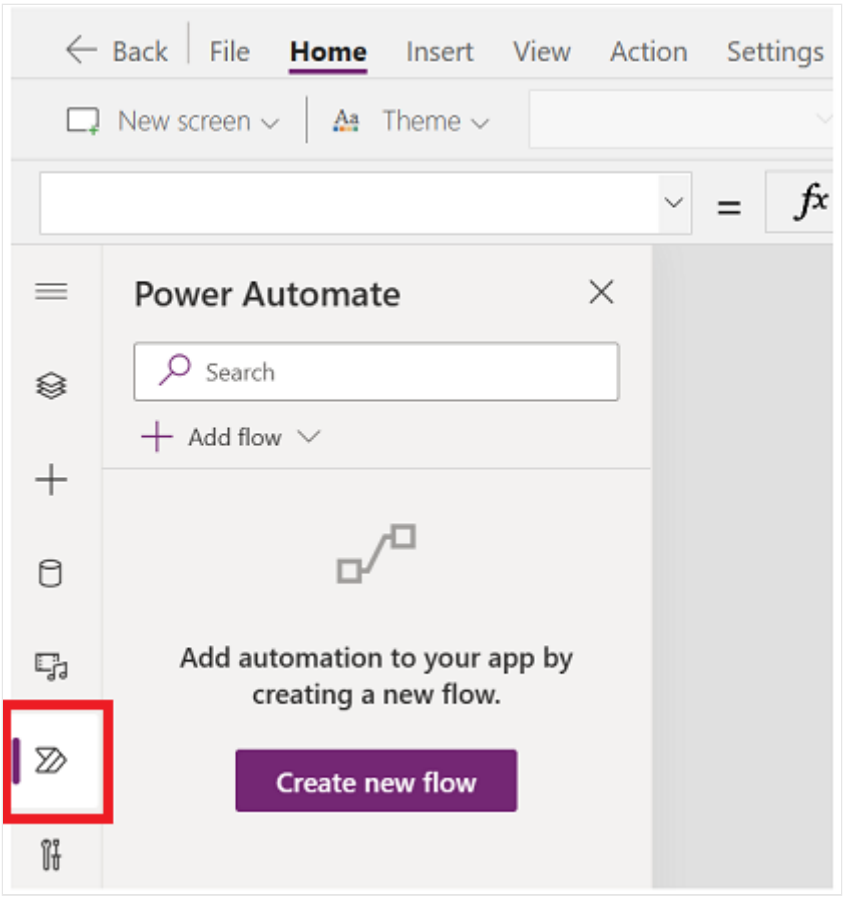
Use Power Automate pane

Create new flows or add and edit existing flows using the Power Automate pane within Power Apps Studio. The Power Automate pane is enabled by default.

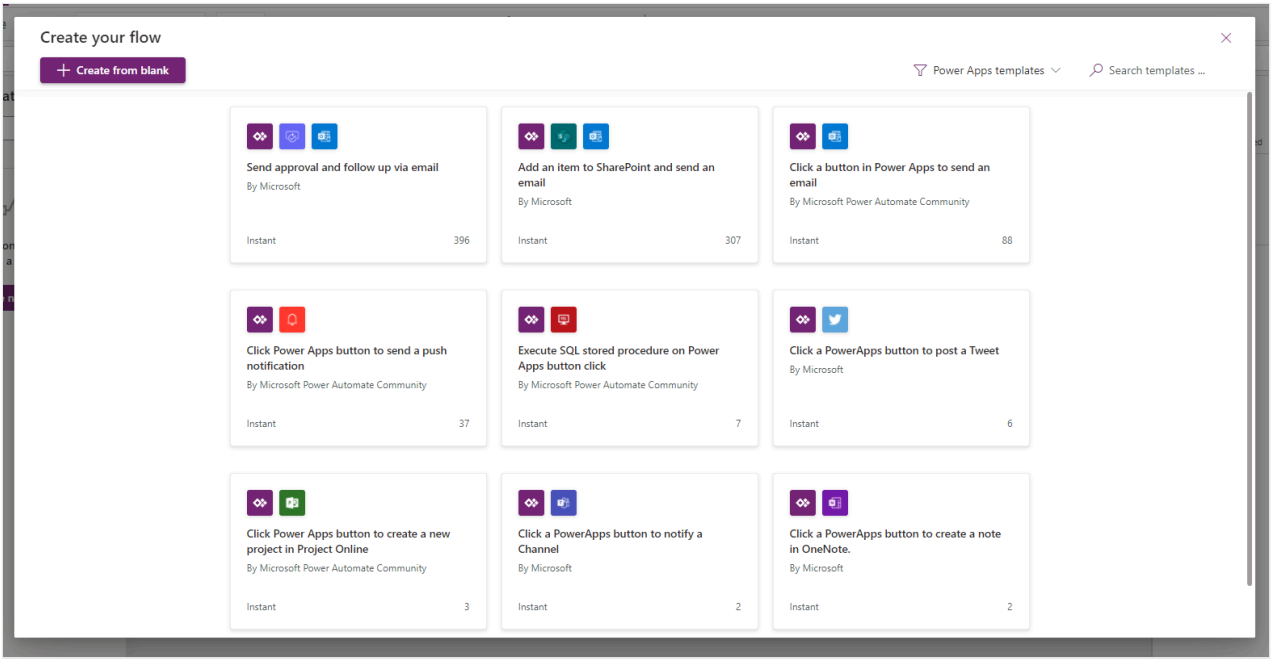
> **ⓘ Important**
>
> Arguments that pass from Power Apps to Power Automate are visible as network traffic and can be intercepted. Most traffic is likely harmless data that are irrelevant outside the application, for example arguments like "yes" or "Redmond".
>
> Evaluate the parameters passed to Power Automate and consider the consequences (if any) if they're changed by an exernal actor. To mitigate risks, validate the parameter values passed.
>
> For example, if you send sensitive data to a person in your organization through email, for example `someuser@contoso.com`, validate the address in Power Automate. You can check the incoming arguments to confirm the organization, `@contoso.com`, and only allow the flow to proceed if the right organization is present.

Create a new flow

1. Open a new or an existing app in Power Apps Studio.
2. On the app authoring menu, select **Power Automate**.



3. In the Power Automate pane, select **Create new flow**.



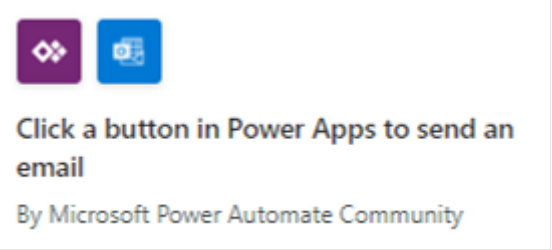
This action opens the **Create your flow** modal dialog within Power Apps Studio. You can choose to create the flow from the available templates, or create a flow from scratch.

Start with a template

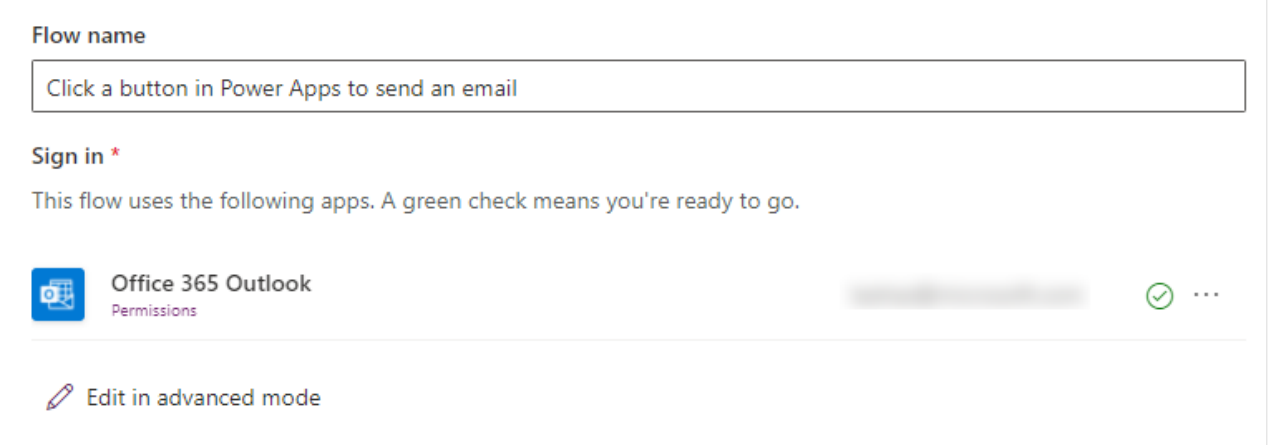
Power Automate provides several flow templates that you can choose from by default. This section explains how to create a flow using such available templates from within Power Apps

Studio.

1. From the list of available templates, select a template of your choice. For this example, we use **Click a button in Power Apps to send an email**.



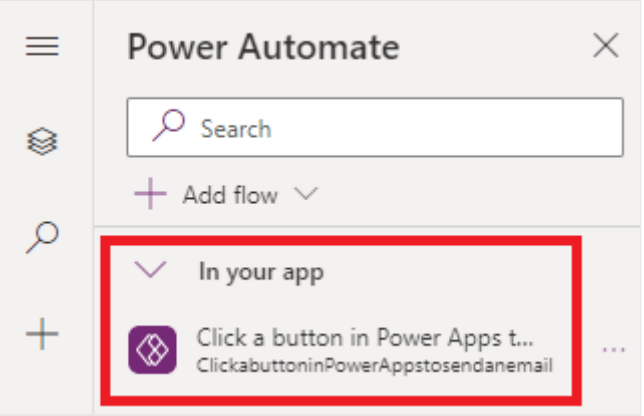
2. The next step shows the connections required to create a flow based on the selected template. More information: Connectors overview



3. (Optional) You can use **Edit in advanced mode** to update the connection, and customize the flow template. When done, select **Save** to save the flow. Skip the next step since your flow creation process is now complete.

4. Select **Next** > **Create** to create the flow.

   The flow now appears in the list of flows inside the Power Automate pane, under the **In your app** section.



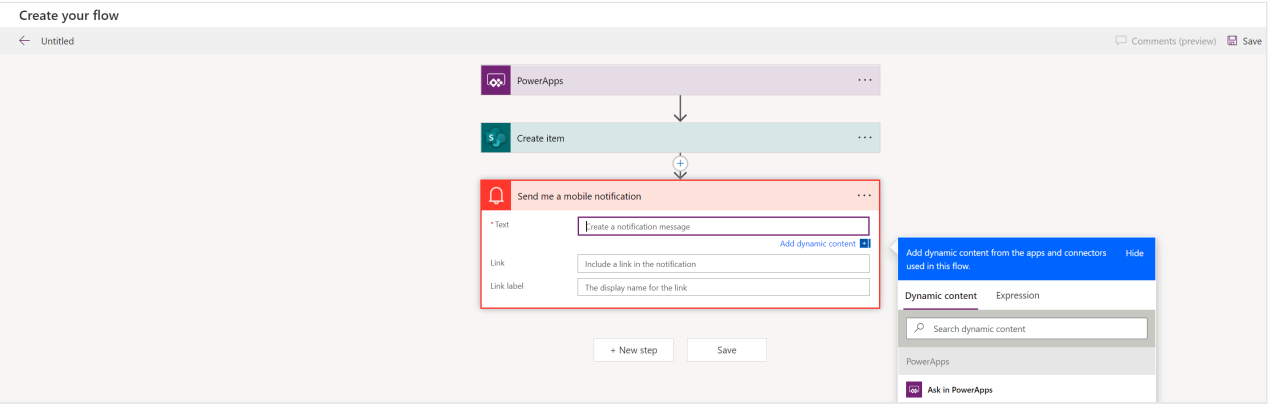
> **Tip**

For more information about creating cloud flows from templates, see Create a cloud flow from a template.

Create from blank

Instead of using the available templates, you can create a flow from scratch, and customize the steps as per your requirement.

1. Select **Create from blank**.
2. Add and customize the flow with steps and actions, as shown in the following example.

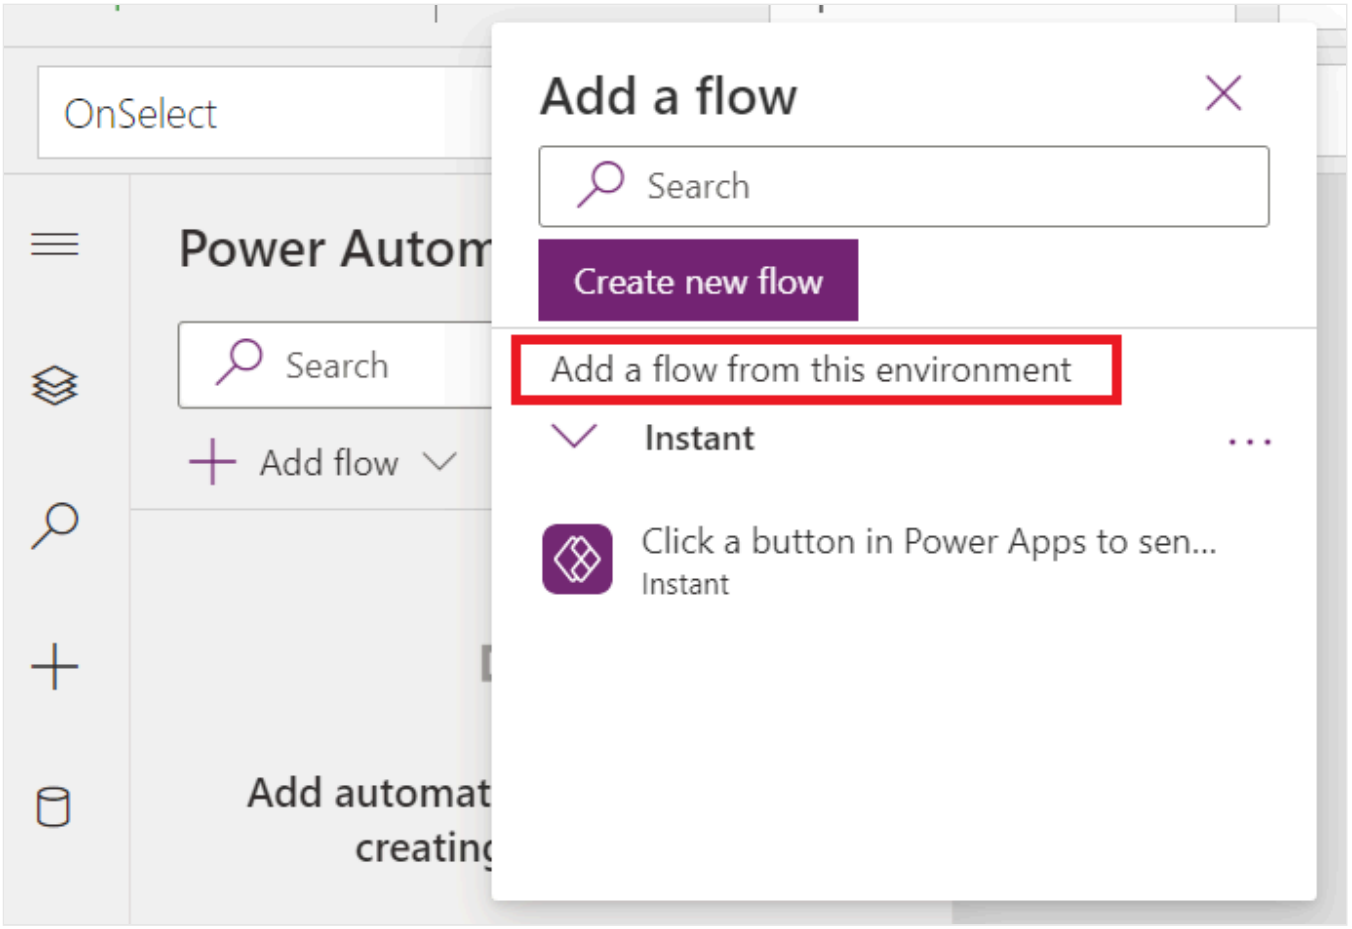


3. When done, select **Save** from upper right corner of the screen.

> **Tip**
>
> For more information about customizing and configuring cloud flows, see the **How to** articles starting from Add multiple actions and advanced options to a cloud flow.

Add an existing flow

You might have access to the existing flows in the environment where you're creating your app. To add and use these flows in your app, select **Add a flow**, and then choose the flow from the **Add a flow from this environment** section.



> **Tip**
>
> You can hover over the flow to see more details before adding to your app.

You must meet the following requirements to be able to add an existing flow to a canvas app:

- Have access to the flow
- Have access to see the flows that are part of the same solution
- Have a Power Apps trigger for your flows.

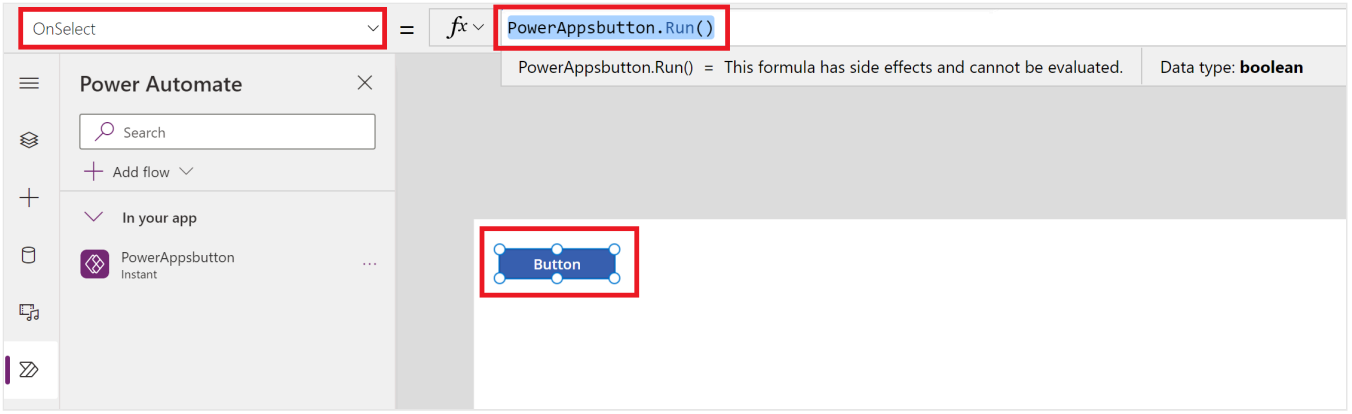
After being added, the flow will appear under the **In your app** section inside the Power Automate pane.

Reference a flow

To reference the added flow, update the formula bar for the control or component within Power Apps Studio with the flow details. For example, to reference a flow named "PowerAppsbutton" that triggers an email without accepting any input parameters, use the following formula on the button's **OnSelect** property:

```
Power Fx
```

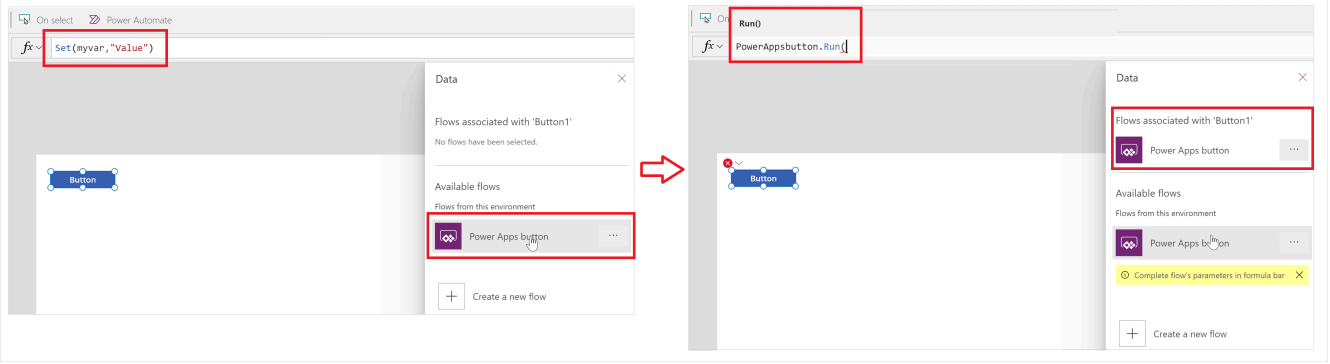
```
PowerAppsbutton.Run()
```



This behavior is different from how the reference to a flow works within Power Apps Studio if the Power Automate pane is disabled.

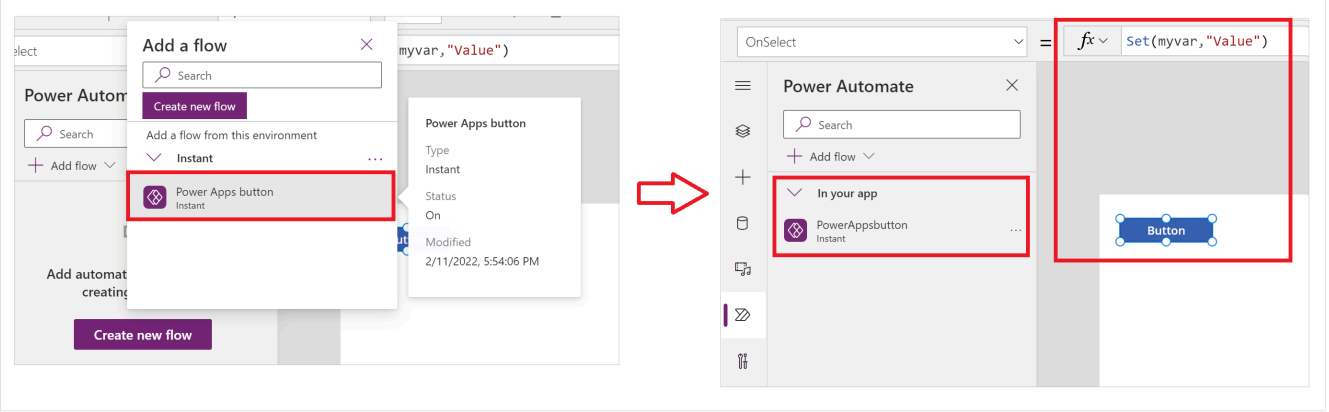
When you add a flow with the Power Automate pane disabled, you must choose a behavior property of the control or the component that you want to associate with the flow. Adding a flow, in this case, clears any formula already associated with the chosen property (when the flow reference is added). Any existing formula gets removed, and you must carefully make a copy of the existing formula before adding the flow in order to preserve it. You can then paste your copied formula back after the flow reference is added.

For example, on a button's OnSelect property, adding the flow removes your existing formula, and you have to carefully make a copy of the existing formula before adding the flow. The following example shows the process with the Power Automate pane disabled. In this case, the formula added for the button property is removed to reference the added flow.



Whereas with the Power Automate pane enabled, any existing formula is preserved automatically (isn't removed). You can add the flow reference in the formula for a behavior property as per your requirement.

The following example shows the process with the Power Automate pane enabled. When the flow is added, the existing formula for the button's OnSelect property is preserved, and the flow reference isn't added automatically.



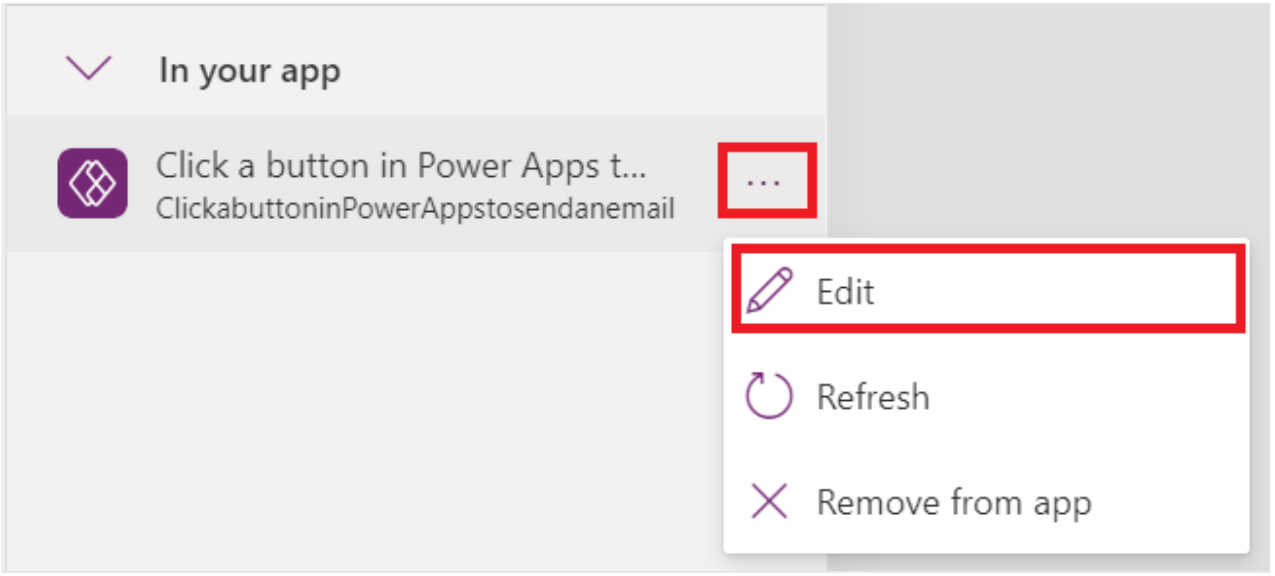
Now you can reference the flow through the regular process of updating the formula for the control or component—as explained earlier.

Edit an existing flow

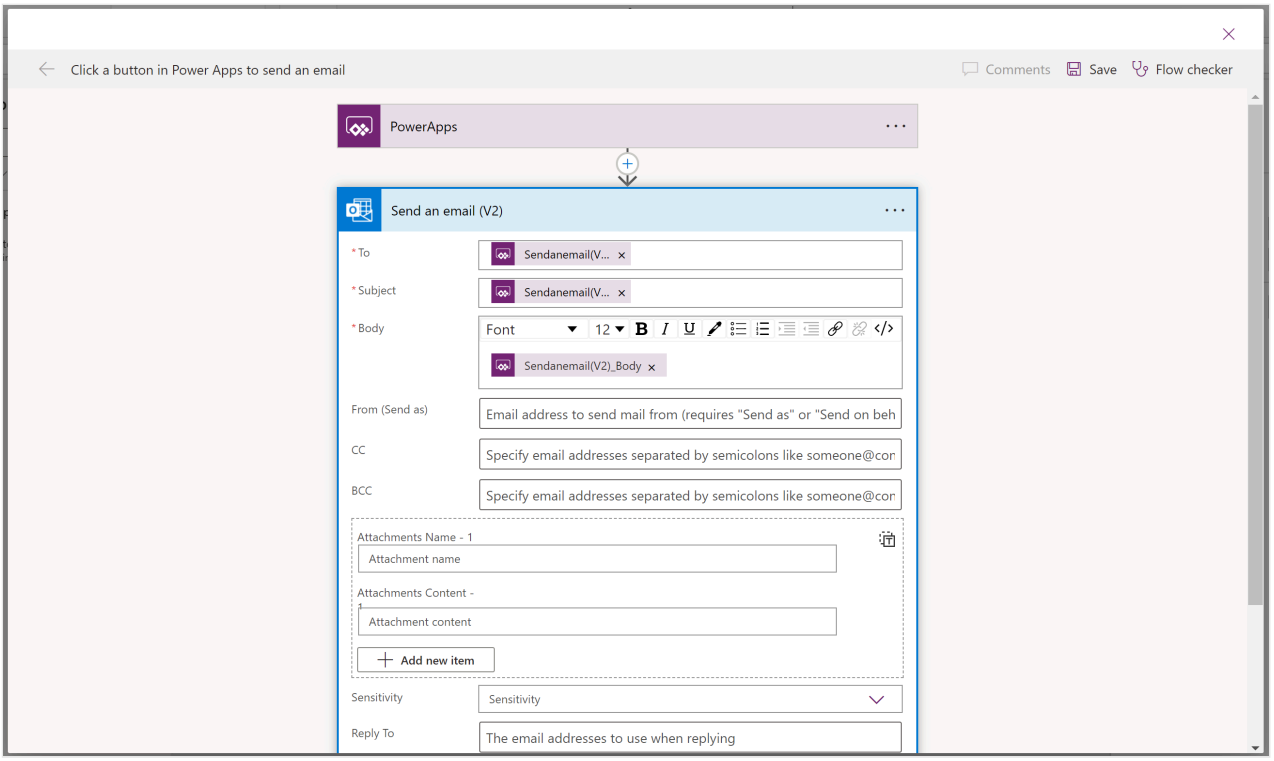
You can now edit flows added to your app without leaving Power Apps Studio.

1. Under the **In your app** section of the Power Automate pane, select **...** (ellipsis) to the right of a flow.

2. Select **Edit**.



The flow opens inside the editor.



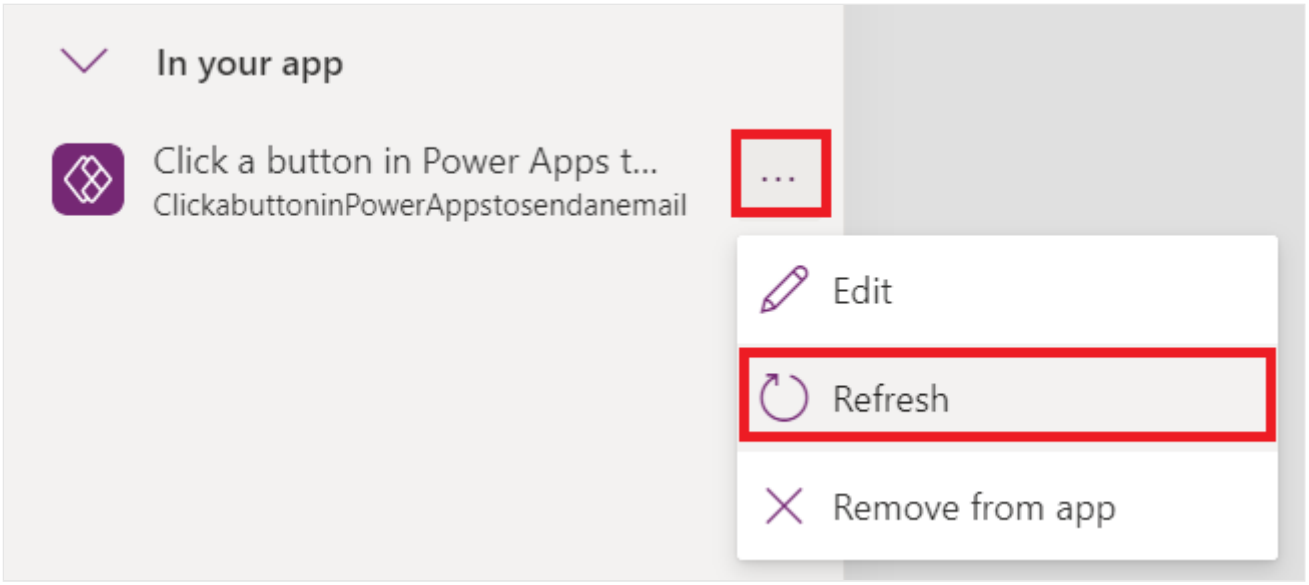
3. Make your changes, and then select **Save**.

> **Important**
>
> To avoid losing unsaved changes, ensure you select **Save** before closing the editor.

Refresh a flow

If any changes are made to the flow in Power Automate (instead of using Power Apps Studio), refresh your flow to get the latest changes.

To refresh the flow and pull the latest changes, select **...** (ellipsis) to the right of your flow, and then select **Refresh**.

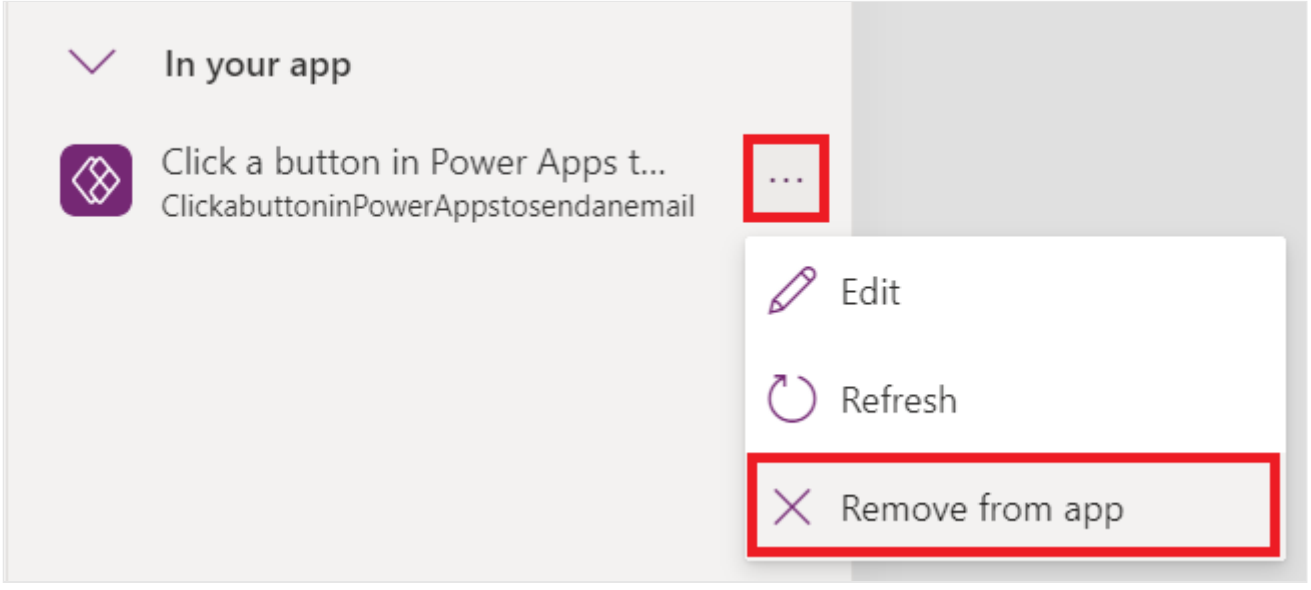


A loading spinner appears, and the flow is refreshed.

> **Important**
>
> After making changes to a flow outside of Power Apps Studio, you must perform this step; otherwise, the flow may fail to run—even in previously published apps. Skipping this step can also lead to performance issues in the Power Platform admin center, as each time the canvas app runs, it will try to validate the flow's connections using outdated information, which may not succeed.

Remove a flow

To remove a flow from your app, select **...** (ellipsis) to the right of your flow, and then select **Remove from app**.



This action only removes the flow from the app, while the flow remains intact in the environment. You can add the flow again to the same app, or use it in other apps.

Classic Power Automate experience

The Power Automate pane is now enabled by default. To use the classic Power Automate experience to create a flow, switch back to the old experience manually.

> **Important**
>
> It's recommended that you use the Power Automate pane to create a flow. The classic Power Automate experience should only be used for troubleshooting. The classic experience will be retired soon and won't be available.

1. Open a new or an existing app in Power Apps Studio.
2. Select **Settings** at the top.
3. Select **Upcoming features**.
4. Under the **Retired** tab, select **Enable Classic Power Automate pane** to set the toggle to **On**.

- Add and configure controls

Last updated on 11/10/2025

Start a flow in a canvas app (retired)

Article • 12/18/2024

You can use Power Automate to create logic that performs one or more tasks when an event occurs in a canvas app. For example, you can configure a button that performs a single task or multiple tasks. When the button is pressed, an item is created in a list (Microsoft Lists), an email or meeting request is sent, and a file is added to the cloud. You can configure any control in the app to start the flow, which continues to run even if you close Power Apps.

> **Note**
>
> When a user runs a flow from within an app, that user must have permission to perform the tasks that are specified in the flow. Otherwise, the flow will fail.

Enable classic Power Automate experience

By default, the new Power Automate pane is enabled by default. To use the classic Power Automate experience to create a flow, switch back to the old experience manually.

> **Important**
>
> It's recommended that you use the **Power Automate pane** to create a flow. The classic Power Automate experience should only be used for troubleshooting. The classic experience will be retired soon and won't be available.

1. Open a new or an existing app in Power Apps Studio.
2. Select **Settings** at the top.
3. Select **Upcoming features**.
4. Under the **Retired** tab, select **Enable Classic Power Automate pane** to set the toggle to **On**.

Prerequisites

- Sign up for Power Apps.
- Learn how to configure a control.

- A SharePoint site with two lists.
  - List **RepairShop** contains Title, and ContactEmail columns.
  - List **Assets** contains Title, AssetType, and RepairShop columns. The AssetType column is a choice column with choices such as "Desktop" or "Laptop".
  - The RepairShop column in Assets list is a lookup column that gets values from the ContactEmail column in RepairShop list.
  - Create a few items in the **RepairShop** list for sample contacts.

Create a flow

In this section, you create a flow using Power Automate that creates an item in a list using the input value for the list column from an app created using Power Apps. You create the app that uses this flow in the next section.

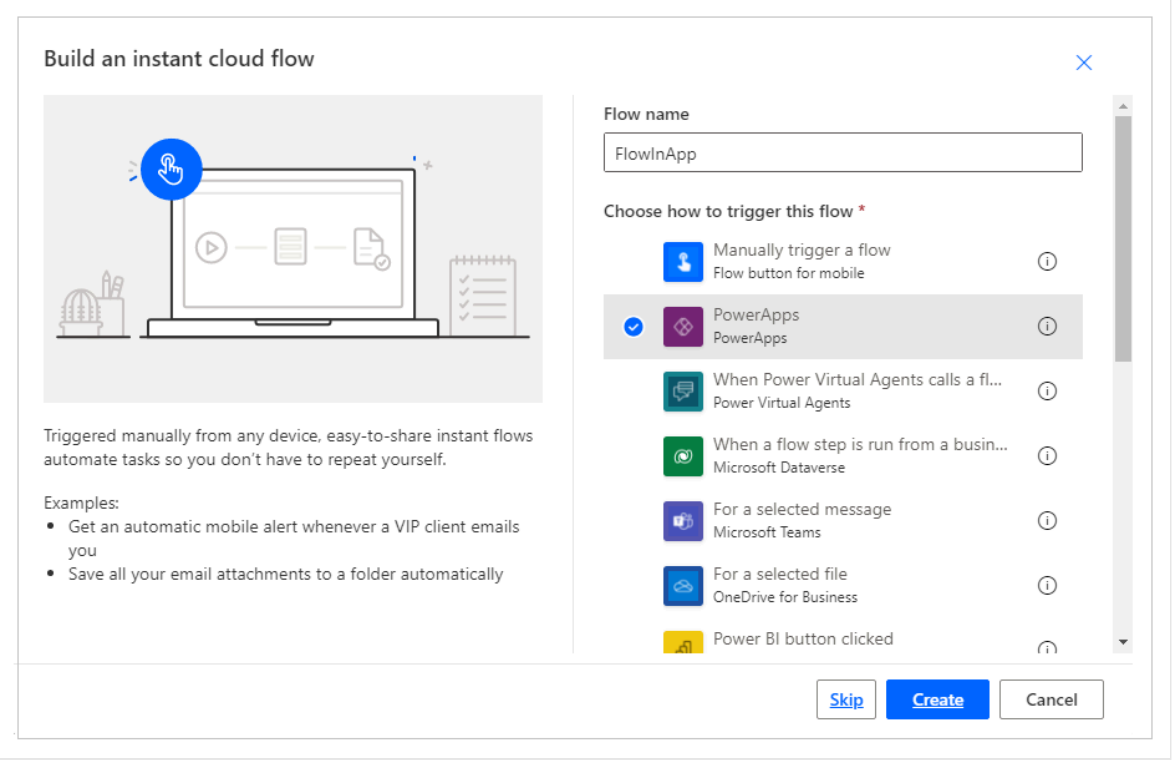
1. Sign in to Power Apps.

2. On the left-pane, select **Flows**.

3. Select **+ New flow** > **Instant cloud flow**.

4. Enter flow name, such as **FlowInApp**.

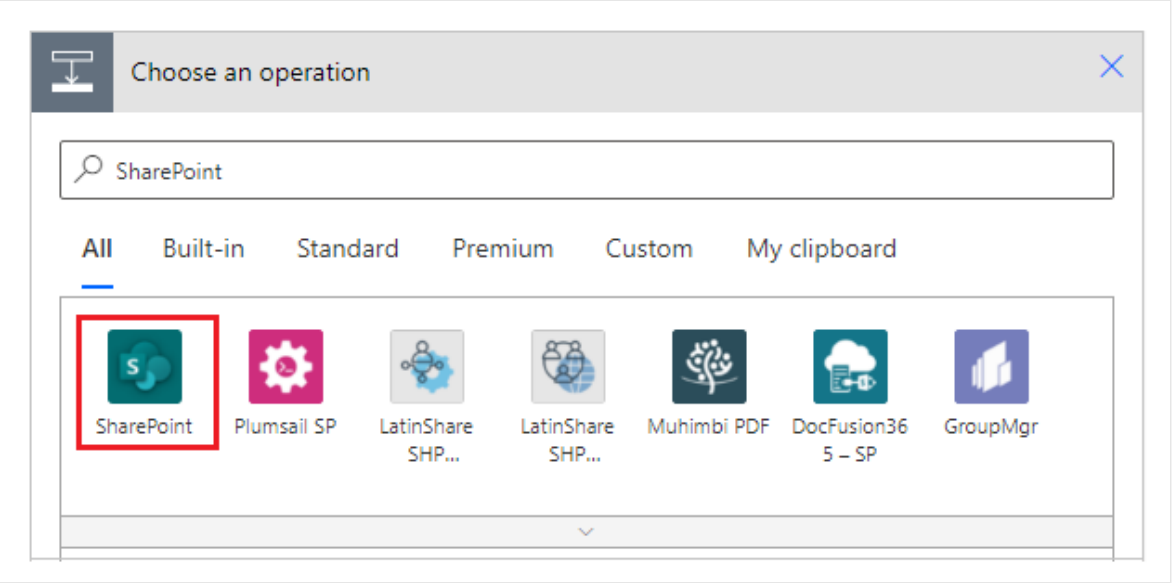
5. Under **Choose how to trigger this flow**, select **Power Apps**.



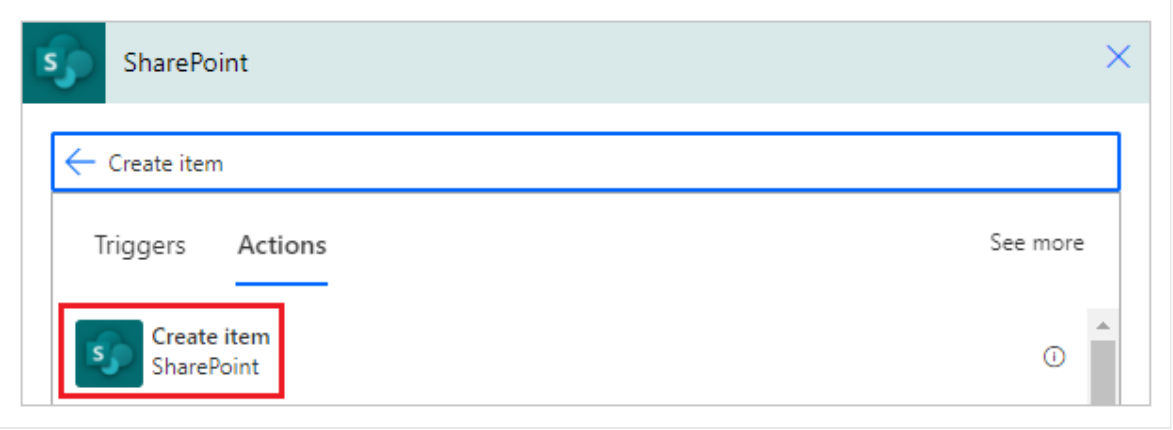
6. Select **Create**.

7. Select **+ New step**.

8. Under **Choose an operation**, search for or select **SharePoint** connector.

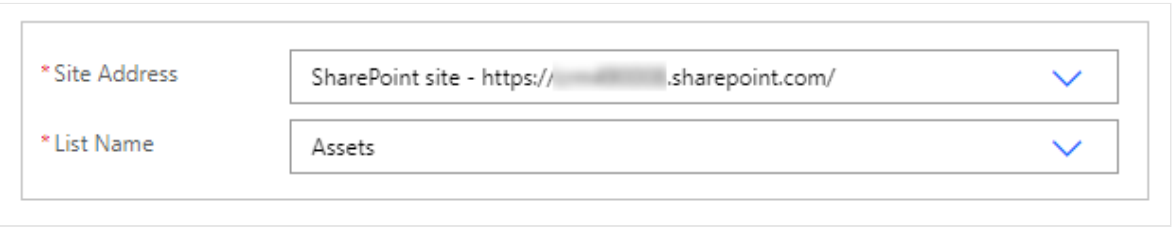


9. Search for, or select **Create item** action.

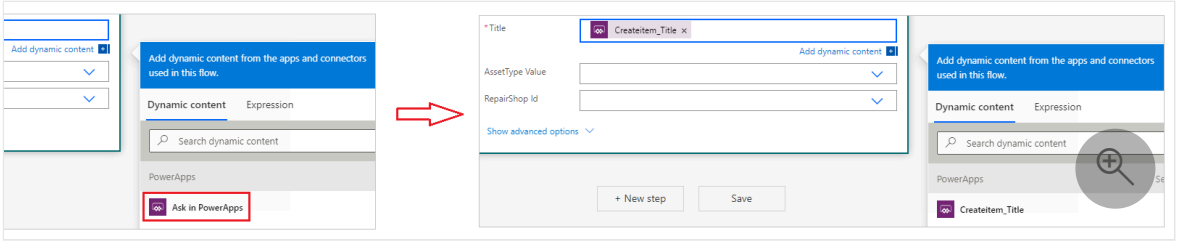


10. For **Site Address**, enter or choose your SharePoint site that has the lists **Assets** and **RepairShop**.

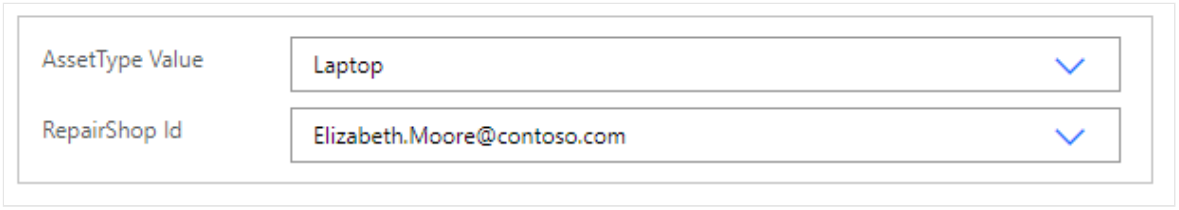
11. For **List Name**, select the **Assets** list.



12. For **Title**, choose **Ask in Power Apps** from the **Dynamic content** tab. The action automatically updates to **Createitem_Title**.



13. Choose values for **AssetType Value**, and **RepairShop Id** of your choice.



14. Select **Save**.

> **ⓘ Important**
>
> Arguments that pass from Power Apps to Power Automate are visible as network traffic and can be intercepted. Most traffic is likely harmless data that are irrelevant outside the application, for example arguments like "yes" or "Redmond".
>
> Evaluate the parameters passed to Power Automate and consider the consequences (if any) if they're changed by an exernal actor. To mitigate risks, validate the parameter values passed.
>
> For example, if you send sensitive data to a person in your organization through email, for example `someuser@contoso.com`, validate the address in Power Automate. You can check the incoming arguments to confirm the organization, `@contoso.com`, and only allow the flow to proceed if the right organization is present.

Add a flow to an app

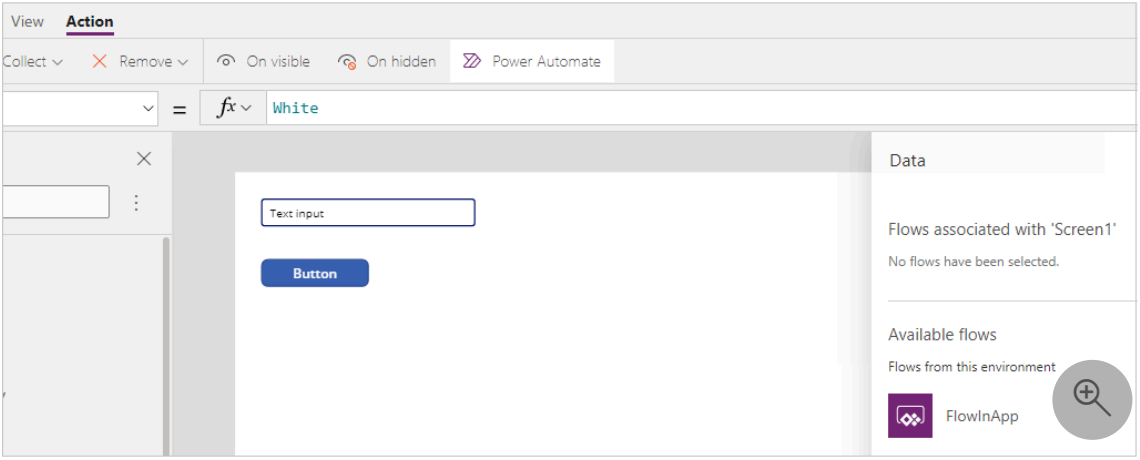
In this section, you create an app using Power Apps that uses the flow created in the earlier section. The app uses text entered in a text box when the button is selected to trigger the flow to create an item in the selected list.

1. Create a blank canvas app with a name such as **AppWithFlow**.
2. Select + (Insert) on the left-pane.
3. Select **Text input** control.
4. Select **Button** control.

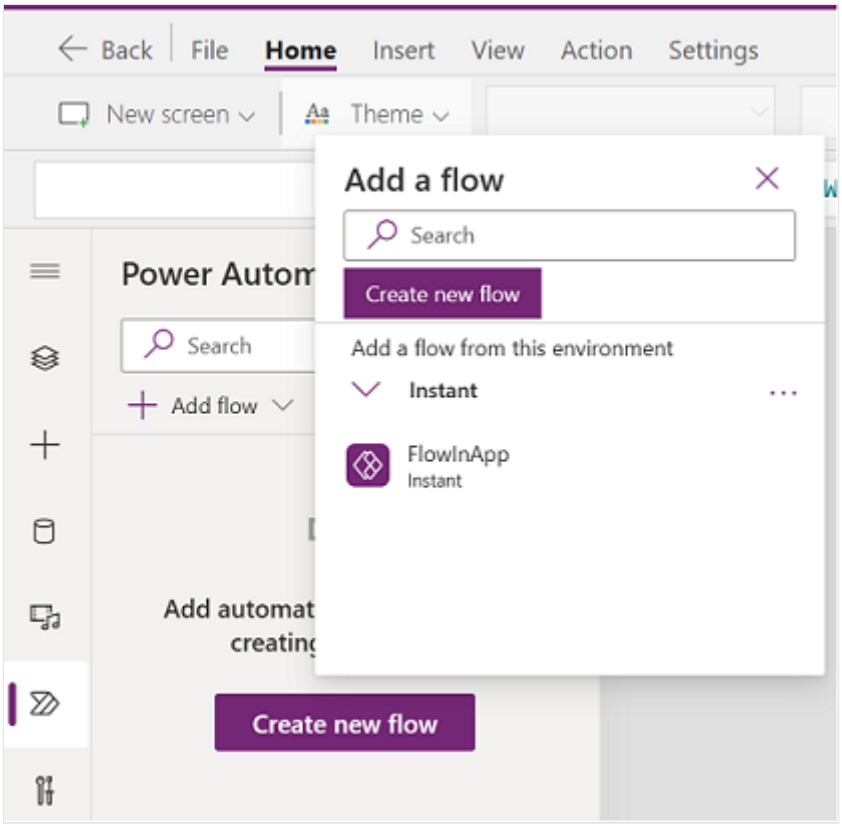
5. On the canvas, move the button control below the text input control.

6. Select **Action** menu at the top, and then select **Power Automate**.

> **Note**
>
> Adding a flow to the selected control or component clears out any existing formula for the chosen property. For example, when you add a flow to a button's `OnSelect` property that has a complex formula, the flow addition clears out this formula. Ensure you make a copy of the formula before adding the flow. However, this behavior is different when adding flow with the Power Automate pane enabled. Learn more in Reference a flow.



Alternatively, if you enabled the **Enable Power Automate pane** preview feature, you can choose your flow from the left-pane inside Power Apps Studio.



More information: Use Power Automate pane (preview)

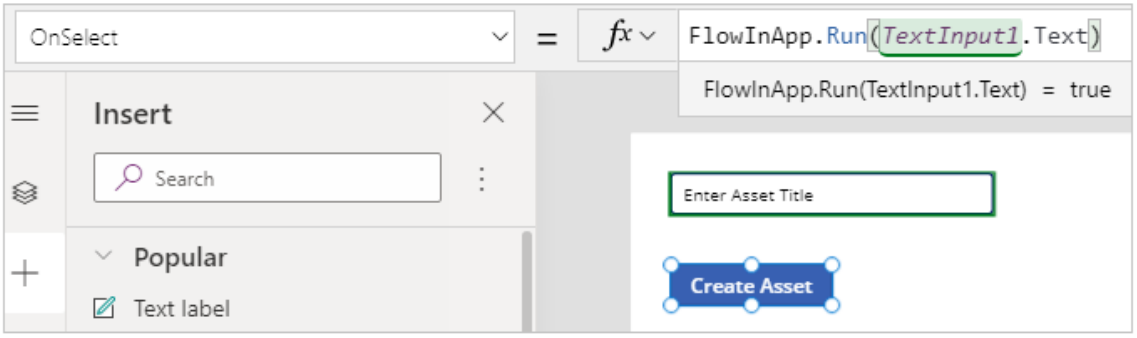
7. Select **FlowInApp**.
8. In the formula bar, remove the formula for the selected **OnVisible** property.
9. Select the text input control.
10. From the top-left side of the screen, select the property list drop-down, and then select the **Default** property.
11. In the formula bar, change the default property value from `"Text input"` to `"Enter Asset Title"`.
12. Select the button control.
13. From the top-left side of the screen, select the property list drop-down, and then select the **Text** property.
14. In the formula bar, change the text property value from `"Button"` to `"Create Asset"`.
15. From the top-left side property list, select the **OnSelect** property for the button.
16. Enter the following formula in the formula bar.

```
Power Fx
```

```
FlowInApp.Run(TextInput1.Text)
```

In this formula, **FlowInApp** is the name of the flow you added using Power Automate. The **.Run** specifies the flow to execute. The flow executes with **TextInput1** text input control added to this canvas, with the value entered in this text box (**.Text**).

When this button is selected, the app runs the flow with the value from the text input control, passing the text value to the flow to execute. And the flow creates the list item with this text input value along with rest of the selection inside the flow configuration.

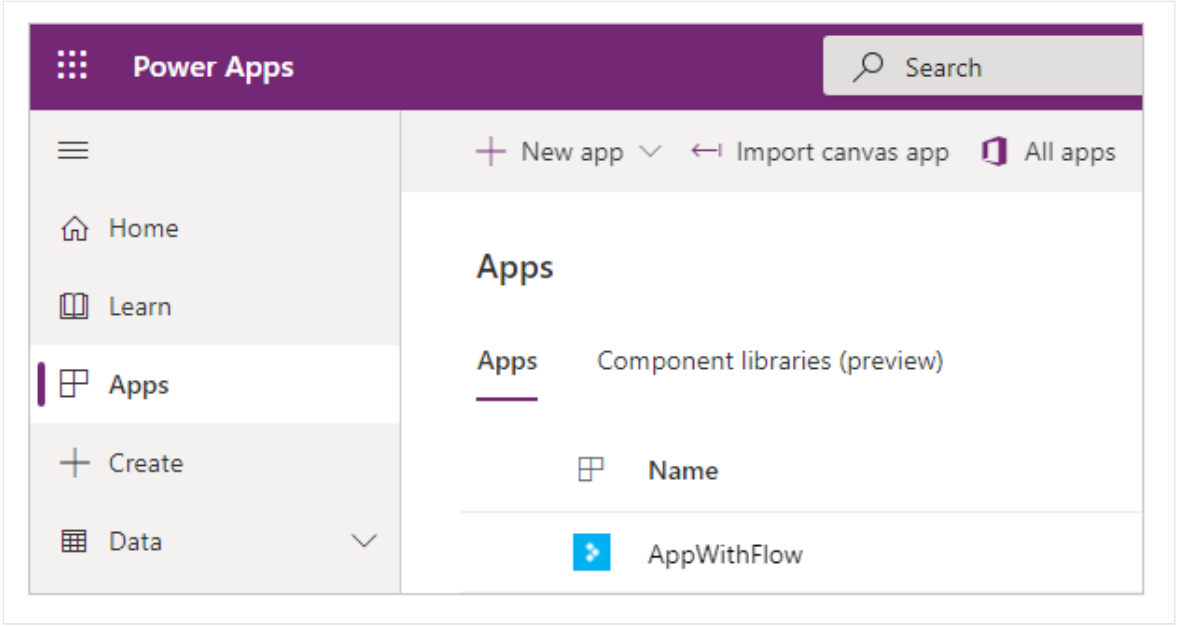


17. Save and publish the app.

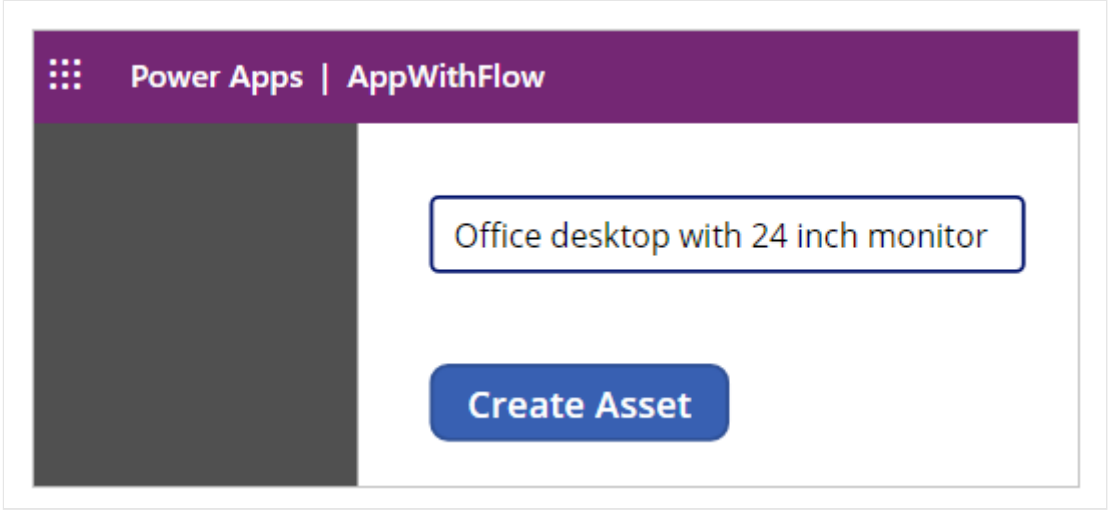
Test the flow

Now that you have both the flow and the app created, run the app and verify the creation of an item inside the selected list.

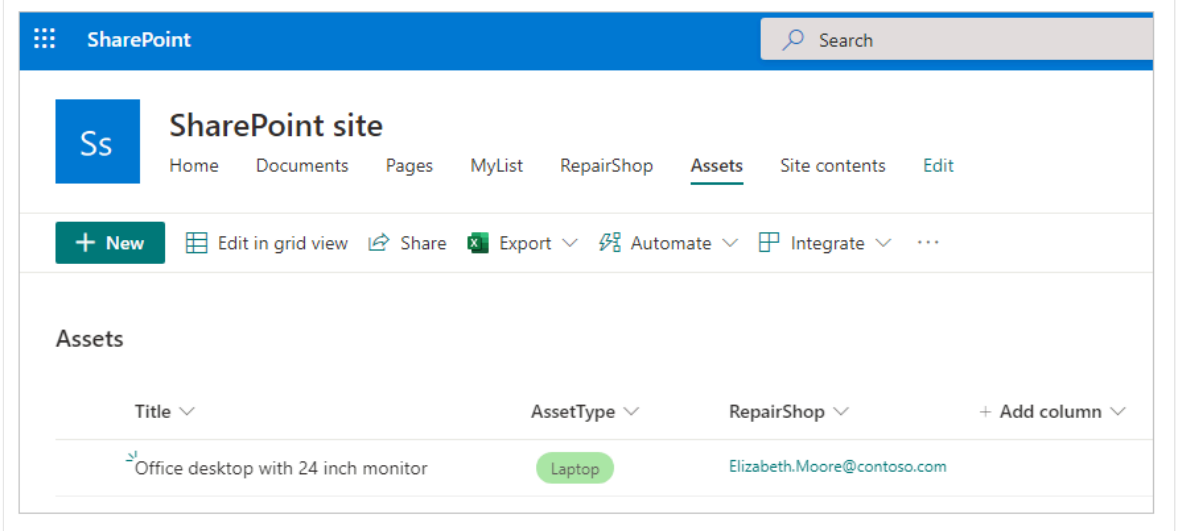
1. In Power Apps, select **Apps**, and then, select the **AppWithFlow** app.



2. Enter a value in the text input box, and then select **Create Asset**.



3. Verify that the item is created in your list.



Now that you created a sample app that runs a flow and adds an item inside a list, you can create more complex applications. Your apps can interact with Power Automate and

manipulate data inside various data sources.

Convert rules to expressions

Article • 03/16/2023

The capability to create rules in canvas apps for automated app modification based on specified criteria will be removed. This feature was retired in 2019 and will now be fully removed.

You'll have a few months to convert the rules into expressions using a converter. If there are any rules remaining in your canvas app that haven't been converted by the end of this period, the system will perform the conversion automatically.

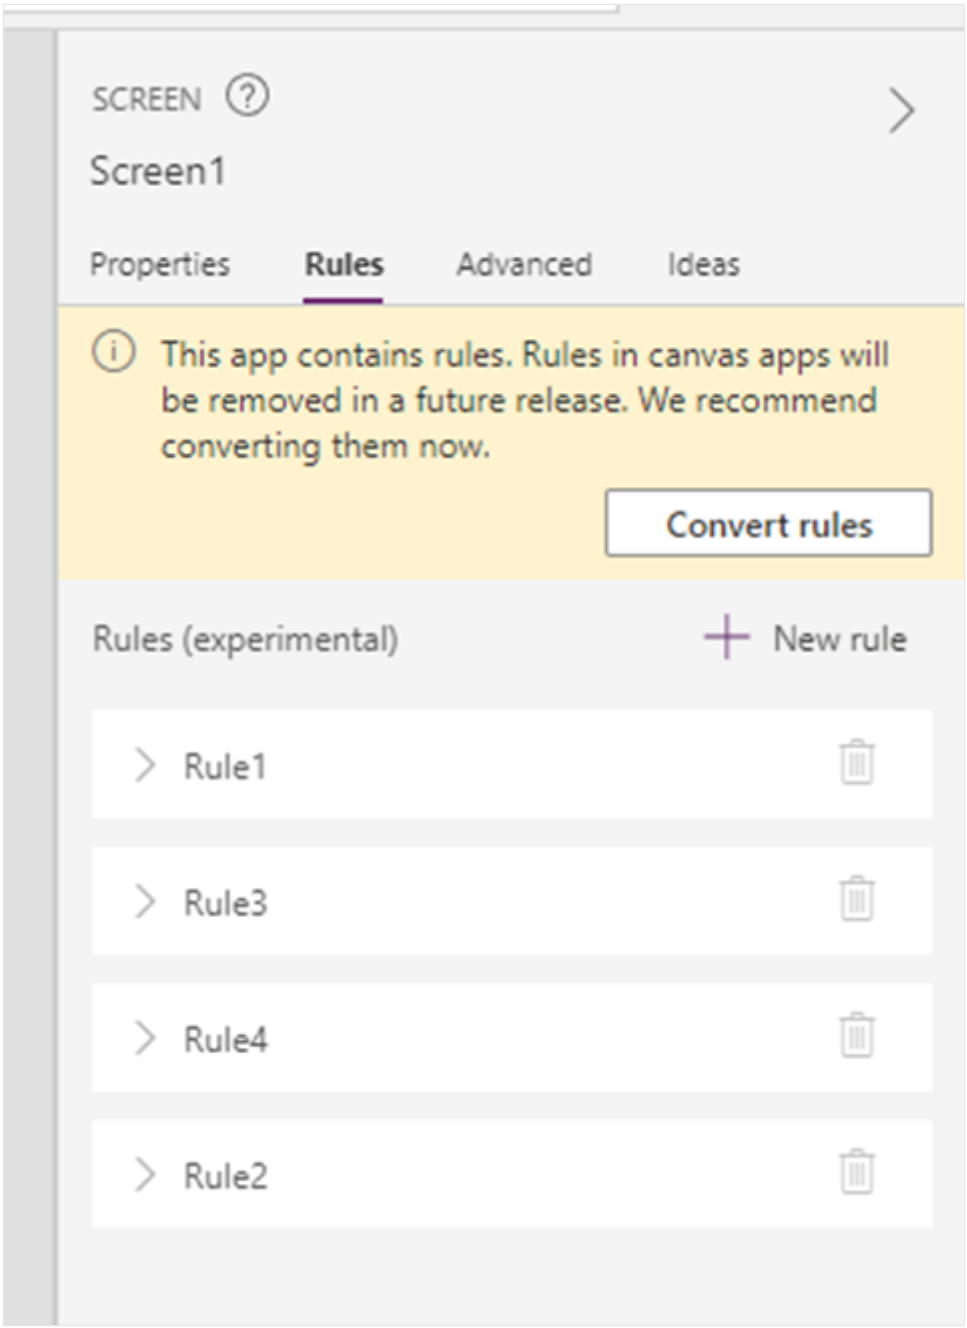
> **Important**
>
> Effective October 14, 2019, the rules feature in canvas apps is deprecated. More information: **Blog: Canvas Rules feature deprecation**.

Convert rules

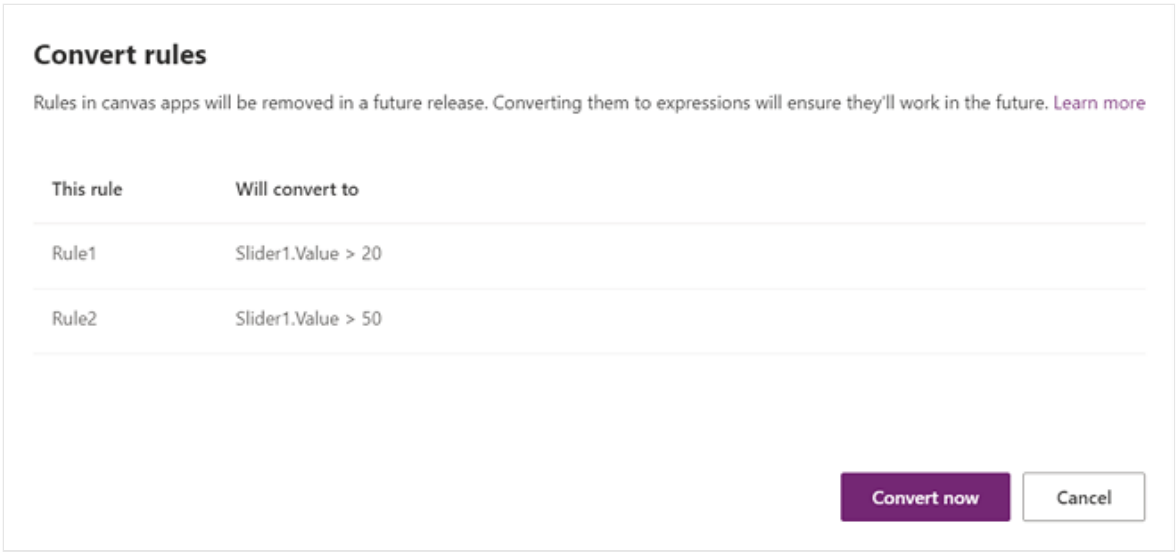
When you edit an app that has rules, you'll receive a prompt to convert them. The converter helps in migrating the rules within your app to a format that is compatible with future versions of Power Apps Studio. By utilizing the rules conditions in your app, the converter substitutes the references with corresponding inline expressions.

Follow these steps to convert rules in your app:

1. Open your app for editing and go to the Rules panel.
2. On the warning message, select **Convert rules**.



3. A dialog opens, which shows all the rules which will be converted. The rule name is shown on the left, and its associated conditional expression is shown on the right. On the **Convert rules** dialog box, select **Convert now**.



When the conversion is complete, a notification appears to alert you whether the conversion was successful. Formulas that previously referenced rule names have been updated to directly use their associated conditional expression instead.

Before the conversion, the Power Fx formula references rule names in the formula in place of their associated conditional expressions.

```
If(Rule2, DarkSeaGreen
, If(Rule1, DarkRed

, RGBA(56, 96, 178, 1)

)
)
```

After the conversion, rule name references have been removed and replaced. In this example, **Rule2** was converted to **Slider1.Value > 50**.

```
If(Slider1.Value > 50, DarkSeaGreen
, If(Slider1.Value > 20, DarkRed

, RGBA(56, 96, 178, 1)

)
)
```

Reverting the conversion

When the conversion is done, the rules are converted to the corresponding expression. During the conversion period, you can revert your changes to bring the rules back to your app for review and troubleshooting if necessary. While in the same session, you can use the Undo button or Ctrl-Z to revert the rule conversion. If you save the app, you can restore the previous version to revert the change. However, you will be prompted to convert the rules again the next time the app is opened for editing.

Known Issues

If your rules are in an error state or are empty, they will be replaced with the following formula: Boolean(Blank()). This formula preserves the behavior of rules in this state.

Create or update bulk records in Power Apps

Article • 12/16/2022

Updating or creating records in bulk allows you to act on many records at once. Here are some scenarios where you would want to bulk *update* records:

- You have many photos and want to upload them all at once.
- You want to submit a time sheet with a week's data at once.

You might also want to *create* new records in bulk. For example, when your app has to select many images, you might want to upload them all at once.

This article explains how to update or create bulk records depending on your scenario.

Formulas to bulk update records

The formulas in this section can be used to bulk update records in canvas apps.

- Patch() function—Use this function when the collection matches the data source.

  Power Fx

  ```
  Patch( DataSource, Collection )
  ```

- ForAll() function + nested Patch + disambiguation operator—Use this function when the data sources have different columns that you need to join.

  Power Fx

  ```
  ForAll( Collection,
      Patch( DataSource,
          LookUp( DataSource, Id = Collection[@Id] ),
          { Column: Value }
      )
  )
  ```

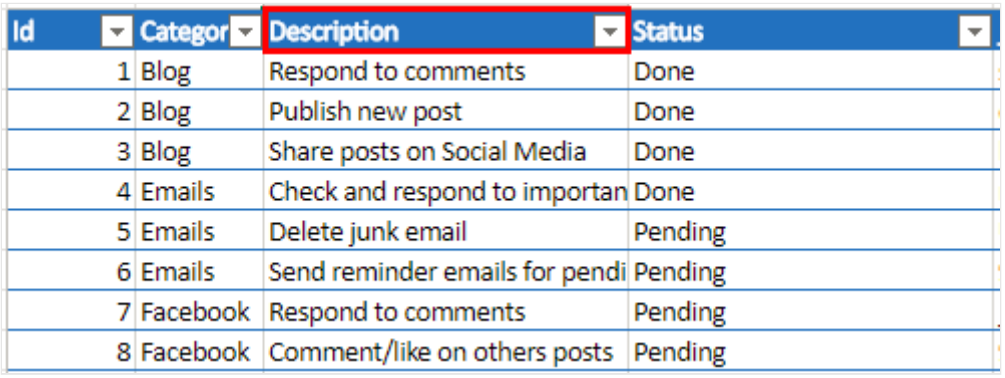
- AddColumns() function—This function can be used to provide a lookup reference in the Collection that contains the updates to the DataSource if it doesn't have fields that easily reference the table.

Example of a checklist

This example uses a checklist of tasks. When you're done with a few tasks, you can mark them as complete. You could extend this scenario to a product launch checklist, home inspection checklist, or other lists.

The following screenshot shows the checklist items in Microsoft Excel file. You can check off the tasks related to your blogging or posting on social media in this example. The table in Excel is called `ChecklistItems`.

The example uses collections to demo this behavior. The approach works for any tabular backend of your choice.

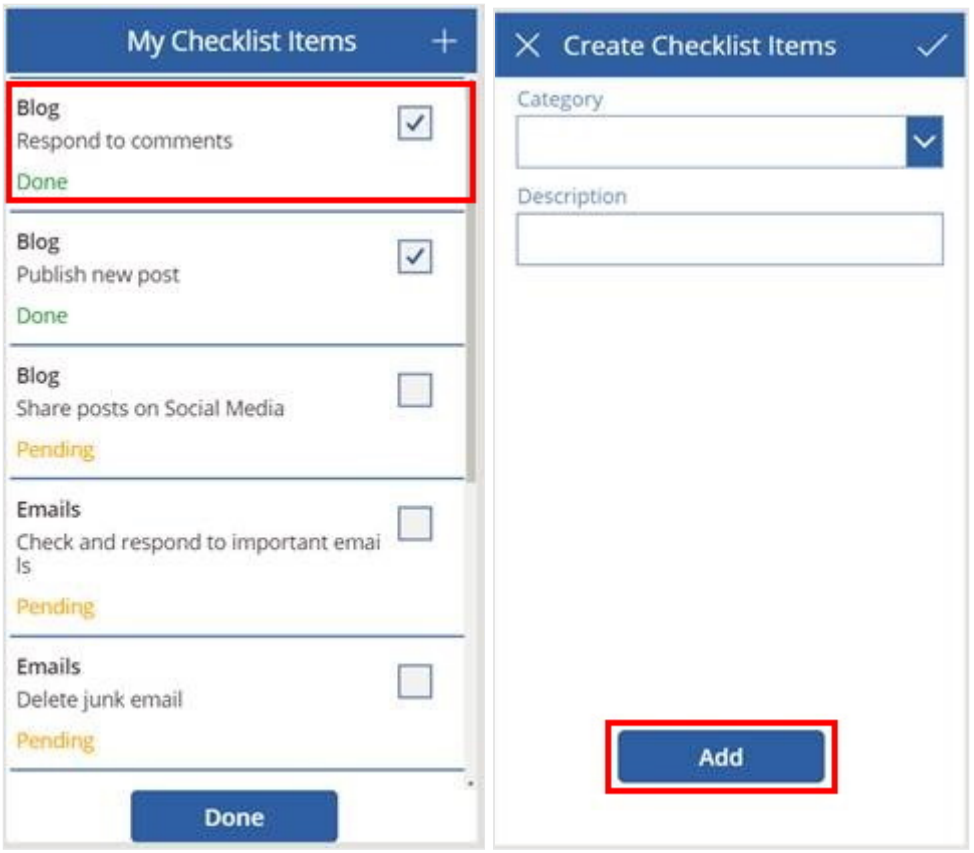


Id	Categor	Description	Status
1	Blog	Respond to comments	Done
2	Blog	Publish new post	Done
3	Blog	Share posts on Social Media	Done
4	Emails	Check and respond to importan	Done
5	Emails	Delete junk email	Pending
6	Emails	Send reminder emails for pendi	Pending
7	Facebook	Respond to comments	Pending
8	Facebook	Comment/like on others posts	Pending

The Excel data is imported as static data into the app. On the `App.OnStart` property, `Collect()` the Excel ChecklistItems data into the `ChecklistItemsSource` collection. The `ChecklistItemsSource` collection will be used as the source data throughout the app.

This example uses a two screen app:

- **Screen 1**—Used to review the checklist items and mark them as complete.
- **Screen 2**—Used to create a new checklist item. The new item will be added to `ChecklistItemsSource` collection.



Every time a checklist item is checked, it's added into a collection called `CheckedItems`. It uses the formula below on the `OnCheck` event property of the checkbox control. If the item is already checked and is part of the collection, it's removed. If not, the checked item is added.

You can toggle the status between **Done** and **Pending**, or you can use the `Oncheck` and `OnUncheck` events:

Power Fx

```
If( !IsBlank(
        LookUp( CheckedItems, Id = ThisItem.Id )
    ),
    Remove( CheckedItems, ThisItem ),
    Collect( CheckedItems, ThisItem )
)
```

Create multiple records at once

There are different ways of bulk updating records depending on the scenario. This section explains how to create multiple records at once in canvas apps.

When the user selects **Done** in the above example, you need to update `ChecklistItemsSource` with changes from the CheckedItems collection.

For columns with the same name

If your source and destination have the same column names, you can use a Patch statement. For example, `ChecklistItemsSource` and the `CheckedItems` collections have the same column names. You can use the formula below to update the source at once with all the changes.

Power Fx

```
Patch( ChecklistItemsSource, CheckedItems )
```

For columns with different names

If the columns in source and destination tables vary, use ForAll with Patch instead.

With `ForAll()`, you must loop through each record using a condition. The condition is a comparison between similar columns (for example, `Id` column) of the different tables. This comparison becomes complicated when the source table and the destination table have the same column names (for example, if `ProjectId` was a column found in both `Project` and `PurchaseOrder` tables).

Here are the alternatives:

Use with disambiguation operator

To update the `Status` of `CheckedItems` to "Done", when the source and destination table column names are the same, use this formula:

Power Fx

```
ForAll( CheckedItems,
    Patch( ChecklistItemsSource,
        LookUp( ChecklistItemsSource, Id = CheckedItems[@Id] ),
        { Status: "Done" }
    )
)
```

For each item in the `CheckedItems` collection, the Id (represented by the disambiguation operator `CheckedItems[@Id])` is compared against the Id column of the `ChecklistItemsSource` collection. Then, each matched record is updated with the status as "Done". The disambiguation operator is used when two columns belonging to

different tables have the same name. If you don't use this disambiguation operator, you'll see that only the first record gets updated.

Use an extra label within the gallery

If you don't want to use an extra collection to store the checked items, you can try the following steps:

1. Create an extra label within the gallery template.
   a. Bind it to the Id column.
   b. Rename the label to IdText.

2. Remove the code on the **OnCheck** of the checkbox control mentioned above.

3. Write the following formula on the OnSelect event of the Done Button:

```
Power Fx
```

```
ForAll(
    Filter( ChecklistGallery.AllItems,
      StatusCheckbox.Value = true
    ),
    Patch( ChecklistItemsSource,
      LookUp( ChecklistItemsSource, Id = IdText.Text ),
      { Status: "Done" }
    )
)
```

Here, you're directly applying the filter on the Gallery's items to find the checked items. For each record in the filtered items, a match is found on the **ChecklistItemsSource** table by comparing the Id with value stored in IdText label.

The status is updated to "Done".

The disambiguation operator can't be used on the Gallery's items. Instead, you can store a label within the gallery and reference it for comparison.

Use an alternative to create a new column with a different label

This method is an alternative to using the disambiguation operator or a label inside gallery.

While creating a local copy of your data source, you can use the `AddColumns()` formula to create a new column with a different label (`NewId`) for the Id column in your source

collection. When using ForAll with Patch, you compare the NewId column against the Id column in your source data.

Bulk create records

You may want to create new records in bulk if, for example, you want to upload many images all at once.

Here's an example using Example of a checklist.

On the Create Checklist Items screen, each time you select **Add**, the information is stored in the `NewChecklistItems` collection. When you select **Submit**, `ForAll()` with `Patch()` are used to update the source collection.

Power Fx

```
ForAll( NewChecklistItems,
    Patch( ChecklistItemsSource,
        Defaults( ChecklistItemsSource ),{
            Id: Id,
            Category: Category,
            Description: Description,
            Status:Status
        }
    )
)
```

For each item in the `NewChecklistItems`, a new record is created (indicated by `Defaults(ChecklistItemsSource)`) in the `ChecklistItemsSource` collection. The `Id` is set to the `Id` from the `NewChecklistItems` collection. Similarly, `Category`, `Description`, and `Status` values are set.

Power Apps Ideas

Article • 03/20/2025

Power Fx is the open-source programming language for low code. It enables millions of people with Excel-like skills to add advanced logic to their apps. However, sometimes it's not easy to write a formula, even for the most experienced Power Fx users, as it can sometimes take a lot of time searching for, learning about, and debugging complex formulas.

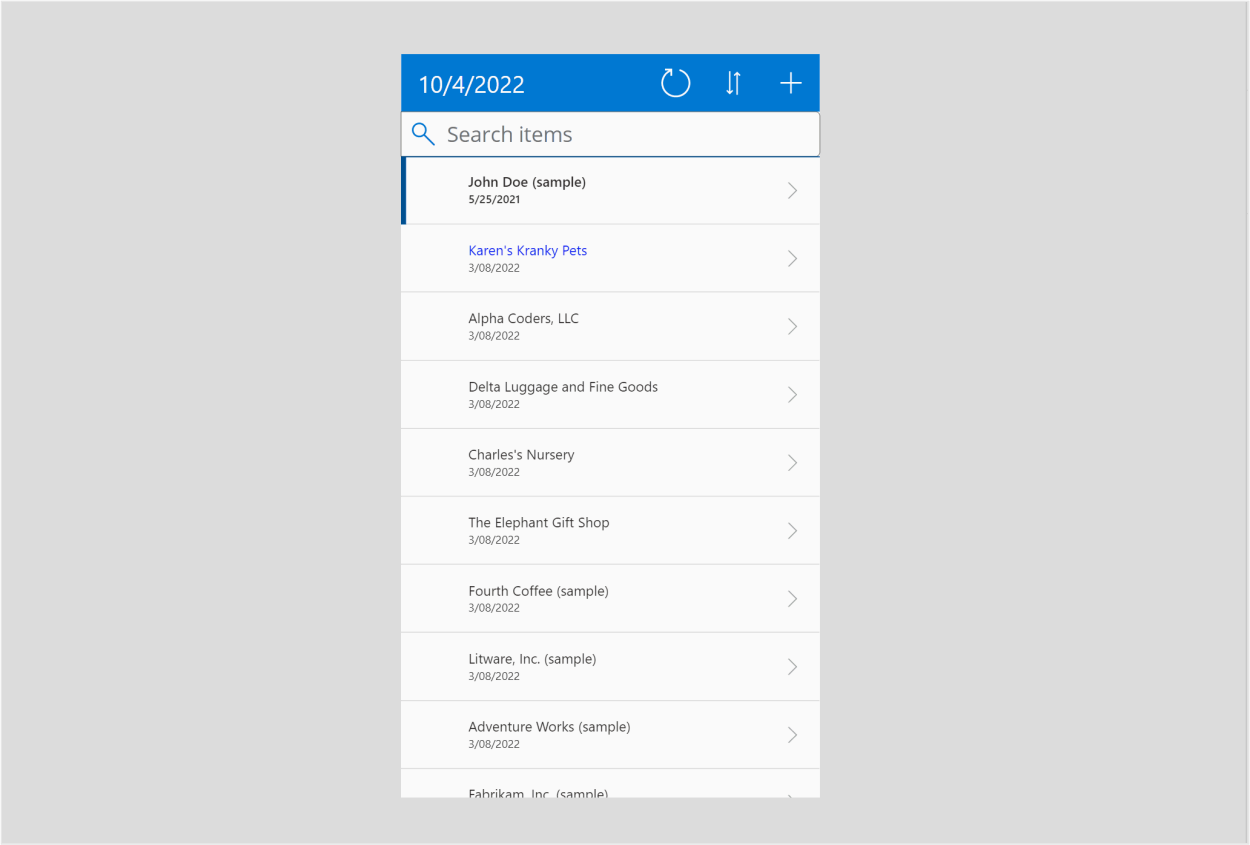
Power Apps Ideas is created to help everyone from the new makers to the seasoned IT pros to ease and speed up the formula authoring experience by using the power of AI models.

If you’re struggling with Power Fx and don’t want to spend time on it, try Power Apps Ideas.

Use Power Apps Ideas in your app

When you're building a canvas app, Power Apps Ideas will automatically suggest ideas for supported controls such as **Gallery**, **Data table**, **Text box**, **Drop down**, **Combo box**, and **Text label**.

When you select the name field in a gallery, you'll see an idea for a formula that you may want to use. However, if you select the plus icon, then you won’t see an idea because we currently don’t have ideas for icons.



There are two methods to benefit from Power Apps Ideas in your app.

Transform natural language to Power Fx formulas

You can enter your requirements in plain natural language (currently limited to English (en-us)), and Power Apps will transform your requirement to a Power Fx formula.

For details, go to Transform natural language to Power Fx formulas.

Dismiss an idea

If you don't want to see Ideas, select the close button (**X**) and then confirm that you don't want to see Ideas anymore.

If you want to see Ideas again, right-click on the control to see suggested Ideas.

Transform natural language to Power Fx formulas

Article • 01/18/2023

Power Apps Ideas can generate ideas for formulas using the following controls on different properties:

- **Gallery**
- **Data table**
- **Text box**
- **Drop down**
- **Combo box**
- **Text label**

Power Apps Ideas also supports Microsoft Dataverse, Microsoft Lists, SharePoint library, and Excel as connectors. So, if you're using one of the supported controls and want to write a formula for Gallery or Dropdown items, or for Label's text content, color, or visibility, then check out Power Apps Ideas.

For example, instead of figuring out how to write the following formula ...

```
Power Fx
```

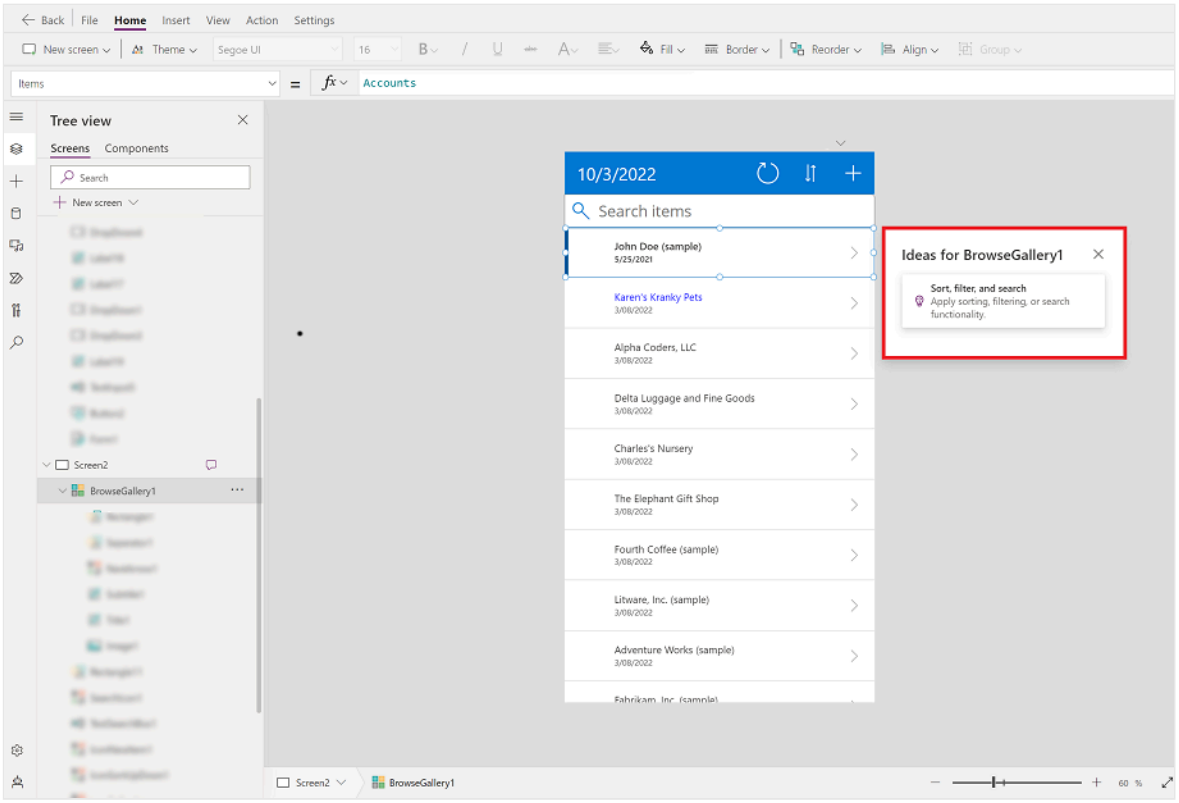
```
Filter('Table1', StartsWith('fullname', "Yvonne"))
```

... You can type `'name starts with Yvonne` instead.

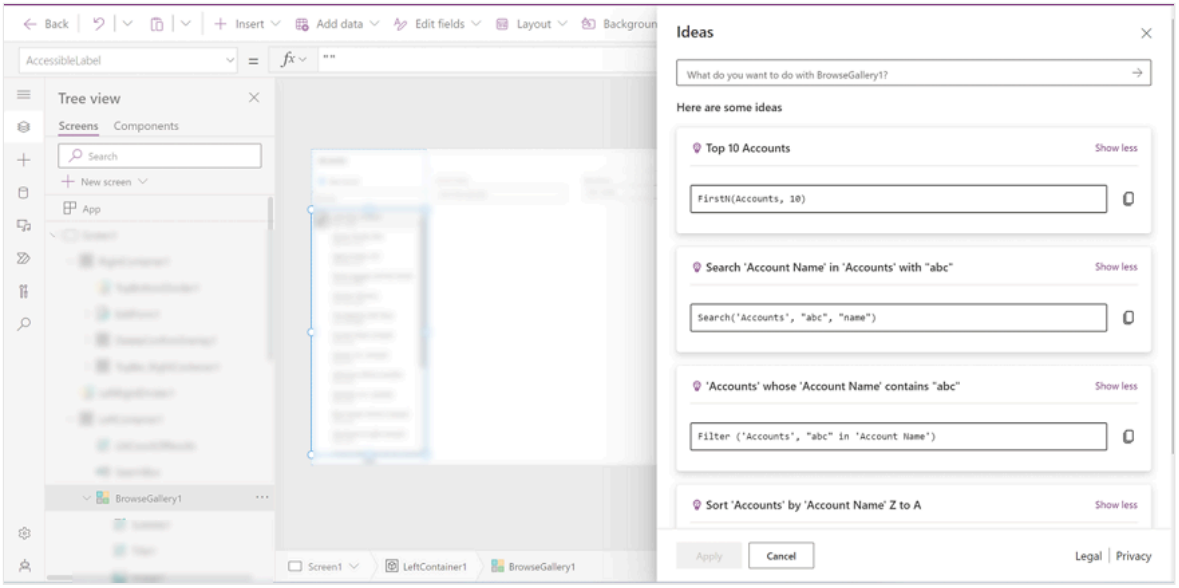
To begin, let's look at a simple app to see how you can use Power Apps Ideas to help write formulas.

You can follow the steps mentioned in Create a canvas app from Microsoft Dataverse to generate that app using the **Accounts** table from Dataverse.

1. Select **BrowseGallery1,** which is bound to the **Accounts** table.
2. Select **Sort, filter, and search** on the ideas box.



3. Select one of the default suggestions to check how it works or start entering your own query in natural language such as English (en-us).



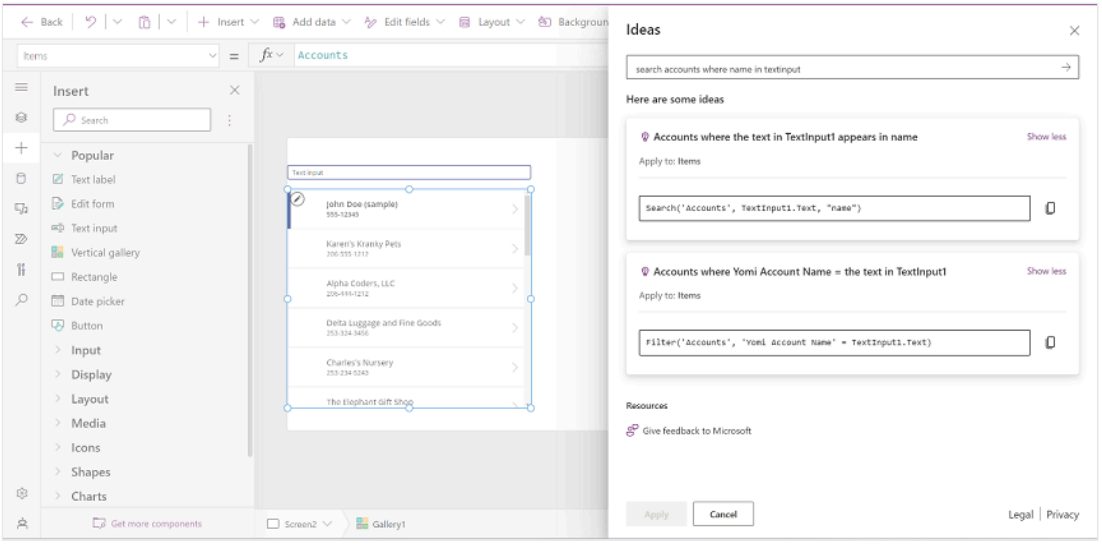
4. When typing you can use the default query, modify it, or describe it in your own way.

5. You'll see one or more formula suggestions produced. Let's use the example **search accounts where name in textinput**. You'll see two suggestions in the results. Each of those formula suggestions includes three parts:

    - **Accounts** where the text in **TextInput1** appears in **name**. This is trying to explain what the suggested formula is doing so that it's easier for users who

aren't familiar with Power Fx to understand the result. The names of the components used in the app are shown in bold.

- **Apply to: Items**: This suggests which property the formula will be applied to. As Power Apps controls have many properties, Ideas can identify which property a formula should be applied to.
- The formula suggestion in this scenario is `Search('Accounts', TextInput1.Text, "name")`.



6. Select your preferred suggestion and then select **Apply**. In this case, let's select the first suggestion since it's the best fit. The formula gets updated automatically and runs so you can check the result in your app. You can then decide whether to keep the selected formula or modify it.

More examples

Consider the following examples for inspiration while working with Power Apps Ideas.

Expand table

Scenario	Description	Ideas example
Sort your table	Sort by a single column	sort accounts by Account Name
		sort accounts by Account Name A-Z
		sort accounts by Account Name Z-A
	Sort accounts by Account	

Scenario	Description	Ideas example
	Name and Created On	
		sort accounts by Account Name A-Z and Created On latest on top
	Sort existing tables	sort Gallery3 by Account Name Z to A
Filter or search table by some conditions	A number condition	accounts with length of Account Name bigger than 10
	A date condition	accounts created a week ago, accounts modified last 3 days
	A text condition	accounts with name contains Karen
	A few conditions	accounts whose name contains Karen and created 7 days ago
	A choice value	inactive accounts
	Search table by user input	search accounts with name in textinput
	Find a single record	first record in accounts where name contains Karen
	Find records on the top or the bottom of the table	top 10 accounts
		last 10 accounts
Conditional formatting (apply to color and visible)	A number condition	accounts with length of Account Name bigger than 10
	A date condition	red if created 7 days ago
	A text condition	blue if name contains Karen
Text generation	Numbers	count of gallery sum of slider1 and slider2
	String	label4 and label5 Trim textinput1First 3 characters of TextInput1

Best practices

To get the best results, follow these tips when writing the plain natural language query in the Ideas pane.

- Leverage default queries to see what kind of scenarios are supported.
- Be precise in your query. Ideas can recognize controls such as tables and columns. However, if you don't get a suggestion, try using the full name of the assets you're referencing. For example, use **TextInput1** when you have multiple text input controls in the app. This way the system knows which control you're referring to.

Limitations

> **Note**
>
> We're improving the model so it can accomplish more complex tasks and support more functions, controls, and properties. If you have a wish list, submit your ideas through Power Apps Ideas - Power Platform Community.

Power Apps Ideas currently has the following limitations:

- Regions and language: Currently available in environments created inside the United States, with English (en-us) set as the browser's default language.
- Recognizes control value of **TextInput**, **Dropdown**, **DatePicker**, **Slider**, **Toggle**, **Checkbox**, and **Radio** as input.

Expand table

Controls	Properties
Gallery, **Data table**, **Drop down**, **Combo box**	Items
Text Box, **Label**	Text, Color, Visible

- Data sources: Currently Ideas supports Dataverse tables, Microsoft Lists, and Excel sheets.
- Functions: See Supported Power Fx functions. We'll continue to add support for more functions.
- Data types: Supports Text, Whole Number, Date and Time, Date Only, Decimal Number, Choice, Choices, Yes/No Lookup. Not supported: File and Image.

- This feature's model understands some commonly used expressions in natural language. For example, it can translate from `latest on top`, `big to small` to a descending order and `oldest on top`, `small to big` to ascending order. And it can understand most of the context so even if you didn't specify the table names, it will make the best prediction based on the current table that is bound to the control.

Formula reference - canvas apps

This article explains all the functions you can use in canvas apps.

Formulas in canvas apps combine several elements. Here are the main types:

- **Functions** take parameters, perform an operation, and return a value. For example, **Sqrt(25)** returns **5**. Functions are similar to Microsoft Excel functions. Some functions can have side effects, like **SubmitForm**, which you use only in a behavior formula such as **Button.OnSelect**.
- **Signals** return information about the environment. For example, **Location** returns the device's current GPS coordinates. Signals don't take parameters or have side effects.
- **Enumerations** return a predefined constant value. For example, **Color** is an enumeration with predefined values like **Color.Red** and **Color.Blue**. Common enumerations are included here, and function-specific enumerations are described with the function.
- **Named operators**, like **ThisItem** and **Self**, let you access information from within a container.

Other elements include:

- Operators and identifiers
- Controls and their properties
- Data types

A

Abs – Returns the absolute value of a number.

Acceleration – Reads the acceleration sensor in your device.

Acos – Returns the arccosine of a number, in radians.

Acot – Returns the arccotangent of a number, in radians.

AddColumns – Returns a table with additional columns.

And – Boolean logic AND. Returns **true** if all arguments are **true**. You can also use the **&&** operator.

AIClassify – Classifies text into one or more categories.

AIExtract – Extracts specified entities like registration numbers, phone numbers, or people's names.

AIReply – Drafts a reply to the message that you provide.

AISentiment – Detects the sentiment of the text that you provide.

AISummarize – Summarizes the text that you provide.

AITranslate – Translates text from one language to another.

App – Provides information about the currently running app and lets you control the app's behavior.

Asin – Returns the arcsine of a number, in radians.

Assert – Evaluates to true or false in a test.

As – Names the current record in gallery, form, and record scope functions like **ForAll**, **With**, and **Sum**.

AsType – Treats a record reference as a specific table type.

Atan – Returns the arctangent of a number, in radians.

Atan2 – Returns the arctangent based on an (*x*,*y*) coordinate, in radians.

Average – Calculates the average of a table expression or a set of arguments.

B

Back – Shows the previous screen.

Blank – Returns a *blank* value you can use to insert a NULL value in a data source.

Boolean – Converts a text string, number, or dynamic value to a Boolean value.

C

Calendar – Retrieves information about the calendar for the current locale.

Char – Translates a character code into a string.

Choices – Returns a table of the possible values for a lookup column.

Clear – Deletes all data from a collection.

ClearCollect – Deletes all data from a collection and then adds a set of records.

ClearData – Clears a collection or all collections from an app host such as a local device.

Clock – Retrieves information about the clock for the current locale.

Coalesce – Replaces *blank* values while leaving non-*blank* values unchanged.

Collect – Creates a collection or adds data to a data source.

Color – Sets a property to a built-in color value.

ColorFade – Fades a color value.

ColorValue – Translates a CSS color name or a hex code to a color value.

Column – Retrieves column names and values from a Dynamic value.

ColumnNames – Retrieves column names and values from a Dynamic value.

Compass – Returns your compass heading.

Concat – Concatenates strings in a data source.

Concatenate – Concatenates strings.

Concurrent – Evaluates multiple formulas concurrently with one another.

Confirm - Display a confirmation dialog box.

Connection – Returns information about your network connection.

Copy – Copies text to the clipboard on the device where the app is running.

Count – Counts table records that contain numbers.

Cos – Returns the cosine of an angle specified in radians.

Cot – Returns the cotangent of an angle specified in radians.

CountA – Counts table records that aren't empty.

CountIf – Counts table records that satisfy a condition.

CountRows – Counts table records.

D

DataSourceInfo – Provides information about a data source.

Date – Returns a date/time value, based on **Year**, **Month**, and **Day** values.

DateAdd – Adds days, months, quarters, or years to a date/time value.

DateDiff – Subtracts two date values, and shows the result in days, months, quarters, or years.

DateTime – Returns a date/time value, based on both date and time components.

DateTimeValue – Converts a date and time string to a date/time value.

DateValue – Converts a date-only string to a date/time value.

Day – Retrieves the day portion of a date/time value.

Dec2Hex – Convert a number to a hexadecimal text string.

Defaults – Returns the default values for a data source.

Degrees – Converts radians to degrees.

Disable – Disables a signal, such as **Location** for reading the GPS.

Distinct – Summarizes records of a table, removing duplicates.

Download – Downloads a file from the web to the local device.

DropColumns – Returns a table with one or more columns removed.

E

EDate – Adds or subtracts months to a date, without changing the day of the month.

EditForm – Resets a form control for editing of an item.

Enable – Enables a signal, such as **Location** for reading the GPS.

EncodeHTML – Encodes characters that need to be escaped to be used in an HTML context.

EncodeUrl – Encodes special characters using URL encoding.

EndsWith – Checks whether a text string ends with another text string.

EOMonth – Adds or subtracts months to a date, returning the last day of that month.

Error – Create a custom error or pass through an error.

Errors – Provides error information for previous changes to a data source.

exactin – Checks if a text string is contained within another text string or table, case dependent. Also used to check if a record is in a table.

Exit – Exits the currently running app and optionally signs out the current user.

Exp – Returns *e* raised to a power.

F

Filter – Returns a filtered table based on one or more criteria.

Find – Checks whether one string appears within another and returns the location.

First – Returns the first record of a table.

FirstN – Returns the first set of records (N records) of a table.

Float – Converts a string to a Float value.

ForAll – Calculates values and performs actions for all records of a table.

G

GroupBy – Returns a table with records grouped together.

GUID – Converts a GUID string to a GUID value or creates a new GUID value.

H

HashTags – Extracts the hashtags (#strings) from a string.

Hex2Dec – Convert a hexadecimal text string to a number.

Host – Provides information about the current host running the app.

Hour – Returns the hour portion of a date/time value.

I

If – Returns one value if a condition is true and another value if not.

IfError – Detects errors and provides an alternative value or takes action.

in – Checks if a text string is contained within another text string or table, case independent. Also used to check if a record is in a table.

Index – Returns a record from a table based on ordered position.

Int – Rounds down to the nearest integer.

IsBlank – Checks for a blank value.

IsBlankOrError – Checks for a blank value or error.

IsEmpty – Checks for an empty table.

IsError – Checks for an error.

IsMatch – Checks a string against a pattern. Regular expressions can be used.

IsNumeric – Checks for a numeric value.

ISOWeekNum – Returns the ISO week number of a date/time value.

IsToday – Checks whether a date/time value is sometime today in the user's time zone.

IsType – Checks whether a record reference refers to a specific table type.

J

JSON – Generates a JSON text string for a table, a record, or a value.

L

Language – Returns the language tag of the current user.

Last – Returns the last record of a table.

LastN – Returns the last set of records (N records) of a table.

Launch – Launches a webpage or a canvas app.

Left – Returns the left-most portion of a string.

Len – Returns the length of a string.

Ln – Returns the natural log.

LoadData – Loads a collection from an app host such as a local device.

Location – Returns your location as a map coordinate by using the Global Positioning System (GPS) and other information.

Log – Returns the logarithm in any base of a number.

LookUp – Looks up a single record in a table based on one or more criteria.

Lower – Converts letters in a string of text to all lowercase.

M

Match – Extracts a substring based on a pattern. Regular expressions can be used.

MatchAll – Extracts multiple substrings based on a pattern. Regular expressions can be used.

Max – Maximum value of a table expression or a set of arguments.

Mid – Returns the middle portion of a string.

Min – Minimum value of a table expression or a set of arguments.

Minute – Retrieves the minute portion of a date/time value.

Mod – Returns the remainder after a dividend is divided by a divisor.

Month – Retrieves the month portion of a date/time value.

N

Navigate – Changes which screen is displayed.

NewForm – Resets a form control for creation of an item.

Not – Boolean logic NOT. Returns **true** if its argument is **false**, and returns **false** if its argument is **true**. You can also use the ! operator.

Notify – Displays a banner message to the user.

Now – Returns the current date/time value in the user's time zone.

O

Or – Boolean logic OR. Returns **true** if any of its arguments are **true**. You can also use the || operator.

P

Param – Access parameters passed to a canvas app when launched.

Parent – Provides access to a container control's properties.

ParseJSON – Converts JSON document represented as text to a Dynamic value value.

Patch – Modifies or creates a record in a data source, or merges records outside of a data source.

PDF – Export contents from the current screen to an object for use in multiple scenarios.

Pi – Returns the number π.

PlainText – Removes HTML and XML tags from a string.

Power – Returns a number raised to a power. You can also use the ^ operator.

Print - Opens the current screen in the default browser print dialog.

Proper – Converts the first letter of each word in a string to uppercase, and converts the rest to lowercase.

R

Radians – Converts degrees to radians.

Rand – Returns a pseudo-random number between 0 and 1.

RandBetween – Returns a pseudo-random number between two numbers.

ReadNFC – Reads a Near Field Communication (NFC) tag.

RecordInfo – Provides information about a record of a data source.

RecordOf - Extracts the type of a record from a table.

Refresh – Refreshes the records of a data source.

Relate – Relates records of two tables through a one-to-many or many-to-many relationship.

Remove – Removes one or more specific records from a data source.

RemoveIf – Removes records from a data source based on a condition.

RenameColumns – Renames columns of a table.

Replace – Replaces part of a string with another string, by starting position of the string.

RequestHide – Hides a SharePoint form.

Reset – Resets an input control to its default value, discarding any user changes.

ResetForm – Resets a form control for editing of an existing item.

Revert – Reloads and clears errors for the records of a data source.

RGBA – Returns a color value for a set of red, green, blue, and alpha components.

Right – Returns the right-most portion of a string.

Round – Rounds to the closest number.

RoundDown – Rounds down to the largest previous number.

RoundUp – Rounds up to the smallest next number.

S

SaveData – Saves a collection to an app host such as a local device.

Search – Finds records in a table that contain a string in one of their columns.

Second – Retrieves the second portion of a date/time value.

Select – Simulates a select action on a control, causing the **OnSelect** formula to be evaluated.

Self – Provides access to the properties of the current control.

Sequence – Generate a table of sequential numbers, useful when iterating with **ForAll**.

Set – Sets the value of a global variable.

SetFocus – Moves input focus to a specific control.

SetProperty – Simulates interactions with input controls.

ShowColumns – Returns a table with only selected columns.

ShowHostInfo – Displays information to the user in the app.

Shuffle – Randomly reorders the records of a table.

Sin – Returns the sine of an angle specified in radians.

Sort – Returns a sorted table based on a formula.

SortByColumns – Returns a sorted table based on one or more columns.

Split – Splits a text string into a table of substrings.

Sqrt – Returns the square root of a number.

StartsWith – Checks if a text string begins with another text string.

StdevP – Returns the standard deviation of its arguments.

Substitute – Replaces part of a string with another string, by matching strings.

SubmitForm – Saves the item in a form control to the data source.

Sum – Calculates the sum of a table expression or a set of arguments.

Switch – Matches with a set of values and then evaluates a corresponding formula.

T

Table – Creates a temporary table.

Tan – Returns the tangent of an angle specified in radians.

Text – Converts any value and formats a number or date/time value to a string of text.

ThisItem – Returns the record for the current item in a gallery or form control.

ThisRecord – Returns the record for the current item in a record scope function, such as **ForAll**, **With**, and **Sum**.

Time – Returns a date/time value, based on **Hour**, **Minute**, and **Second** values.

TimeValue – Converts a time-only string to a date/time value.

TimeZoneOffset – Returns the difference between UTC and the user's local time in minutes.

Today – Returns the current date-only value.

Trace – Provide additional information in your test results.

Trim – Removes extra spaces from the ends and interior of a string of text.

TrimEnds – Removes extra spaces from the ends of a string of text only.

Trunc – Truncates the number to only the integer portion by removing any decimal portion.

Type - Defines a user defined type.

U

Ungroup – Removes a grouping.

UniChar – Translates a Unicode code into a string.

Unrelate – Unrelates records of two tables from a one-to-many or many-to-many relationship.

Update – Replaces a record in a data source.

UpdateContext – Sets the value of one or more context variables of the current screen.

UpdateIf – Modifies a set of records in a data source based on a condition.

Upper – Converts letters in a string of text to all uppercase.

User – Returns information about the current user.

V

Validate – Checks whether the value of a single column or a complete record is valid for a data source.

Value – Converts a string to a number.

VarP – Returns the variance of its arguments.

ViewForm – Resets a form control for viewing of an existing item.

W

Weekday – Retrieves the weekday portion of a date/time value.

WeekNum – Returns the week number of a date/time value.

With – Calculates values and performs actions for a single record, including inline records of named values.

Y

Year – Retrieves the year portion of a date/time value.

Log	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Calculates absolute values, logarithms, square roots, and the results of raising *e* or any number to specified powers.

Description

The **Abs** function returns the non-negative value of its argument. If a number is negative, **Abs** returns the positive equivalent.

The **Exp** function returns *e* raised to the power of its argument. The transcendental number *e* begins 2.7182818...

The **Ln** function returns the natural logarithm (base *e*) of its argument.

The **Power** function returns a number raised to a power. It's equivalent to using the ^ operator.

The **Log** function returns the logarithm of its first argument in the base specified by its second argument (or 10 if not specified).

The **Sqrt** function returns the number that, when multiplied by itself, equals its argument.

If you pass a single number, the return value is a single result based on the function called. If you pass a single-column table that contains numbers, the return value is a single-column table of results in a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined valued, the result is *blank*. Which can happen with square roots and logarithms of negative numbers.

Syntax

Abs(*Number*)
Exp(*Number*)
Ln(*Number*)
Sqrt(*Number*)

- *Number* - Required. Number to operate on.

Power(*Base*, *Exponent*)

- *Base* - Required. Base number to raise.
- *Exponent* - Required. The exponent to which the base number is raised.

Log(*Number*, *Base*)

- *Number* - Required. Number to calculate the logarithm.
- *Base* - Optional. The base of the logarithm to calculate. By default, 10 (when not specified).

Abs(*SingleColumnTable*)
Exp(*SingleColumnTable*)
Ln(*SingleColumnTable*)
Sqrt(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Examples

Single number

Expand table

Formula	Description	Result
Abs(-55)	Returns the number without the negative sign.	55
Exp(2)	Returns *e* raised to the power of 2, or *e* * *e*.	7.389056...
Ln(100)	Returns the natural logarithm (base *e*) of the number 100.	4.605170...
Log(100)	Returns the logarithm in base 10 of the number 100.	2
Log(64, 2)	Returns the logarithm in base 2 of the number 64.	6

Formula	Description	Result
Power(5, 3)	Returns 5 raised to the power of 3, or 5 * 5 * 5.	125
Sqrt(9)	Returns the number that, when multiplied by itself, results in 9.	3

Single-column table

The examples in this section use a data source that's named **ValueTable** and that contains this data:

Expand table

Value
9
-4
2

Expand table

Formula	Description	Result
Abs(ValueTable)	Returns the absolute value of each number in the table.	A single-column table with a `Value` column containing the following values: 9, 4, 2
Exp(ValueTable)	Returns *e* raised to the power of each number in the table.	A single-column table with a `Value` column containing the following values: 8103.083927..., 0.018315..., 7.389056...
Ln(ValueTable)	Returns the natural logarithm of each number in the table.	A single-column table with a `Value` column containing the following values: 2.197224..., Blank(), 0.693147...
Sqrt(ValueTable)	Returns the square root of each number in the table	A single-column table with a `Value` column containing the following values: 3, Blank(), 1.414213...

Step-by-step example

1. Add a **Text input** control, and name it **Source**.
2. Add a **Label** control, and set its **Text** property to this formula:
   Sqrt(Value(Source.Text))

3. Type a number into **Source**, and confirm that the **Label** control shows the square root of the number that you typed.

Acceleration, App, Compass, Connection, and Location signals in Power Apps

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

Returns information about the app's environment, such as where the user is located in the world and which screen is displayed.

Description and syntax

Signals are values that can change at any time, independent of how the user may be interacting with the app. Formulas that are based on signals automatically recalculate as these values change.

Signals typically return a record of information. You can use and store this information as a record, or you can extract individual properties by using the . operator.

> **Note**
>
> The **Acceleration** and **Compass** functions return accurate values in a native player such as on iOS or Android, but those functions return zero values as you create or modify an app in the browser.

Acceleration

The **Acceleration** signal returns the device's acceleration in three dimensions relative to the device's screen. Acceleration is measured in *g* units of 9.81 m/second^2 or 32.2 ft/second^2 (the acceleration that the Earth imparts to objects at its surface due to gravity).

Expand table

Property	Description
Acceleration.X	Right and left. Right is a positive number.
Acceleration.Y	Forward and back. Forward is a positive number.

Property	Description
Acceleration.Z	Up and down. Up is a positive number.

App

Among other properties, the **App** object includes a signal that indicates which screen is showing.

Expand table

Property	Description
App.ActiveScreen	Screen that's showing. Returns a screen object, which you can use to reference properties of the screen or compare to another screen to determine which screen is showing. You can use the **Back** or **Navigate** function to change the screen that's showing.

More information: **App** object documentation.

Compass

The **Compass** signal returns the compass heading of the top of the screen. The heading is based on magnetic north.

Expand table

Property	Description
Compass.Heading	Heading in degrees. Returns a number 0 to 360, and 0 is north.

Connection

The **Connection** signal returns the information about the network connection. When on a metered connection, you may want to limit how much data you send or receive over the network. Or, if your app is enabled for offline, you may want to display different information depending on the current sync state.

Expand table

Property	Description
Connection.Connected	Returns a Boolean **true** or **false** value that indicates whether the device is connected to a network.
Connection.Metered	Returns a Boolean **true** or **false** value that indicates whether the connection is metered.
Connection.Sync	Returns an enum named **ConnectionSync** which holds the current synchronization state for an app that is enabled for offline.

Below are the enums values available for Connection.Sync.

Expand table

Enum value	Description
Connected	Your device is connected to the network and your app is ready to work offline
ConnectedWithWarning	Your device is connected with a warning.
ConnectedPendingUpsync	Some data on your device must be synchronized with the service.
ConnectedError	There was an error on the last synchronization attempt.
ConnectedRefresh	Your app is currently synchronizing data with the service.
NotConnected	Your device isn't connected to the service.
NotConnectedWithWarning	The last synchronization warning.
NotConnectedPendingUpsync	There are updates on your device waiting to be synchronized.
NotConnectedSyncError	The last synchronization error.

Location

The **Location** signal returns the location of the device based on the Global Positioning System (GPS) and other device information, such as cell-tower communications and IP address.

When a user accesses the location information for the first time, the device may prompt that user to allow access to this information.

As the location changes, dependencies on the location will continuously recalculate, which will consume power from the device's battery. To conserve battery life, you can

use the **Enable** and **Disable** functions to turn location updates on and off. Location is automatically turned off if the displayed screen doesn't depend on location information.

Expand table

Property	Description
Location.Altitude	Returns a number that indicates the altitude, measured in meters, above sea level.
Location.Latitude	Returns a number, from –90 to 90, that indicates the latitude, as measured in degrees from the equator. A positive number indicates a location that's north of the equator.
Location.Longitude	Returns a number, from –180 to 180, that indicates the longitude, as measured in degrees from Greenwich, England. A positive number indicates a location that's east of Greenwich.

Examples

In a baseball field, a pitcher throws a phone from the pitcher's mound to a catcher at home plate. The phone is lying flat with respect to the ground, the top of the screen is pointed at the catcher, and the pitcher adds no spin. At this location, the phone has cellular network service that's metered but no WiFi. The **PlayBall** screen is displayed. The app is enabled for offline and is connected to the service.

Expand table

Formula	Description	Result
Location.Latitude	Returns the latitude of the current location. The field is located at map coordinates 47.591 N, 122.333 W.	47.591 The latitude will change continuously as the ball moves between the pitcher and the catcher.
Location.Longitude	Returns the longitude of the current location.	122.333 The longitude will change continuously as the ball moves between the pitcher and the catcher.
Location	Returns the latitude and longitude of the current location, as a record.	{ Latitude: 47.591, Longitude: 122.333 }

Formula	Description	Result
Compass.Heading	Returns the compass heading of the top of the screen. At this field, home plate is roughly southwest from the pitcher's mound.	230.25
Acceleration.X	Returns the acceleration of the device side to side. The pitcher is throwing the phone straight ahead with respect to the screen's top, so the device isn't accelerating side to side.	0
Acceleration.Y	Returns the acceleration of the device front to back. The pitcher initially gives the device a large acceleration when throwing the device, going from 0 to 90 miles per hour (132 feet per second) in half a second. After the device is in the air, ignoring air friction, the device doesn't accelerate further. The device decelerates when the catcher catches it, bringing it to a stop.	8.2, while the pitcher throws the device. 0, while the device is in the air. -8.2, as the catcher catches the device.
Acceleration.Z	Returns the acceleration of the device top to bottom. While in the air, the device experiences the effects of gravity.	0, before the pitcher throws the device. 1, while the device is in the air. 0, after the catcher catches the device.
Acceleration	Returns the acceleration as a record.	{ X: 0, Y: 264, Z: 0 } as the pitcher throws the device.
Connection.Connected	Returns a Boolean value that indicates whether the device is connected to a network	**true**
Connection.Metered	Returns a Boolean value that indicates whether the connection is metered	**true**
Connection.Sync	Returns an enum value that indicates current sync state.	**ConnectionSync.Connected**
App.ActiveScreen = PlayBall	Returns a Boolean value that indicates whether **PlayBall** is	**true**

Formula	Description	Result
	displayed.	
App.ActiveScreen.Fill	Returns the background color for the displayed screen.	**Color.Green**

Acos, Acot, Asin, Atan, Atan2, Cos, Cot, Degrees, Pi, Radians, Sin, and Tan functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Calculates trigonometric values.

Description

Primary functions

The **Cos** function returns the cosine of its argument, an angle specified in radians.

The **Cot** function returns the cotangent of its argument, an angle specified in radians.

The **Sin** function returns the sine of its argument, an angle specified in radians.

The **Tan** function returns the tangent of its argument, an angle specified in radians.

Inverse functions

The **Acos** function returns the arccosine, or inverse cosine, of its argument. The arccosine is the angle whose cosine is the argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Acot** function returns the principal value of the arccotangent, or inverse cotangent, of its argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Asin** function returns the arcsine, or inverse sine, of its argument. The arcsine is the angle whose sine is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan** function returns the arctangent, or inverse tangent, of its argument. The arctangent is the angle whose tangent is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan2** function returns the arctangent, or inverse tangent, of the specified *x* and *y* coordinates as arguments. The arctangent is the angle from the *x*-axis to a line that contains the origin (0, 0) and a point with coordinates (*x*, *y*). The angle is given in radians between -π and π, excluding -π. A positive result represents a counterclockwise angle from the *x*-axis; a negative result represents a clockwise angle. **Atan2(*a*, *b*)** equals **Atan(*b*/*a*)**, except that ***a*** can equal 0 (zero) with the **Atan2** function.

Helper functions

The **Degrees** function converts radians to degrees. π radians equals 180 degrees.

The **Pi** function returns the transcendental number π, which begins 3.141592...

The **Radians** function converts degrees to radians.

Notes

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results with a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined value, the result is *blank*. This can happen, for example, when using inverse functions with arguments that are out of range.

Syntax

Primary Functions

Cos(*Radians*)
Cot(*Radians*)
Sin(*Radians*)
Tan(*Radians*)

- *Radians* - Required. Angle to operate on.

Cos(*SingleColumnTable*)
Cot(*SingleColumnTable*)
Sin(*SingleColumnTable*)
Tan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of angles to operate on.

Inverse Functions

Acos(*Number*)
Acot(*Number*)
Asin(*Number*)
Atan(*Number*)

- *Number* - Required. Number to operate on.

Acos(*SingleColumnTable*)
Acot(*SingleColumnTable*)
Asin(*SingleColumnTable*)
Atan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Atan2(*X*, *Y*)

- *X* - Required. *X*-axis coordinate.
- *Y* - Required. *Y*-axis coordinate.

Helper Functions

Degrees(*Radians*)

- *Radians* - Required. Angle in radians to convert to degrees.

Pi()

Radians(*Degrees*)

- *Degrees* - Required. Angle in degrees to convert to radians.

Examples

Single number

Expand table

Formula	Description	Result
Cos(1.047197)	Returns the cosine of 1.047197 radians or 60 degrees.	0.5
Cot(Pi()/4)	Returns the cotangent of 0.785398... radians or 45 degrees.	1
Sin(Pi()/2)	Returns the sine of 1.570796... radians or 90 degrees.	1
Tan(Radians(60))	Returns the tangent of 1.047197... radians or 60 degrees.	1.732050...
Acos(0.5)	Returns the arccosine of 0.5, in radians.	1.047197...
Acot(1)	Returns the arccotangent of 1, in radians.	0.785398...
Asin(1)	Returns the arcsine of 1, in radians.	1.570796...
Atan(1.732050)	Returns the arctangent of 1.732050, in radians.	1.047197...
Atan2(5, 3)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (5,3), which is approximately 31 degrees.	0.540419...
Atan2(4, 4)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (4,4), which is exactly π/4 radians or 45 degrees.	0.785398...
Degrees(1.047197)	Returns the equivalent number of degrees for 1.047197 radians.	60
Pi()	Returns the transcendental number π.	3.141592...
Radians(15)	Returns the equivalent number of radians for 15 degrees.	0.261799...

Calculates trigonometric values.

Description

Primary functions

The **Cos** function returns the cosine of its argument, an angle specified in radians.

The **Cot** function returns the cotangent of its argument, an angle specified in radians.

The **Sin** function returns the sine of its argument, an angle specified in radians.

The **Tan** function returns the tangent of its argument, an angle specified in radians.

Inverse functions

The **Acos** function returns the arccosine, or inverse cosine, of its argument. The arccosine is the angle whose cosine is the argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Acot** function returns the principal value of the arccotangent, or inverse cotangent, of its argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Asin** function returns the arcsine, or inverse sine, of its argument. The arcsine is the angle whose sine is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan** function returns the arctangent, or inverse tangent, of its argument. The arctangent is the angle whose tangent is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan2** function returns the arctangent, or inverse tangent, of the specified *x* and *y* coordinates as arguments. The arctangent is the angle from the *x*-axis to a line that contains the origin (0, 0) and a point with coordinates (*x*, *y*). The angle is given in radians between -π and π, excluding -π. A positive result represents a counterclockwise angle from the *x*-axis; a negative result represents a clockwise angle. **Atan2(*a*, *b*)** equals **Atan(*b*/*a*)**, except that ***a*** can equal 0 (zero) with the **Atan2** function.

Helper functions

The **Degrees** function converts radians to degrees. π radians equals 180 degrees.

The **Pi** function returns the transcendental number π, which begins 3.141592...

The **Radians** function converts degrees to radians.

Notes

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results with a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined value, the result is *blank*. This can happen, for example, when using inverse functions with arguments that are out of range.

AddColumns, DropColumns, RenameColumns, and ShowColumns functions

06/21/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions

Shapes a table or record by adding, dropping, renaming, and selecting its columns.

The ForAll function can also be used to shape a table, by returning a table of new records created from existing columns.

Overview

These functions shape a table or record by adjusting its columns:

- Reduce a table or record that contains multiple columns down to a single column for use with single-column functions, such as **Lower** or **Sqrt**.
- Add a calculated column to a table or record (for example, a **Total Price** column that shows the results of multiplying **Quantity** by **Unit Price**).
- Rename a column to something more meaningful, for display to users or for use in formulas.

A table is a value in Power Apps, just like a string or a number. You can specify a table as an argument in a formula, and functions can return a table as a result.

> **Note**
>
> The functions that this topic describes don't modify the original table. Instead, they take that table as an argument and return a new table with a transform applied. For more information, see working with tables.

You can't modify the columns of a data source by using these functions. You must modify the data at its source. You can add columns to a collection with the **Collect** function. For more information, see working with data sources.

Description

The **AddColumns** function adds a column to a table or record, and a formula defines the values in that column. Existing columns remain unmodified.

The formula is evaluated for the provided record, or for each record of the provided table.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

The **DropColumns** function excludes columns from a table or record. All other columns remain unmodified. **DropColumns** excludes columns, and **ShowColumns** includes columns.

Use the **RenameColumns** function to rename one or more columns of a table or record by providing at least one argument pair that specifies the name of a column that the table or record contains (the old name, which you want to replace) and the name of a column that the table or record doesn't contain (the new name, which you want to use). The old name must already exist in the table or record, and the new name must not exist. Each column name may appear only once in the argument list as either an old column name or a new column name. To rename a column to an existing column name, first drop the existing column with **DropColumns**, or rename the existing column out of the way by nesting one **RenameColumns** function within another.

The **ShowColumns** function includes columns of a table or record and drops all other columns. You can use **ShowColumns** to create a single-column table or record from a multi-column table or record. **ShowColumns** includes columns, and **DropColumns** excludes columns.

For all these functions, the result is a new table or record with the transform applied. The original table or record isn't modified. You can't modify an existing table or record with a formula. SharePoint, Microsoft Dataverse, SQL Server, and other data sources provide tools for modifying the columns of lists and tables, which are often referred to as the schema. The functions in this topic only transform an input table or record, without modifying the original, into an output table or record for further use.

The arguments to these functions support delegation. For example, a **Filter** function used as an argument to pull in related records searches through all listings, even if the '**[dbo].[AllListings]**' data source contains a million rows:

Power Fx

```
AddColumns( RealEstateAgents,
   Listings,
```

```
    Filter(  '[dbo].[AllListings]', ListingAgentName = AgentName )
)
```

However, the output of these functions is subject to the non-delegation record limit. In this example, only 500 records are returned even if the **RealEstateAgents** data source has 501 or more records.

If you use **AddColumns** in this manner, **Filter** must make separate calls to the data source for each of those first records in **RealEstateAgents**, which causes lots of network chatter. If **[dbo](.[AllListings]** is small enough and doesn't change often. You can call the **Collect** function in OnStart to cache the data source in your app when it starts. As an alternative, you could restructure your app so that you pull in the related records only when the user asks for them.

> **Note**
>
> In Power Apps prior to version 3.24042, column names were specified with a text string using double quotes, and if connected to a data source they also needed to be logical names. For example, the logical name **"cr43e_name"** with double quotes was used instead of the display name **Name** without quotes. For SharePoint and Excel data sources that contain column names with spaces, each space was specified with **"_x0020_"**, for example **"Column Name"** as **"Column_x0020_Name"**. After this version, all apps were automatically updated to the new syntax described in this article.

Syntax

AddColumns(*TableOrRecord*, *ColumnName1*, *Formula1* [, *ColumnName2*, *Formula2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.
- *ColumnName(s)* - Required. Names of the columns to add.
- *Formula(s)* - Required. Formulas to evaluate for each record. The result is added as the value of the corresponding new column. You can reference other columns of the table or record in this formula.

DropColumns(*TableOrRecord*, *ColumnName1* [, *ColumnName2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.
- *ColumnName(s)* - Required. Names of the columns to drop.

RenameColumns(*TableOrRecord*, *OldColumnName1*, *NewColumnName1* [, *OldColumnName2*, *NewColumnName2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.

- *OldColumnName(s)* - Required. Names of the columns to rename from the original table or record. This element appears first in the argument pair (or first in each argument pair if the formula includes more than one pair).
- *NewColumnName(s)* - Required. Replacement names. This element appears last in the argument pair (or last in each argument pair if the formula includes more than one pair).

ShowColumns(*TableOrRecord*, *ColumnName1* [, *ColumnName2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.
- *ColumnName(s)* - Required. Names of the columns to include.

Examples

The examples in this section use the **IceCreamSales** data source, which contains the data in this table:

Flavor	UnitPrice	QuantitySold
"Strawberry"	1.99	20
"Chocolate"	2.99	45
"Vanilla"	1.50	35

None of these examples modify the **IceCreamSales** data source. Each function transforms the value of the data source as a table and returns that value as the result.

Expand table

Formula	Description	Result
AddColumns(IceCreamSales, Revenue, UnitPrice * QuantitySold)	Adds a **Revenue** column to the result. For each record, **UnitPrice * QuantitySold** is evaluated, and the result is placed in the new column.	
DropColumns(IceCreamSales, UnitPrice)	Excludes the **UnitPrice** column from the result. Use this function to exclude columns, and use **ShowColumns** to include them.	ShowColumns(IceCreamSales, Flavor)	Includes only the **Flavor** column in the result. Use this function include columns, and use **DropColumns** to exclude them.	
RenameColumns(IceCreamSales, UnitPrice, Price)	Renames the **UnitPrice** column in the result.	

Formula	Description	Result
RenameColumns(IceCreamSales, UnitPrice, Price, QuantitySold, Number)	Renames the **UnitPrice** and **QuantitySold** columns in the result.	<table><tr><th>Flavor</th><th>Price</th><th>Number</th></tr><tr><td>"Strawberry"</td><td>1.99</td><td>20</td></tr><tr><td>"Chocolate"</td><td>2.99</td><td>45</td></tr><tr><td>"Vanilla"</td><td>1.50</td><td>35</td></tr></table>
DropColumns(RenameColumns(AddColumns(IceCreamSales, Revenue, UnitPrice * QuantitySold), UnitPrice, Price), Quantity)	Performs the following table transforms in order, starting from the inside of the formula: 1. Adds a **Revenue** column based on the per record calculation of **UnitPrice * Quantity**. 2. Renames **UnitPrice** to **Price**. 3. Excludes the **Quantity** column. Order is important, for example we can't calculate with **UnitPrice** after it's renamed.	<table><tr><th>Flavor</th><th>Price</th><th>Revenue</th></tr><tr><td>"Strawberry"</td><td>1.99</td><td>39.80</td></tr><tr><td>"Chocolate"</td><td>2.99</td><td>134.55</td></tr><tr><td>"Vanilla"</td><td>1.49</td><td>52.15</td></tr></table>

Step by step

Let's try some of the examples from earlier in this article.

1. Create a collection by adding a **Button** control and setting its **OnSelect** property to this formula:

   Power Fx

   ```
   ClearCollect( IceCreamSales,
      Table(
          { Flavor: "Strawberry", UnitPrice: 1.99, QuantitySold: 20 },
          { Flavor: "Chocolate", UnitPrice: 2.99, QuantitySold: 45 },
          { Flavor: "Vanilla", UnitPrice: 1.50, QuantitySold: 35 }
      )
   )
   ```

2. Run the formula by selecting the button while holding down the Alt key.

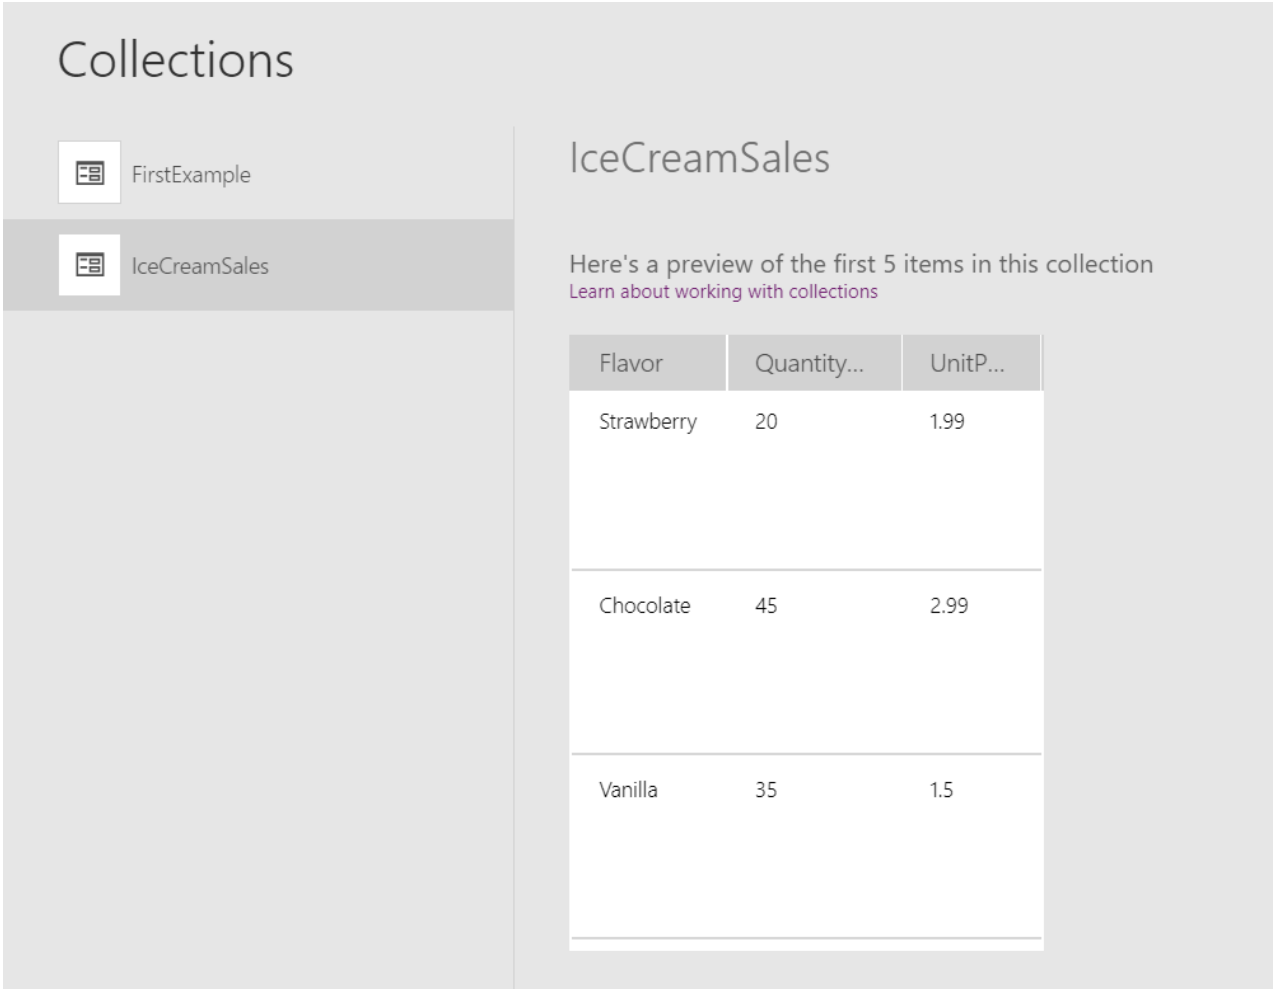
3. Add a second **Button** control, set its **OnSelect** property to this formula, and then run it:

   Power Fx

   ```
   ClearCollect( FirstExample,
      AddColumns( IceCreamSales, Revenue, UnitPrice * QuantitySold )
   )
   ```

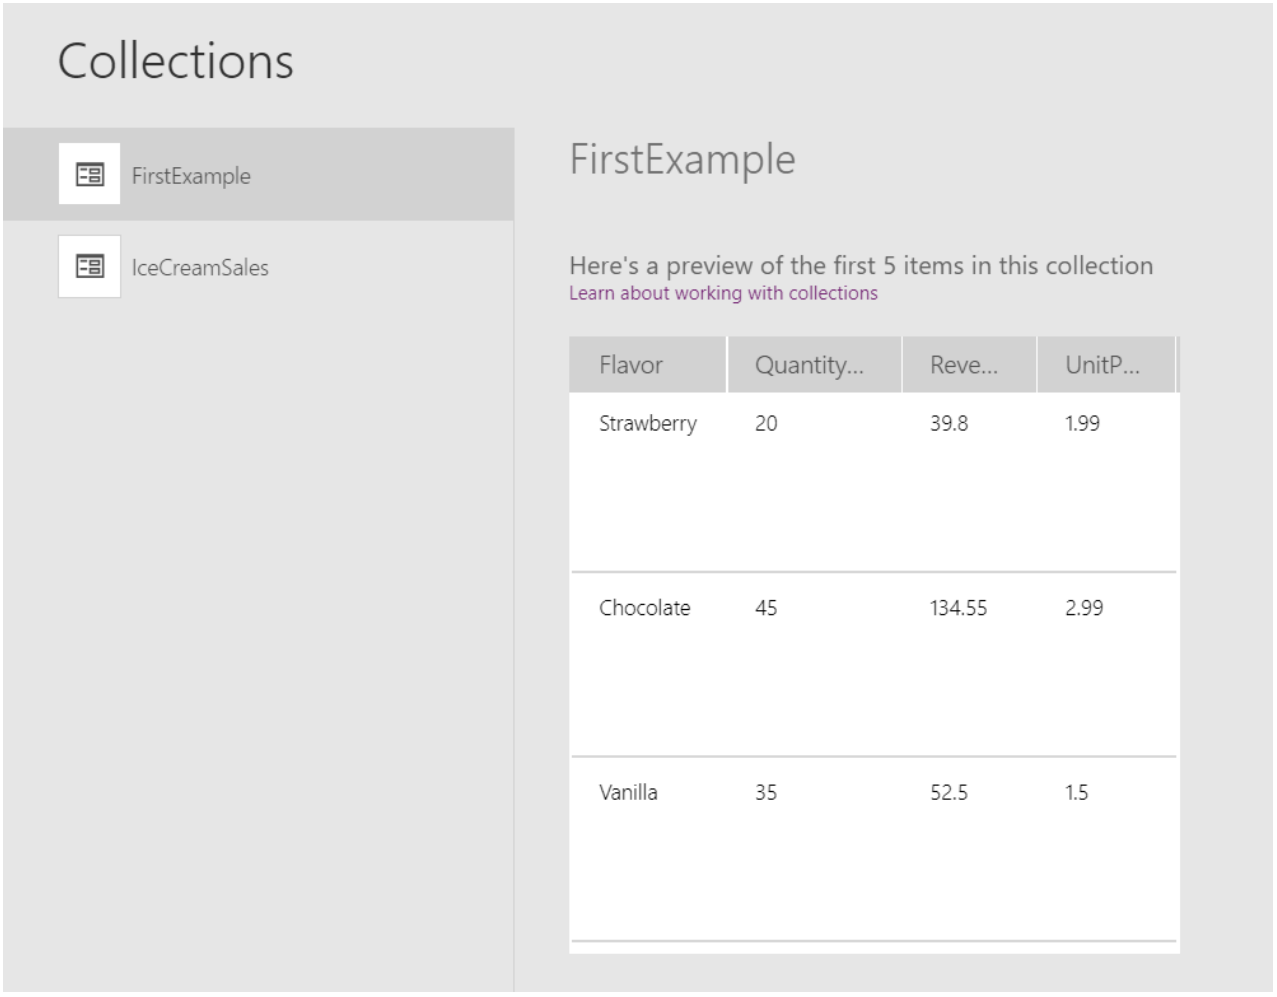
4. On the **File** menu, select **Collections**, and then select **IceCreamSales** to show that collection.

As this graphic shows, the second formula didn't modify this collection. The **AddColumns** function used **IceCreamSales** as a read-only argument; the function didn't modify the table to which that argument refers.



5. Select **FirstExample**.

   As this graphic shows, the second formula returned a new table with the added column. The **ClearCollect** function captured the new table in the **FirstExample** collection, adding something to the original table as it flowed through the function without modifying the source:



Map columns in a component

See Map columns.

And, Or, and Not functions

Article • 06/10/2024

Applies to: Canvas apps Dataverse formula columns Desktop flows Model-driven apps Power Pages Power Platform CLI

Boolean logic functions, commonly used to manipulate the results of comparisons and tests.

Description

The **And** function returns **true** if all of its arguments are **true**.

The **Or** function returns **true** if any of its arguments are **true**.

The **Not** function returns **true** if its argument is **false**; it returns **false** if its argument is **true**.

These functions work the same way as they do in Excel. You can also use operators to perform these same operations, using either Visual Basic or JavaScript syntax:

Expand table

Function notation	Visual Basic operator notation	JavaScript operator notation
And(x, y)	x And y	x && y
Or(x, y)	x Or y	x || y
Not(x)	Not x	! x

These functions work with logical values. You can't pass them a number or a string directly; instead, you must make a comparison or a test. For example, this logical formula **x** > **1** evaluates to the Boolean value **true** if **x** is greater than **1**. If **x** is less than **1**, the formula evaluates to **false**.

Syntax

And(*LogicalFormula1*, *LogicalFormula2* [, *LogicalFormula3*, ...])
Or(*LogicalFormula1*, *LogicalFormula2* [, *LogicalFormula3*, ...])
Not(*LogicalFormula*)

- *LogicalFormula(s)* - Required. Logical formulas to evaluate and operate on.

Examples

The examples in this section use these global variables:

- **a** = *false*
- **b** = *true*
- **x** = 10
- **y** = 100
- **s** = "Hello World"

To create these global variables in an app, insert a **Button** control, and set its **OnSelect** property to this formula:

Power Apps

```
Set( a, false ); Set( b, true ); Set( x, 10 ); Set( y, 100 ); Set( s, "Hello World" )
```

Select the button (by clicking it while you hold down the Alt key), and then set the **Text** property of a **Label** control to a formula in the first column of the next table.

Expand table

Formula	Description	Result
And(a, b)	Tests the values of **a** and **b**. One of the arguments is *false*, so the function returns *false*.	*false*
a And b	Same as the previous example, using Visual Basic notation.	*false*
a && b	Same as the previous example, using JavaScript notation.	*false*
Or(a, b)	Tests the values of **a** and **b**. One of the arguments is *true*, so the function returns *true*.	*true*
a Or b	Same as the previous example, using Visual Basic notation.	*true*
a || b	Same as the previous example, using JavaScript notation.	*true*
Not(a)	Tests the value of **a**. The argument is *false*, so the function returns the opposite result.	*true*
Not a	Same as the previous example, using Visual Basic notation.	*true*
! a	Same as the previous example, using JavaScript notation.	*true*
Len(s) < 20 And Not IsBlank(s)	Tests whether the length of **s** is less than 20 and whether it isn't a **blank** value. The length is less than 20, and the value	*true*

Formula	Description	Result
	isn't blank. Therefore, the result is *true*.	
Or(Len(s) < 10, x < 100, y < 100)	Tests whether the length of **s** is less than 10, whether **x** is less than 100, and whether **y** is less than 100. The first and third arguments are false, but the second one is true. Therefore, the function returns *true*.	*true*
Not IsBlank(s)	Tests whether **s** is *blank*, which returns *false*. **Not** returns the opposite of this result, which is *true*.	*true*

App object in Power Apps

06/19/2025

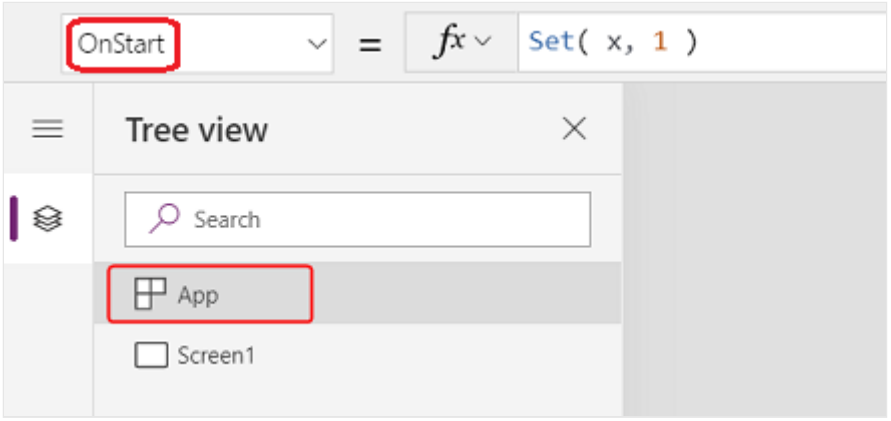
Applies to: Canvas apps

Get information about the currently running app and control the app's behavior.

Description

Like a control, the **App** object has properties that identify which screen is showing and prompt you to save changes so they aren't lost. Every app has an **App** object.

Write formulas for some properties of the **App** object. At the top of the **Tree view** pane, select the **App** object as you would any other control or screen. To view or edit one of the object's properties, select it in the drop-down list to the left of the formula bar.



ActiveScreen property

The **ActiveScreen** property identifies the screen that's currently displayed.

This property returns a screen object. Use it to reference properties of the current screen, like the name with the formula **App.ActiveScreen.Name**. You can also compare this property to another screen object, like with the comparison formula **App.ActiveScreen** = **Screen2** to check if **Screen2** is the current screen.

Use the Back or Navigate function to switch the screen that's displayed.

BackEnabled property

The **BackEnabled** property changes how the app responds to the device back gesture (swipe or use the hardware back button on Android devices, or swipe from the left on iOS devices) when

running in Power Apps mobile. When enabled, the device back gesture goes back to the screen that was most recently shown, which is similar to the **Back** formula. When disabled, the device back gesture takes the user to the app list.

ConfirmExit properties

Nobody wants to lose unsaved changes. Use the **ConfirmExit** and **ConfirmExitMessage** properties to warn the user before closing your app.

> ⓘ **Note**
>
> - **ConfirmExit** doesn't work in apps embedded in, for example, Power BI and SharePoint.
> - **ConfirmExit** isn't supported in custom pages.
> - Now, these properties can reference controls only on the first screen if the **Delayed load** preview feature is enabled (which it is by default for new apps). If you reference other screens, Power Apps Studio doesn't show an error, but the published app doesn't open in Power Apps Mobile or a browser. We're working to lift this limitation. In the meantime, turn off **Delayed load** in **Settings** > **Upcoming features** (under **Preview**).

ConfirmExit

ConfirmExit is a Boolean property that, when *true*, opens a confirmation dialog box before the app closes. By default, this property is *false*, and no dialog box appears.

When the user might have unsaved changes in the app, use this property to show a confirmation dialog box before exiting the app. Use a formula that checks variables and control properties (for example, the **Unsaved** property of the Edit form control).

The confirmation dialog box appears in any situation where data can be lost, such as:

- Run the Exit function.
- If the app runs in a browser:
  - Close the browser or the browser tab where the app runs.
  - Select the browser's back button.
  - Run the Launch function with a *LaunchTarget* of **Self**.
- If the app runs in Power Apps Mobile (iOS or Android):
  - Swipe to switch to a different app in Power Apps Mobile.
  - Select the back button on an Android device.

- Run the **Launch** function to launch another canvas app.

The exact look of the confirmation dialog box can vary across devices and versions of Power Apps.

The confirmation dialog box doesn't show in Power Apps Studio.

ConfirmExitMessage

By default, the confirmation dialog box shows a generic message, such as **"You may have unsaved changes."** in the user's language.

Use **ConfirmExitMessage** to provide a custom message in the confirmation dialog box. If this property is *blank*, the default value is used. Custom messages are truncated as needed to fit within the confirmation dialog box, so keep the message to a few lines at most.

In a browser, the confirmation dialog box can show a generic message from the browser.

> **Note**
>
> The App object has two more properties, `OnMessage` and `BackEnabled`, that are experimental. These properties are removed from the app object eventually. Don't use these properties in your production environment.

Example

1. Set the **App** object's **ConfirmExit** property to this expression:

   ```
   Power Fx

   AccountForm.Unsaved Or ContactForm.Unsaved
   ```

   The dialog box shows if the user changes data in either form and then tries to close the app without saving those changes.e user changes data in either form and then tries to close the app without saving those changes.

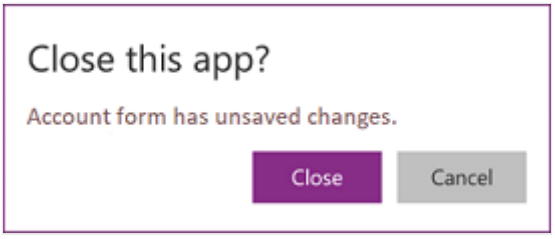
   > [!div clas1. Set the **App** object's **ConfirmExitMessage** property to this formula:

   ```
   Power Fx

   If( AccountsForm.Unsaved,
       "Accounts form has unsaved changes.",
   ```

```
    "Contacts form has unsaved changes."
)
```

The dialog box shows if the user changes data in the Account form and then tries to close the app without saving those changes.



Set up connection string for Application Insights

To export system-generated application logs to Application Insights, set up the **Connection string** for your canvas app.

1. Open your app for editing in Power Apps Studio.
2. Select the **App** object in the left navigation tree view.
3. Enter the **Connection string** in the properties pane.

If data isn't sent to Application Insights, contact your Power Platform admin and check if **App Insights** is disabled at the tenant level.

Formulas property

Use named formulas, in the **Formulas** property, to define a formula that can be reused throughout your app.

In Power Apps, formulas determine the value of control properties. For example, to set the background color consistently across an app, you might set the **Fill** property for each to a common formula:

Power Fx

```
Label1.Fill: ColorValue( Param( "BackgroundColor" ) )
Label2.Fill: ColorValue( Param( "BackgroundColor" ) )
Label3.Fill: ColorValue( Param( "BackgroundColor" ) )
```

With so many places where this formula may appear, it becomes tedious and error prone to update them all if a change is needed. Instead, you can create a global variable in **OnStart** to set the color once, and then reuse the value throughout the app:

Power Fx

```
App.OnStart: Set( BGColor, ColorValue( Param( "BackgroundColor" ) ) )
Label1.Fill: BGColor
Label2.Fill: BGColor
Label3.Fill: BGColor
```

While this method is better, it also depends on **OnStart** running before the value for **BGColor** is established. **BGColor** might also be manipulated in some corner of the app that the maker is unaware of, a change made by someone else, and that can be hard to track down.

Named formulas provide an alternative. Just as we commonly write *control-property* = *expression*, we can instead write *name* = *expression* and then reuse *name* throughout our app to replace *expression*. The definitions of these formulas are done in the **Formulas** property:

Power Fx

```
App.Formulas: BGColor = ColorValue( Param( "BackgroundColor" ) );
Label1.Fill: BGColor
Label2.Fill: BGColor
Label3.Fill: BGColor
```

The advantages of using named formulas include:

- **The formula's value is always available.** There's no timing dependency, no **OnStart** that must run first before the value is set, no time in which the formula's value is incorrect. Named formulas can refer to each other in any order, so long as they don't create a circular reference. They can be calculated in parallel.
- **The formula's value is always up to date.** The formula can perform a calculation that is dependent on control properties or database records, and as they change, the formula's value automatically updates. You don't need to manually update the value as you do with a variable. And formulas only recalculate when needed.
- **The formula's definition is immutable.** The definition in **Formulas** is the single source of truth and the value can't be changed somewhere else in the app. With variables, it's possible that some code unexpectedly changes a value, but this difficult to debug situation isn't possible with named formulas.
- **The formula's calculation can be deferred.** Because its value is immutable, it can always be calculated when needed, which means it need not be calculated until it's needed. Formula values that aren't used until **screen2** of an app is displayed need not be calculated until **screen2** is visible. Deferring this work can improve app load time. Named formulas are declarative and provide opportunities for the system to optimize how and when they're computed.

- **Named formulas is an Excel concept.** Power Fx uses Excel concepts where possible since so many people know Excel well. Named formulas are the equivalent of named cells and named formulas in Excel, managed with the Name Manager. They recalculate automatically like cells of a spreadsheet and control properties do.

Named formulas are defined, one after another in the **Formulas** property, each ending with a semi-colon. The type of the formula is inferred from the types of the elements within the formula and how they're used together. For example, these named formulas retrieve useful information about the current user from Dataverse:

Power Fx

```
UserEmail = User().Email;
UserInfo = LookUp( Users, 'Primary Email' = User().Email );
UserTitle = UserInfo.Title;
UserPhone = Switch( UserInfo.'Preferred Phone',
                    'Preferred Phone (Users)'.'Mobile Phone', UserInfo.'Mobile
Phone',
                    UserInfo.'Main Phone' );
```

If the formula for **UserTitle** needs to be updated, it can be done easily in this one location. If **UserPhone** isn't needed in the app, then these calls to the **Users** table in Dataverse aren't made. There's no penalty for including a formula definition that isn't used.

Some limitations of named formulas:

- They can't use behavior functions or otherwise cause side effects within the app.
- They can't create a circular reference. Having **a = b;** and **b = a;** in the same app isn't allowed.

User defined functions

> **Important**
>
> - User defined functions are a preview feature.
> - Preview features aren't meant for production use and may not be complete. These features are available before an official release so that you can get early access and provide feedback. More information: Understand experimental, preview, and retired features in canvas apps
> - The behavior that this article describes is available only when the **User-defined functions** preview feature in Settings > Upcoming features > Experimental is turned on (it's off by default).

- Your feedback is valuable to us. Let us know what you think in the Power Apps experimental features community forum.

Power Fx includes a long list of built-in functions, such as **If**, **Text**, and **Set**. User defined functions enable you to write your own functions that take parameters and return a value, just as the built-in functions do. You can think of user defined functions as an extension to named formulas that adds parameters and supports behavior formulas.

For example, you might define a named formula that returns fiction books from a library:

Power Apps

```
Library = [ { Title: "The Hobbit", Author: "J. R. R. Tolkien", Genre: "Fiction" },
            { Title: "Oxford English Dictionary", Author: "Oxford University",
Genre: "Reference" } ];

LibraryFiction = Filter( Library, Genre = "Fiction" );
```

Without parameters, we would need to define separate named formulas for each genre. But instead, let's parameterize our named formula:

Power Apps

```
LibraryType := Type( [ { Title: Text, Author: Text, Genre: Text } ] );

LibraryGenre( SelectedGenre: Text ): LibraryType = Filter( Library, Genre =
SelectedGenre );
```

Now we can call `LibraryGenre( "Fiction" )`, `LibraryGenre( "Reference" )`, or filter on other genres with a single user defined function.

The syntax is:

FunctionName([*ParameterName1*: *ParameterType1* [, *ParameterName2*: *ParameterType2* ...]]) : *ReturnType* = *Formula*;

- *FunctionName* – Required. The name of the user defined function.
- *ParameterName(s)* – Optional. The name of a function parameter.
- *ParameterType(s)* – Optional. The name of a type, either a built-in data type name, a data source name, or a type defined with the **Type** function.
- *ReturnType* – Required. The type of the return value from the function.
- *Formula* – Required. The formula that calculates the value of the function based on the parameters.

Each parameter and the output from the user define function must be typed. In this example, `SelectedGenre: Text` defines the first parameter to our function to be of type **Text** and `SelectedGenre` is the name of the parameter that is used in the body for the **Filter** operation. See **Data types** for the supported type names. The **Type** function is used to create an aggregate type for our library, so that we can return a table of books from our function.

We defined `LibraryType` as a plural table of records type. If we want to pass a single book to a function, we can extract the type of the record for this table with the **RecordOf** function:

Power Apps

```
BookType := Type( RecordOf( LibraryType ) );

IsGenre( Book: BookType, SelectedGenre: Text ): Boolean = (Book.Genre =
SelectedGenre);
```

Record matching for function parameters is tighter than it is in other parts of Power Fx. The fields of a record value must be a proper subset of the type definition and can't include additional fields. For example, `IsGenre( { Title: "My Book", Published: 2001 }, "Fiction" )` will result in an error.

Note, recursion isn't yet supported by user defined functions.

Behavior user defined functions

Named formulas and most user defined functions don't support behavior functions with side effects, such as **Set** or **Notify**. In general, it's best to avoid updating state if you can, instead relying on functional programming patterns and allowing Power Fx to recalculate formulas as needed automatically. But, there are cases where it's unavoidable. To include behavior logic in a user defined function, wrap the body in curly braces:

Power Apps

```
Spend( Amount: Number ) : Void = {
    If( Amount > Savings,
        Error( $"{Amount} is more than available savings" ),
        Set( Savings, Savings - Amount );
        Set( Spent, Spent + Amount)
    );
}
```

Now we can call `Spend( 12 )` to check if we have 12 in our Savings, and if so, to debit it by 12 and add 12 to the Spent variable. The return type of this function is **Void** as it doesn't return a value.

The syntax of a behavior user defined function is:

FunctionName([*ParameterName1*: *ParameterType1* [, *ParameterName2*: *ParameterType2* ...]]) : *ReturnType* = { *Formula1* [; *Formula2* ...] };

- *FunctionName* – Required. The name of the user defined function.
- *ParameterName(s)* – Optional. The name of a function parameter.
- *ParameterType(s)* – Optional. The name of a type, either a built-in data type name, a data source name, or a type defined with the **Type** function.
- *ReturnType* – Required. The type of the return value from the function. Use **Void** if the function doesn't return a value.
- *Formula(s)* – Required. The formula that calculates the value of the function based on the parameters.

As with all Power Fx formulas, execution doesn't end when an error is encountered. After the **Error** function has been called, the **If** function prevents the changes to **Savings** and **Spent** from happening. The **IfError** function can also be used to prevent further execution after an error. Even though it returns **Void**, the formula can still return an error if there's a problem.

User defined types

> **Important**
>
> - User defined types is an experimental feature.
> - Experimental features aren't meant for production use and may not be complete. These features are available before an official release so that you can get early access and provide feedback. More information: Understand experimental, preview, and retired features in canvas apps
> - The behavior that this article describes is available only when the **User-defined types** experimental feature in Settings > Upcoming features > Experimental is turned on (it's off by default).
> - Your feedback is valuable to us. Let us know what you think in the Power Apps experimental features community forum.

Named formulas can be used with the **Type** function to create user defined types. Use `:=` instead of `=` to define a user defined type, for example `Book := Type( { Title: Text, Author: Text } )`. See the **Type** function for more information and examples.

OnError property

Use **OnError** to take action when an error happens anywhere in the app. It provides a global opportunity to intercept an error banner before being displayed to the end user. It can also be used to log an error with the **Trace** function or write to a database or web service.

In Canvas apps, the result of every formula evaluation is checked for an error. If an error is encountered, **OnError** is evaluated with the same **FirstError** and **AllErrors** scope variables that would have been used if the entire formula had been wrapped in an **IfError** function.

If **OnError** is empty, a default error banner shows the **FirstError.Message** of the error. Defining an **OnError** formula overrides this behavior, so the maker can handle error reporting as needed. You can request the default behavior in **OnError** by rethrowing the error with the **Error** function. Use the rethrowing approach if you want to filter out or handle some errors differently, but let others pass through.

OnError can't replace an error in calculations the way that **IfError** can. If **OnError** is invoked, the error has already happened and it has already been processed through formula calculations like **IfError**; **OnError** controls error reporting only.

OnError formulas are evaluated concurrently and it's possible that their evaluation might overlap with the processing of other errors. For example, if you set a global variable at the top of an **OnError** and read it later on in the same formula, the value might have changed. Use the **With** function to create a named value that is local to the formula.

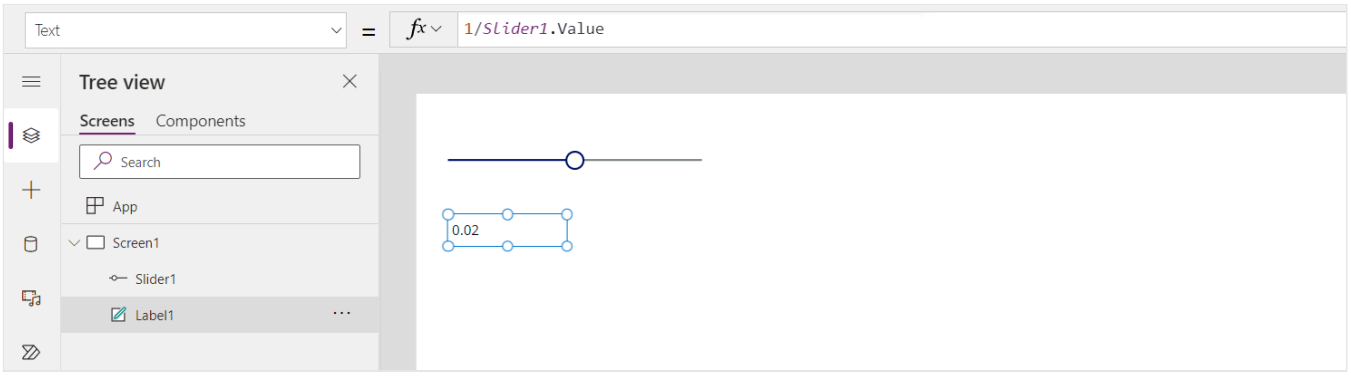
Although each error is processed individually by **OnError**, the default error banner might not appear for each error individually. To avoid having too many error banners displayed at the same time, the same error banner won't be displayed again if it has recently been shown.

Example

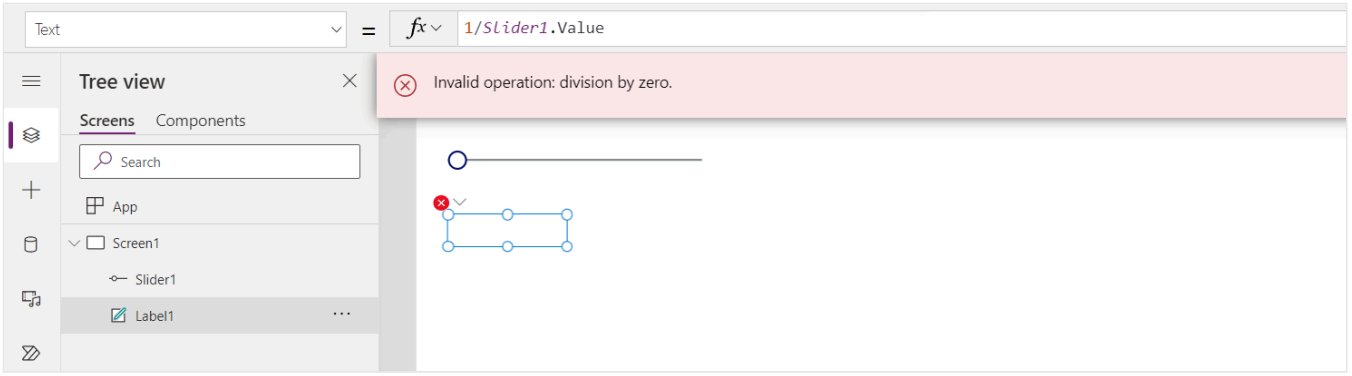
Consider a **Label** control and **Slider** control that are bound together through the formula:

Power Fx

```
Label1.Text = 1/Slider1.Value
```



The slider defaults to 50. If the slider is moved to 0, **Label1** will show no value, and an error banner is shown:



Let's look at what happened in detail:

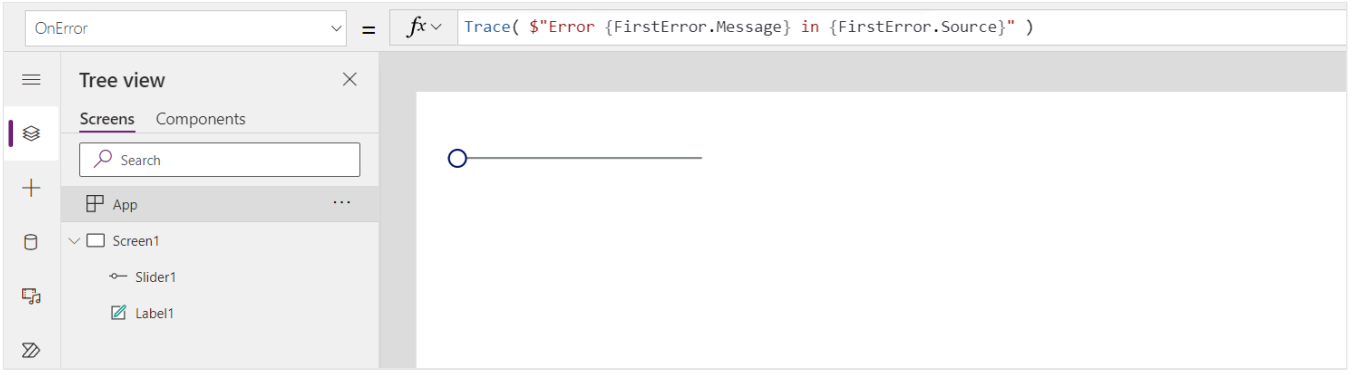
1. User moved the slide to the left and the **Slide1.Value** property changed to 0.
2. **Label1.Text** was automatically reevaluated. Division by zero occurred, generating an error.
3. There's no **IfError** in this formula. The division by zero error is returned by the formula evaluation.
4. **Label1.Text** can't show anything for this error, so it shows a *blank* state.
5. **OnError** is invoked. Since there's no handler, the standard error banner is displayed with error information.

If needed, you can also change the formula to `Label1.Text = IfError( 1/Slider1.Value, 0 )`. Using **IfError** means there's no error or error banner. You can't change the value of an error from **OnError** because the error already happened—**OnError** only controls how it's reported.

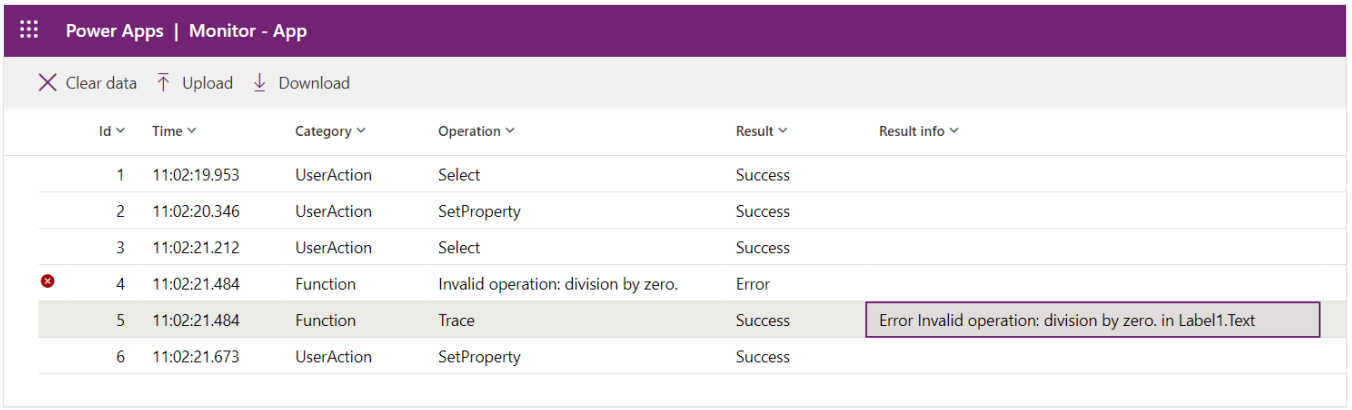
If you add an **OnError** handler, it doesn't affect steps before step 5, but it does change how the error is reported:

Power Fx

```
Trace( $"Error {FirstError.Message} in {FirstError.Source}" )
```



With this **OnError** handler, the app user doesn't see any error. But the error is added to the Monitor's trace, including the source of the error information from **FirstError**:



If you also want to show the default error banner along with the trace, rethrow the error with the **Error** function after the **Trace** call, as if the **Trace** wasn't there:

Power Fx

```
Trace( $"Error {FirstError.Message} in {FirstError.Source}" );
Error( FirstError )
```

OnStart property

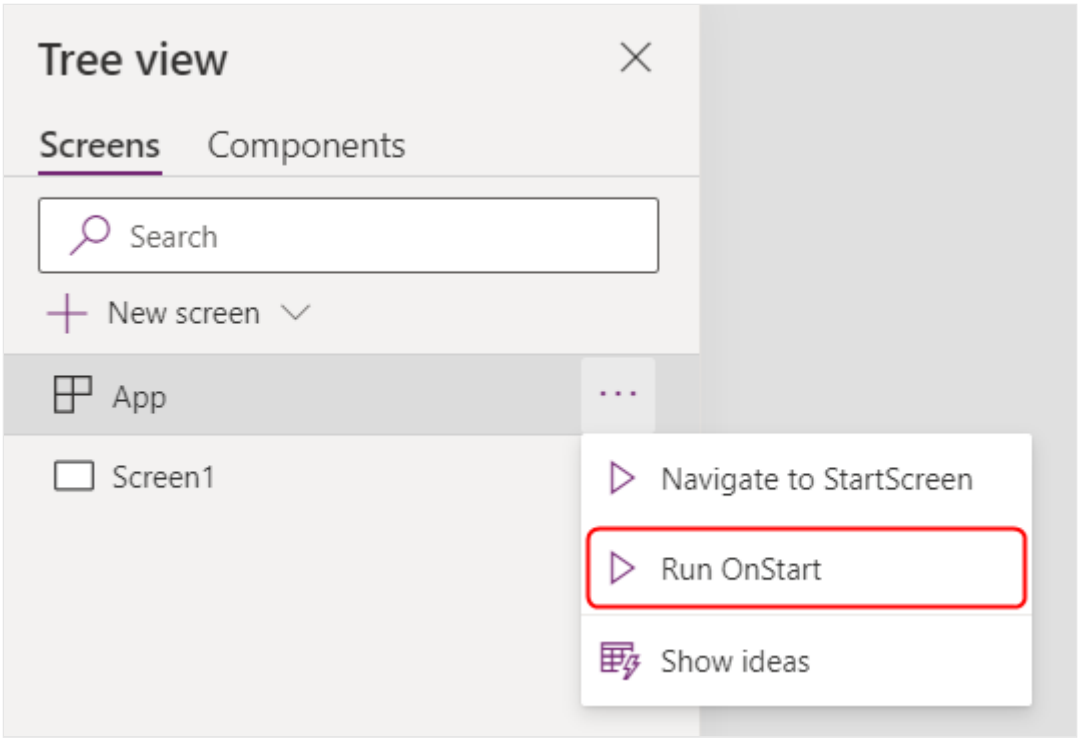
> **Note**
>
> Using the **OnStart** property can cause performance problems when loading an app. We're creating alternatives for the top two reasons to use this property—caching data and setting up global variables. There's already an alternative for defining the first screen to show with Navigate. Depending on your context, this property can be disabled by default. If you don't see it and need to use it, check the app's Advanced settings for a switch to enable it. You can also use the **OnVisible** property of a screen. By default, when the nonblocking **OnStart** rule is enabled, it lets the **OnStart** function run at the same time as other app rules. So, if variables referenced in other app rules are initialized within the **OnStart** function, they might not be fully initialized yet. Also, a screen can render and become interactive before either the **Screen.OnVisible** or **App.OnStart** functions finish running, especially if they take a long time to finish.

The **OnStart** property runs when the user starts the app. This property is often used to:

- Retrieve and cache data in collections by using the Collect function.
- Set up global variables by using the Set function.

This formula runs before the first screen appears. No screen is loaded, so you can't set context variables with the UpdateContext function. But you can pass context variables with the **Navigate** function.

After you change the **OnStart** property, test it by hovering over the **App** object in the **Tree view** pane, selecting the ellipsis (...), and then selecting **Run OnStart**. Unlike when the app loads for the first time, existing collections and variables are already set. To start with empty collections, use the ClearCollect function instead of the **Collect** function.



> **Note**
>
> - Using the Navigate function in the **OnStart** property is retired. Existing apps still work. For a limited time, you can enable it in the app settings (under **Retired**). But using **Navigate** this way can cause app load delays because it forces the system to finish running **OnStart** before showing the first screen. Use the **StartScreen** property instead to set the first screen displayed.
> - The retired switch is off for apps created before March 2021 where you added **Navigate** to **OnStart** between March 2021 and now. When you edit these apps in Power Apps Studio, you can see an error. Turn the retired switch on to clear this error.

StartScreen property

The **StartScreen** property sets which screen shows first. It's evaluated once when the app loads and returns the screen object to show. By default, this property is empty, and the first screen in the Studio Tree view shows first.

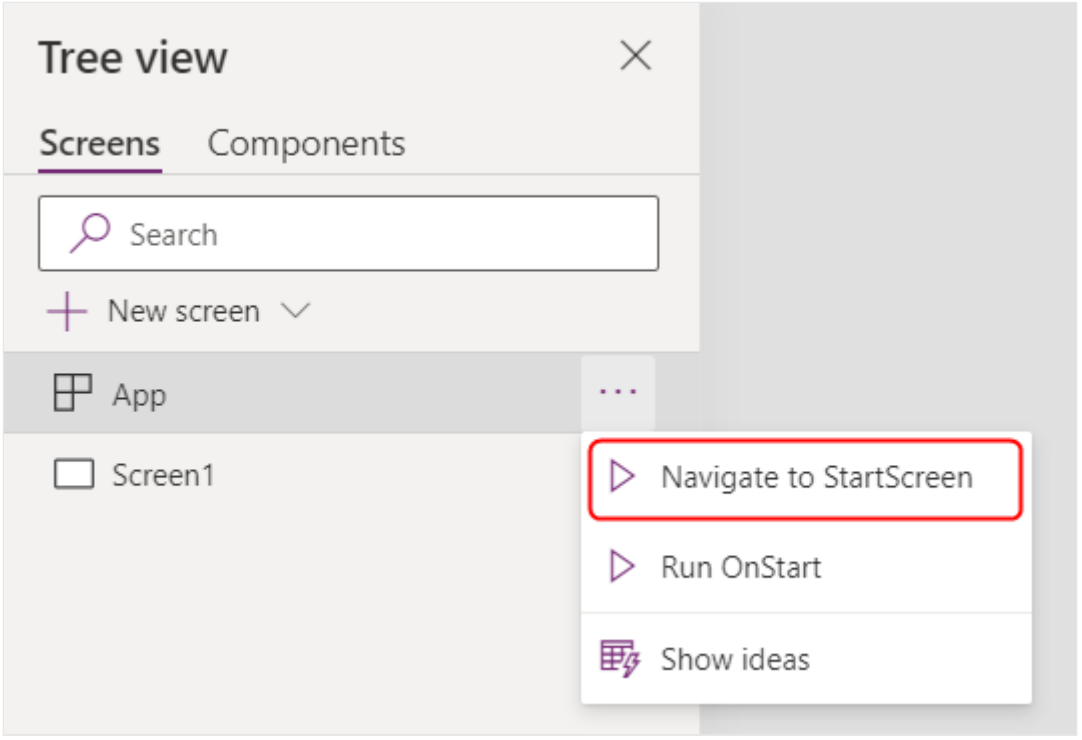
StartScreen is a data flow property that can't contain behavior functions. All data flow functions are available. Use these functions and signals to decide which screen to show first:

- Param function to read parameters used to start the app.
- User function to read information about the current user.
- LookUp, Filter, CountRows, Max, and other functions that read from a data source.
- API calls through a connector. Make sure the call returns quickly.
- Signals such as Connection, Compass, and **App**.

> **Note**
>
> Global variables and collections, including those created in **OnStart**, aren't available in **StartScreen**. Named formulas are available and are often a better alternative for formula reuse across the app.

If **StartScreen** returns an error, the first screen in the Studio Tree view shows as if **StartScreen** isn't set. Use the **IfError** function to catch any errors and redirect to an error screen.

After you change **StartScreen** in Studio, test it by hovering over the **App** object in the **Tree view** pane, selecting the ellipsis (...), and then selecting **Navigate to StartScreen**. The screen changes as if the app just loaded.



Examples

Power Fx

```
Screen9
```

`Screen9` shows first whenever the app starts.

Power Fx

```
If( Param( "admin-mode" ) = 1, HomeScreen, AdminScreen )
```

Checks if the Param "admin-mode" is set and uses it to decide if HomeScreen or AdminScreen shows first.

Power Fx

```
If( LookUp( Attendees, User = User().Email ).Staff, StaffPortal, HomeScreen )
```

Checks if an attendee is a staff member and directs them to the correct screen on startup.

Power Fx

```
IfError( If( CustomConnector.APICall() = "Forest",
             ForestScreen,
             OceanScreen
         ),
         ErrorScreen
)
```

Directs the app based on an API call to either `ForestScreen` or `OceanScreen`. If the API fails, the app uses `ErrorScreen` instead.

StudioVersion property

Use the **StudioVersion** property to show or log the version of Power Apps Studio used to publish an app. This property helps when you're debugging and checking that your app is republished with a recent version of Power Apps Studio.

StudioVersion returns text. The format of this text can change over time, so treat it as a whole and don't extract individual parts.

Operators and Identifiers in Power Apps

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Some of these operators are dependent on the language of the author. For more information about language support in canvas apps, see Global apps.

Expand table

Symbol	Type	Example	Description
'...'	Identifier	**'Account Name'**	Identifiers that contain special characters, including spaces, are enclosed in single quotes
"..."	Text string	**"Hello, World"**	Text strings are enclosed in double quotes
$"..."	String interpolation	**$"Dear {FirstName},"**	Formulas embedded within a text string
.	Property Selector	**Slider1.Value** **Color.Red** **Acceleration.X**	Extracts a property from a table, control, signal, or enumeration. For backward compatibility, **!** may also be used.
. [language dependent]	Decimal separator	**1.23**	Separator between whole and fractional parts of a number. The character depends on the language.
( )	Parentheses	**Filter(T, A < 10)** **(1 + 2) * 3**	Enforces precedence order, and groups subexpressions in a larger expression
+	Arithmetic operators	**1 + 2**	Addition
-		**2 - 1**	Subtraction and sign
*		**2 * 3**	Multiplication
/		**2 / 3**	Division (also see the **Mod** function)
^		**2 ^ 3**	Exponentiation, equivalent to the **Power** function

Symbol	Type	Example	Description
%		**20%**	Percentage (equivalent to "* 1/100")
=	Comparison operators	**Price = 100**	Equal to
>		**Price > 100**	Greater than
>=		**Price >= 100**	Greater than or equal to
<		**Price < 100**	Less than
<=		**Price <= 100**	Less than or equal to
<>		**Price <> 100**	Not equal to
&	String concatenation operator	**"hello" & " " & "world"**	Makes multiple strings appear continuous
&& or **And**	Logical operators	**Price < 100 && Slider1.Value = 20** or **Price < 100 And Slider1.Value = 20**	Logical conjunction, equivalent to the **And** function
|| or **Or**		**Price < 100 || Slider1.Value = 20** or **Price < 100 Or Slider1.Value = 20**	Logical disjunction, equivalent to the **Or** function
! or **Not**		**!(Price < 100)** or **Not (Price < 100)**	Logical negation, equivalent to the **Not** function
exactin	Membership operators	**Gallery1.Selected exactin SavedItems**	Belonging to a collection or a table
exactin		**"Windows" exactin "To display windows in the Windows operating system..."**	Substring test (case-sensitive)
in		**Gallery1.Selected in SavedItems**	Belonging to a collection or a table
in		**"The" in "The keyboard and the monitor..."**	Substring test (case-insensitive)
@	Disambiguation operator	**MyTable[@fieldname]**	Field disambiguation
@		**[@MyVariable]**	Global disambiguation

Symbol	Type	Example	Description
, [language dependent]	List separator	**If(X < 10, "Low", "Good")** **{ X: 12, Y: 32 }** **[1, 2, 3]**	Separates: • arguments in function calls • fields in a record • records in a table This character depends on the language.
; [language dependent]	Formula chaining	**Collect(T, A); Navigate(S1, "")**	Separate invocations of functions in behavior properties. The chaining operator depends on the language.
As	As operator	**AllCustomers As Customer**	Overrides **ThisItem** and **ThisRecord** in galleries and record scope functions. **As** is useful for providing a better, specific name and is especially important in nested scenarios.
Self	Self operator	**Self.Fill**	Access to properties of the current control
Parent	Parent operator	**Parent.Fill**	Access to properties of a control container
ThisItem	ThisItem operator	**ThisItem.FirstName**	Access to fields of a Gallery or form control
ThisRecord	ThisRecord operator	**ThisRecord.FirstName**	Access to the complete record and individual fields of the record within **ForAll**, **Sum**, **With**, and other record scope functions. Can be overridden with the **As** operator.

> ⓘ Note
>
> The @ operator can also be used to validate the type of the record object against a data source. For example, `Collect(coll,Account@{'Account Number: 1111')`

in and exactin operators

Use the **in** and **exactin** operators to find a string in a data source, such as a collection or an imported table. The **in** operator identifies matches regardless of case, and the **exactin** operator identifies matches only if they're capitalized the same way. Here's an example:

1. Create or import a collection named **Inventory**, and show it in a gallery, as the first procedure in Show images and text in a gallery describes.

2. Set the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" in ProductName)

   The gallery shows all products except Callisto because the name of that product is the only one that doesn't contain the letter you specified.

3. Change the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" exactin ProductName)

   The gallery shows only Europa because only its name contains the letter that you specified in the case that you specified.

ThisItem, ThisRecord, and As operators

A few controls and functions apply formulas to individual records of a table. To refer to the individual record in a formula, use one of the following:

Expand table

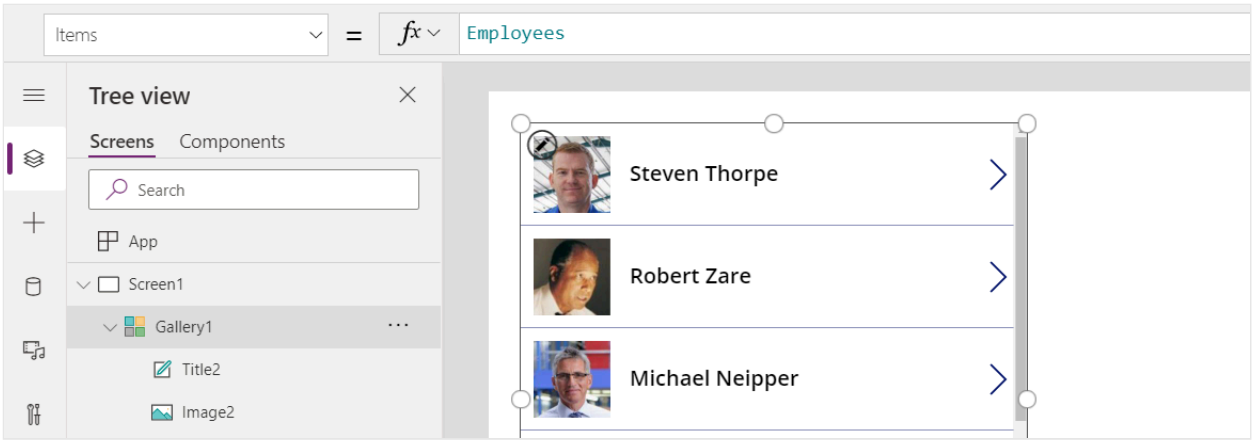
Operator	Applies to	Description
ThisItem	**Gallery** control **Edit form** control **Display form** control	The default name for the current record in a **Gallery** or form control.
ThisRecord	**ForAll**, **Filter**, **With**, **Sum** and other record scope functions	The default name for the current record in **ForAll** and other record scope functions.
As *name*	**Gallery** control **ForAll**, **Filter**, **With**, **Sum** and other record scope functions	Defines a *name* for the current record, replacing default **ThisItem** or **ThisRecord**. Use **As** to make formulas easier to understand and resolve ambiguity when nesting.

ThisItem operator

For example, in the following **Gallery** control, the **Items** property is set to the **Employees** data source (such as the **Employees** table included with the Northwind Traders sample):

Power Apps

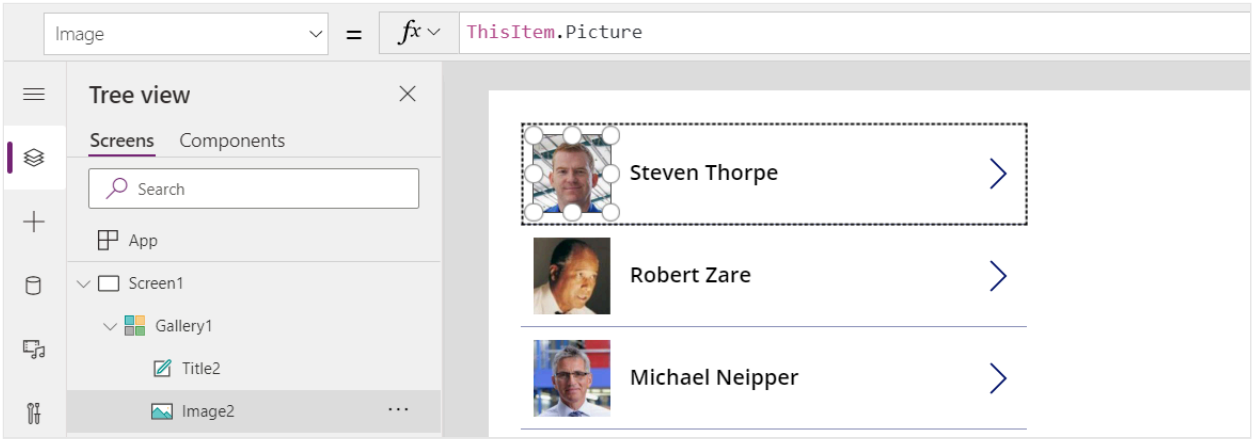
```
Employees
```



The first item in the gallery is a template that is replicated for each employee. In the template, the formula for the picture uses **ThisItem** to refer to the current item:

Power Apps

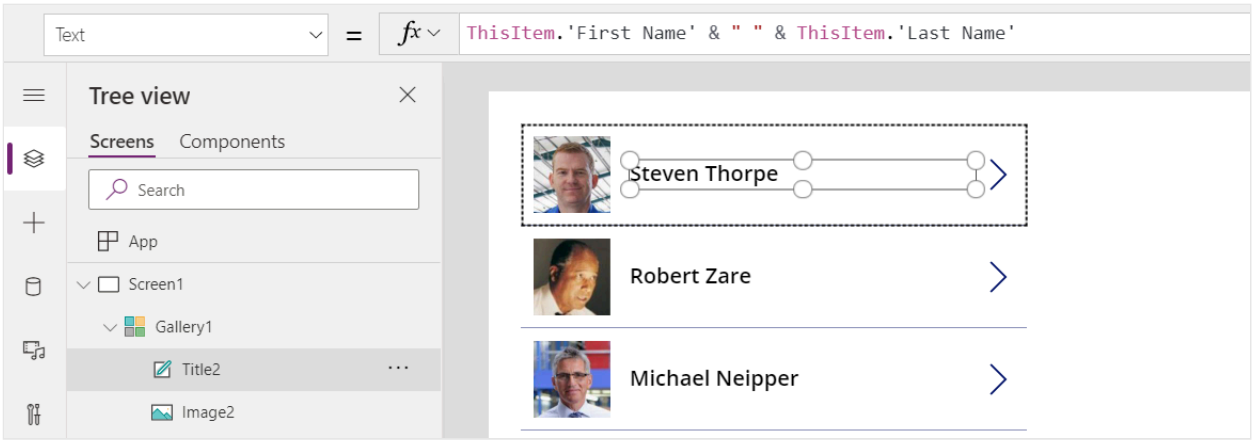
```
ThisItem.Picture
```



Likewise, the formula for the name also uses **ThisItem**:

Power Apps

```
ThisItem.'First Name' & " " & ThisItem.'Last Name'
```

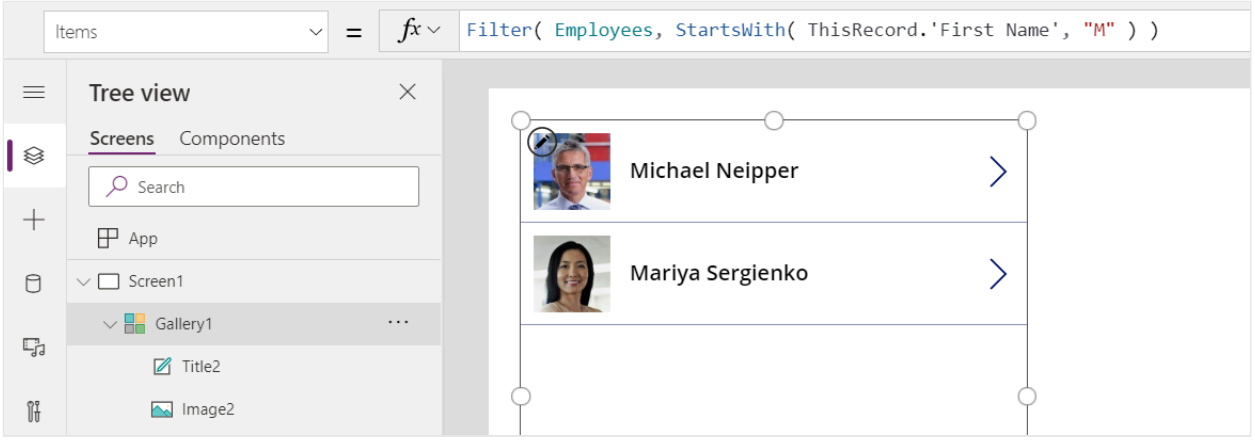


ThisRecord operator

ThisRecord is used in functions that have a record scope. For example, we can use the **Filter** function with our gallery's **Items** property to only show first names that being with *M*:

Power Apps

```
Filter( Employees, StartsWith( ThisRecord.Employee.'First Name', "M" ) )
```



ThisRecord is optional and implied by using the fields directly, for example, in this case, we could have written:

Power Apps

```
Filter( Employees, StartsWith( 'First Name', "M" ) )
```

Although optional, using **ThisRecord** can make formulas easier to understand and may be required in ambiguous situations where a field name may also be a relationship name. **ThisRecord** is optional while **ThisItem** is always required.

Use **ThisRecord** to reference the whole record with **Patch**, **Collect**, and other record scope functions. For example, the following formula sets the status for all inactive employees to active:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees,
              Patch( Employees, ThisRecord, { Status: 'Status
(Employees)'.Active } ) ) )
```

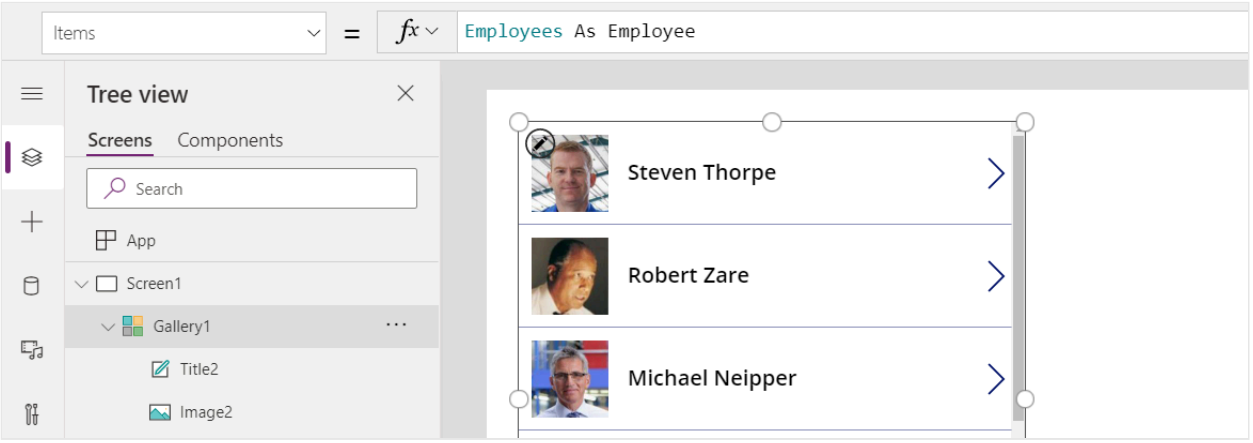
As operator

Use the **As** operator to name a record in a gallery or record scope function, overriding the default **ThisItem** or **ThisRecord**. Naming the record can make your formulas easier to understand and may be required in nested situations to access records in other scopes.

For example, you can modify the **Items** property of our gallery to use **As** to identify that we are working with an Employee:

Power Apps

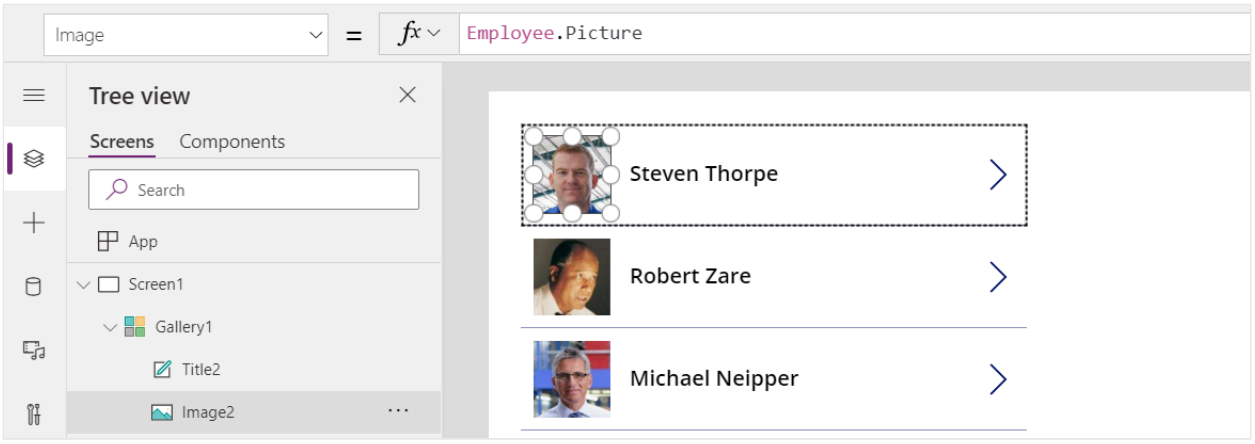
```
Employees As Employee
```



The formulas for the picture and name are adjusted to use this name for the current record:

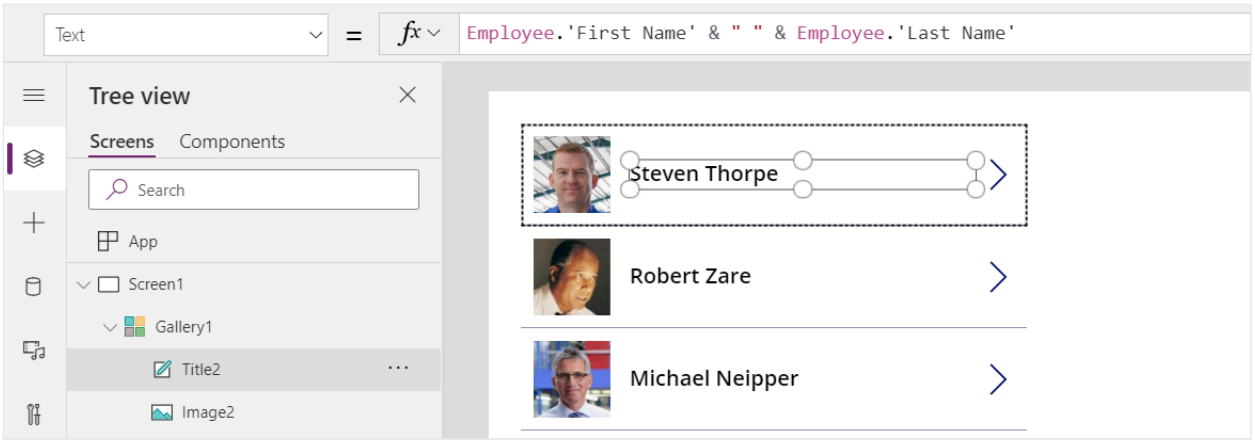
Power Apps

```
Employee.Picture
```



Power Apps

```
Employee.'First Name' & " " & Employee.'Last Name'
```



As can also be used with record scope functions to replace the default name **ThisRecord**. We can apply this to our previous example to clarify the record we're working with:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees As Employee,
              Patch( Employees, Employee, { Status: 'Status
(Employees)'.Active } ) ) )
```

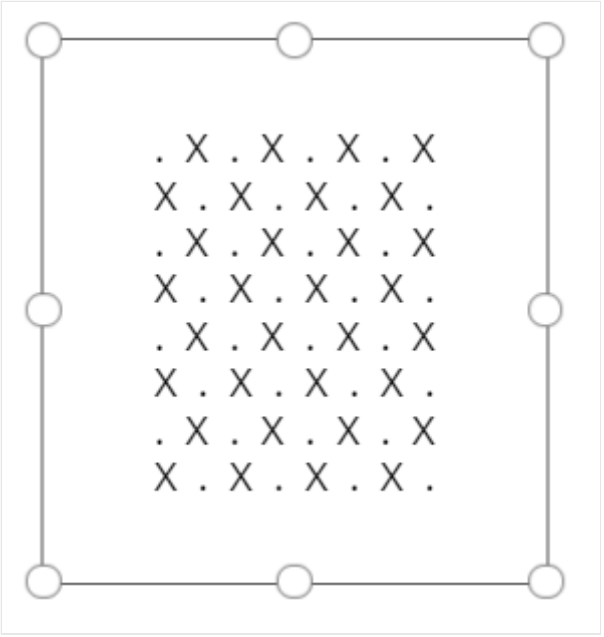
When nesting galleries and record scope functions, **ThisItem** and **ThisRecord** always refers to the inner most scope, leaving records in outer scopes unavailable. Use **As** to make all record scopes available by giving each a unique name.

For example, this formula produces a chessboard pattern as a text string by nesting two **ForAll** functions:

Power Apps

```
Concat(
    ForAll( Sequence(8) As Rank,
        Concat(
            ForAll( Sequence(8) As File,
                    If( Mod(Rank.Value + File.Value, 2) = 1, " X ", " . " )
            ),
            Value
        ) & Char(10)
    ),
    Value
)
```

Setting a **Label** control's **Text** property to this formula displays:



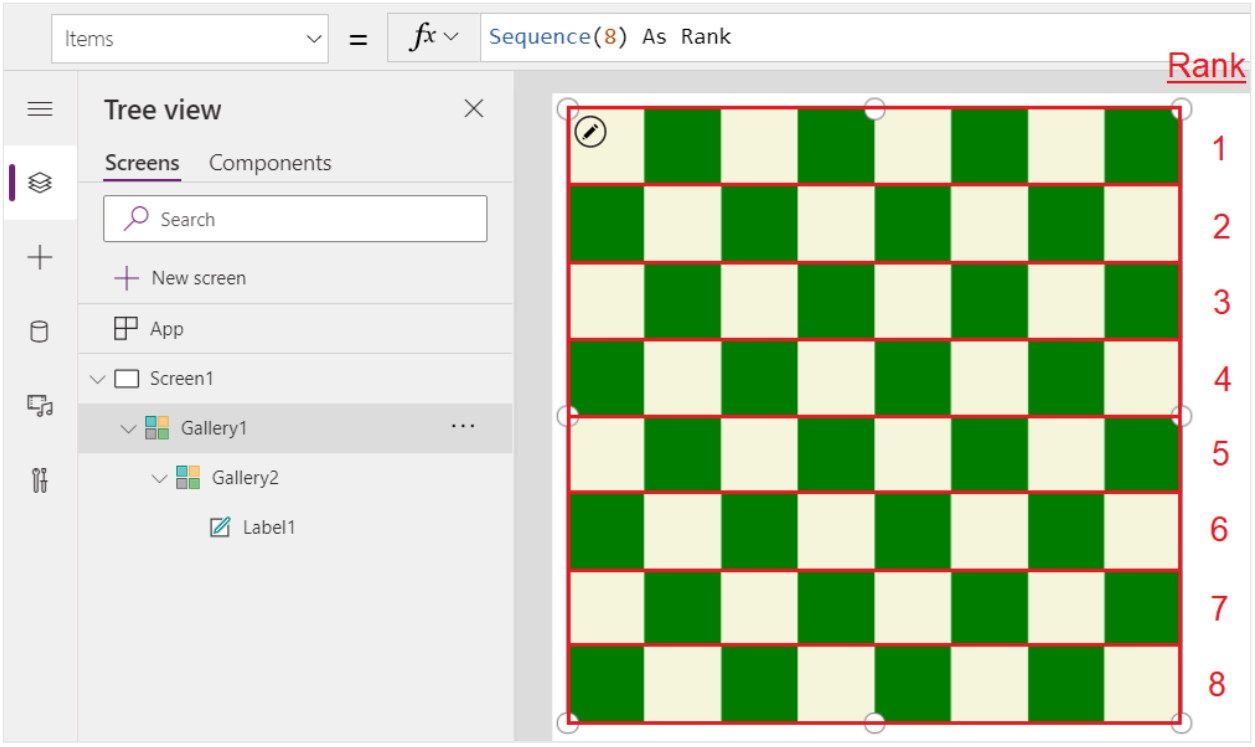
Let's unpack what is happening here:

- We start by iterating an unnamed table of 8 numbered records from the Sequence function. This loop is for each row of the board, which is commonly referred to as **Rank** and so we give it this name.
- For each row, we iterate another unnamed table of 8 columns, and we give the common name **File**.
- If **Rank.Value** + **File.Value** is an odd number, the square gets an **X**, otherwise a dot. This part of the formula is referencing both **ForAll** loops, made possible by using the **As** operator.
- Concat is used twice, first to assemble the columns and then the rows, with a Char(10) thrown in to create a new line.

A similar example is possible with nested **Gallery** controls instead of **ForAll** functions. Let's start with the vertical gallery for the **Rank**. This gallery control will have an **Items** formula of:

Power Apps

```
Sequence(8) as Rank
```



Within this gallery, we'll place a horizontal gallery for the **File**, that will be replicated for each **Rank**, with an **Items** property of:

Power Apps

```
Sequence(8) as File
```

And finally, within this gallery, we'll add a **Label** control that will be replicated for each **File** and each **Rank**. We'll size it to fill the entire space and use the **Fill** property to provide the color with this formula:

Power Apps

```
If( Mod( Rank.Value + File.Value, 2 ) = 1, Green, Beige )
```

Self and Parent operators

There are three ways to refer to a control and its properties within a formula:

Expand table

Method	Description
By control name	Any control can be referenced by name from anywhere within the app. For example, **Label1.Fill** refers to the fill property of the control who's name is **Label1**.
Self operator	It's often convenient to reference another property of the same control when writing a formula. Instead of using an absolute reference by name, it's easier and more portable to use a relative reference to one*self*. The **Self** operator provides that easy access to the current control. For example, **Self.Fill** refers to the fill color of the current control.

Method	Description
Parent operator	Some controls host other controls, such as the **Screen** and **Gallery** controls. The hosting control of the controls within it's called the *parent*. Like the **Self** operator, the **Parent** operator provides an easy relative reference to the container control. For example, **Parent.Fill** refers to the fill property of the control that is the container for the current control.

Self and **Parent** are operators and not properties on the controls themselves. Referring to **Parent.Parent**, **Self.Parent** or **Parent.Self** is not supported.

Identifier names

The names of variables, data sources, columns, and other objects can contain any Unicode.

Use single quotes around a name that contains a space or other special character. Use two single quotes together to represent one single quote in the name. Names that don't contain special characters don't require single quotes.

Here are some example column names you might encounter in a table, and how they're represented in a formula:

Expand table

Column name in a database	Column reference in a formula
SimpleName	`SimpleName`
NameWith123Numbers	`NameWith123Numbers`
Name with spaces	`'Name with spaces'`
Name with "double" quotes	`'Name with "double" quotes'`
Name with 'single' quotes	`'Name with ''single'' quotes'`
Name with an @ at sign	`'Name with an @ at sign'`

Double quotes are used to designate text strings.

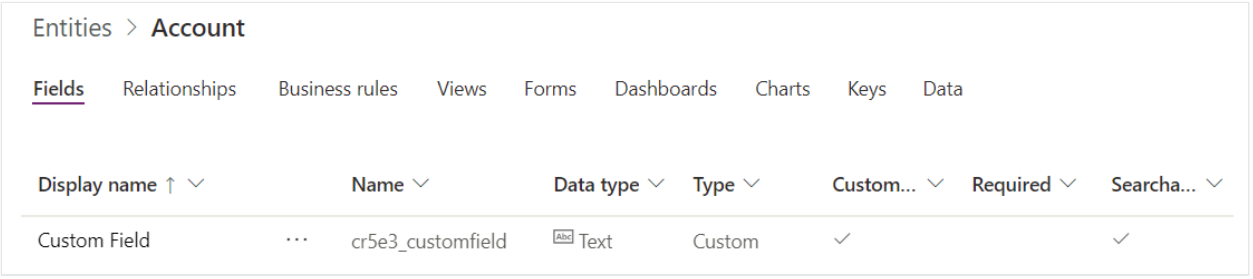
Display names and logical names

Some data sources such as SharePoint and Microsoft Dataverse have two different names to refer to the same table or column of data:

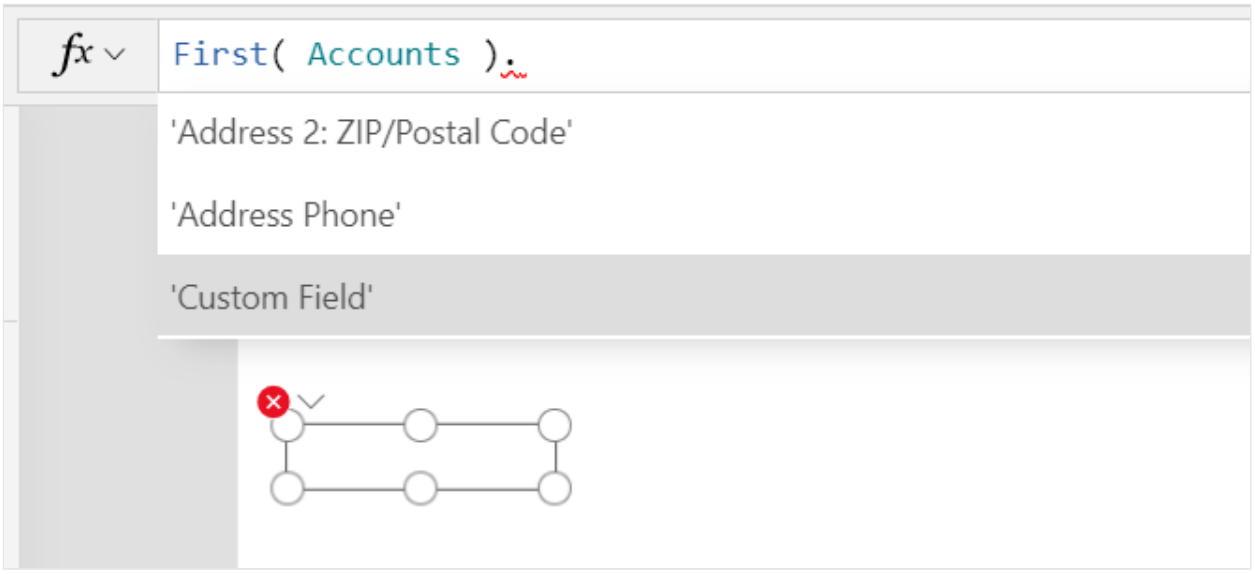
- **Logical name** - A name that is guaranteed to be unique, doesn't change after being created, usually doesn't allow spaces or other special characters, and isn't localized into different languages. As a result, the name can be cryptic. These names are used by professional developers. For example, **cra3a_customfield**. This name may also be referred to as **schema name** or just **name**.
- **Display name** - A name that is user-friendly and intended to be seen by end users. This name may not be unique, may change over time, may contain spaces and any Unicode character, and may be localized into different languages. Corresponding to the example above, the display name may be **Custom Field** with space in between the words.

Since display names are easier to understand, Canvas apps will suggest them as choices and not suggest logical names. Although logical names aren't suggested, they can still be used if typed indirectly.

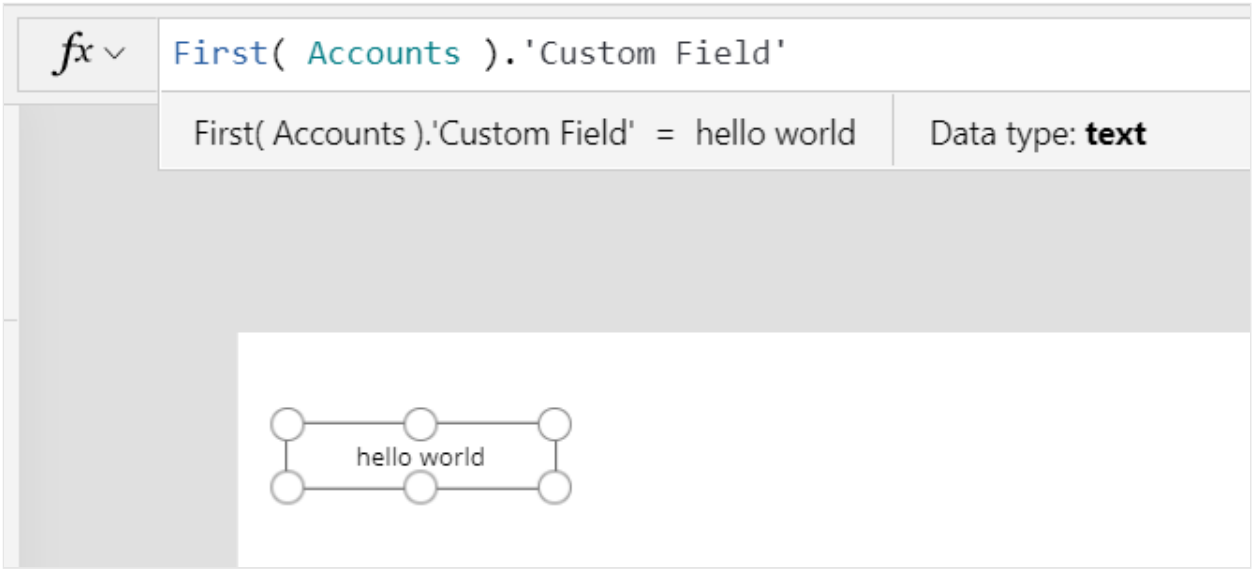
For example, imagine you've added a **Custom Field** to a table in Dataverse. A logical name will be assigned for you by the system, which you can modify only when creating the field. The result would look similar to:



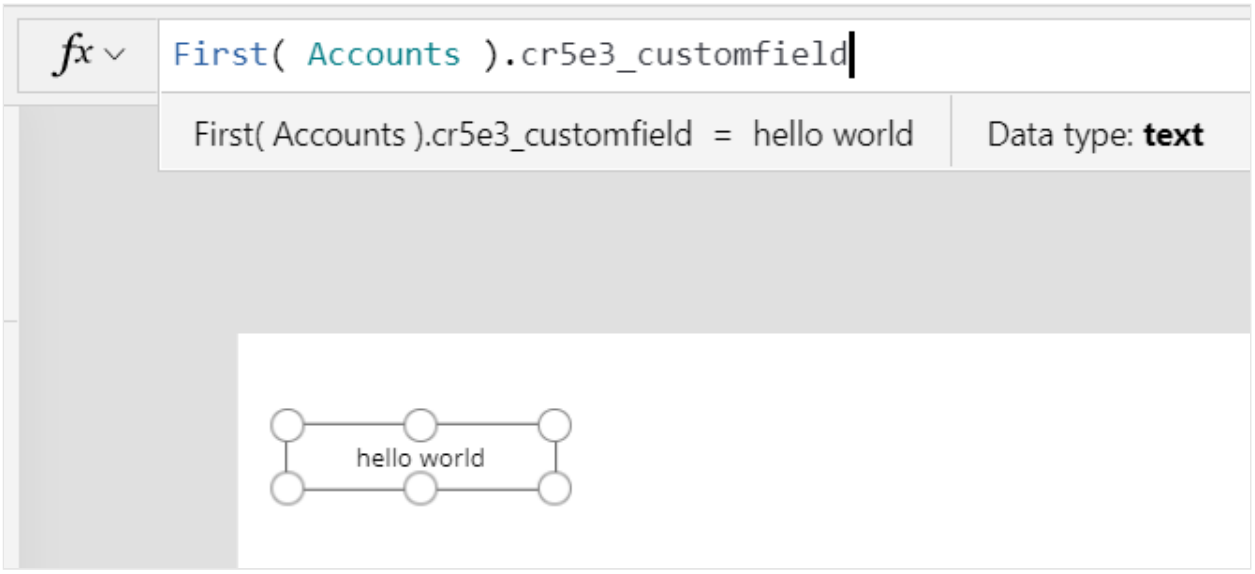
When authoring a reference to a field of Accounts, the suggestion will be made to use '**Custom Field**' since this is the display name. Single quotes must be used because this name has a space in it:



After selecting the suggestion, 'Custom Field' is shown in the formula bar and the data is retrieved:



Although it isn't suggested, we could also use the logical name for this field. This will result in the same data being retrieved. Single quotes are not required since this name doesn't contain spaces or special characters:

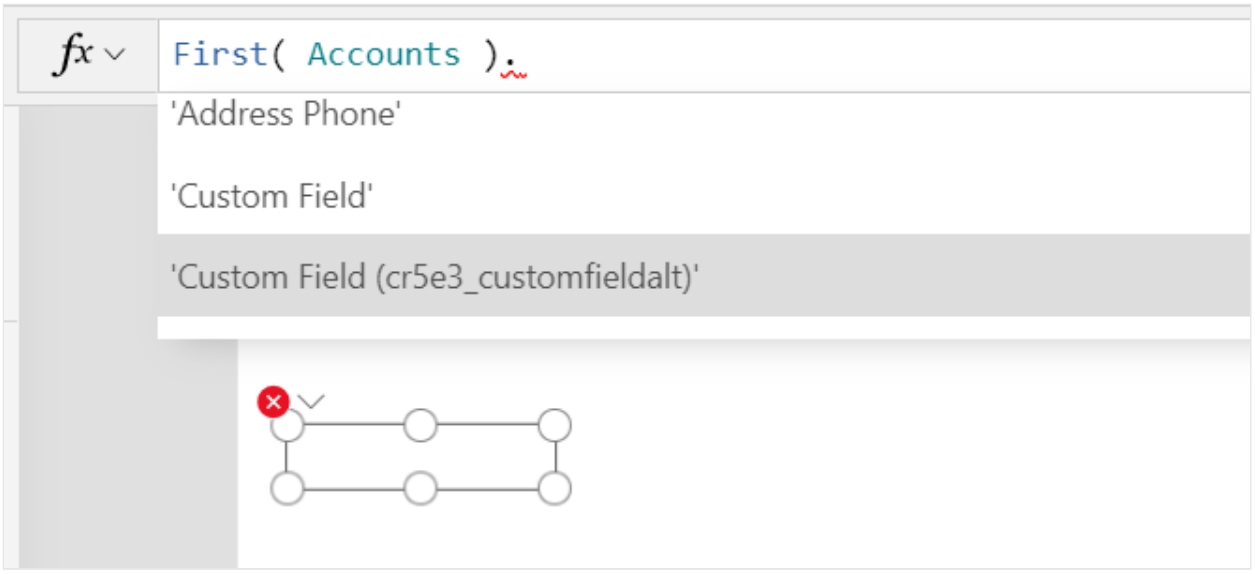


Behind the scenes, a mapping is maintained between the display names seen in formulas and the underlying logical names. Since logical names must be used to interact with the data source, this mapping is used to convert from the current display name to the logical name automatically and that is what is seen in the network traffic. This mapping is also used to convert back to logical names to switch into new display names, for example, if a display name changes or a maker in a different language edits the app.

> **Note**
>
> Logical names are not translated when moving an app between environments. For Dataverse system table and field names, this should not be a problem as logical names are consistent across environments. But any custom fields, such as **cra3a_customfield** in this example above, may have a different environment prefix (**cra3a** in this case). Display names are preferred as they can be matched against display names in the new environment.

Name disambiguation

Since display names aren't unique, the same display name may appear more than once in the same table. When this happens, the logical name will be added to the end of the display name in parentheses for one of more of the conflicting names. Building on the example above, if there was a second field with the same display name of **Custom Field** with a logical name of **cra3a_customfieldalt** then the suggestions would show:



Name disambiguation strings are added in other situations where name conflicts occur, such as the names of table, choices, and other Dataverse items.

Disambiguation operator

Some functions create record scopes for accessing the fields of table while processing each record, such as **Filter**, **AddColumns**, and **Sum**. Field names added with the record scope override the same names from elsewhere in the app. When this happens, you can still access values from outside the record scope with the @ disambiguation operator:

- To access values from nested record scopes, use the @ operator with the name of the table being operated upon using this pattern:
  Table[@*FieldName*]
- To access global values, such as data sources, collections, and context variables, use the pattern [@*ObjectName*] (without a table designation).

For more information and examples, see record scopes.

Acos, Acot, Asin, Atan, Atan2, Cos, Cot, Degrees, Pi, Radians, Sin, and Tan functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Calculates trigonometric values.

Description

Primary functions

The **Cos** function returns the cosine of its argument, an angle specified in radians.

The **Cot** function returns the cotangent of its argument, an angle specified in radians.

The **Sin** function returns the sine of its argument, an angle specified in radians.

The **Tan** function returns the tangent of its argument, an angle specified in radians.

Inverse functions

The **Acos** function returns the arccosine, or inverse cosine, of its argument. The arccosine is the angle whose cosine is the argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Acot** function returns the principal value of the arccotangent, or inverse cotangent, of its argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Asin** function returns the arcsine, or inverse sine, of its argument. The arcsine is the angle whose sine is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan** function returns the arctangent, or inverse tangent, of its argument. The arctangent is the angle whose tangent is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan2** function returns the arctangent, or inverse tangent, of the specified *x* and *y* coordinates as arguments. The arctangent is the angle from the *x*-axis to a line that contains the origin (0, 0) and a point with coordinates (*x*, *y*). The angle is given in radians between -π and π, excluding -π. A positive result represents a counterclockwise angle from the *x*-axis; a negative result represents a clockwise angle. **Atan2(*a*, *b*)** equals **Atan(*b*/*a*)**, except that ***a*** can equal 0 (zero) with the **Atan2** function.

Helper functions

The **Degrees** function converts radians to degrees. π radians equals 180 degrees.

The **Pi** function returns the transcendental number π, which begins 3.141592...

The **Radians** function converts degrees to radians.

Notes

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results with a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined value, the result is *blank*. This can happen, for example, when using inverse functions with arguments that are out of range.

Syntax

Primary Functions

Cos(*Radians*)
Cot(*Radians*)
Sin(*Radians*)
Tan(*Radians*)

- *Radians* - Required. Angle to operate on.

Cos(*SingleColumnTable*)
Cot(*SingleColumnTable*)
Sin(*SingleColumnTable*)
Tan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of angles to operate on.

Inverse Functions

Acos(*Number*)
Acot(*Number*)
Asin(*Number*)
Atan(*Number*)

- *Number* - Required. Number to operate on.

Acos(*SingleColumnTable*)
Acot(*SingleColumnTable*)
Asin(*SingleColumnTable*)
Atan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Atan2(*X*, *Y*)

- *X* - Required. *X*-axis coordinate.
- *Y* - Required. *Y*-axis coordinate.

Helper Functions

Degrees(*Radians*)

- *Radians* - Required. Angle in radians to convert to degrees.

Pi()

Radians(*Degrees*)

- *Degrees* - Required. Angle in degrees to convert to radians.

Examples

Single number

Expand table

Formula	Description	Result
Cos(1.047197)	Returns the cosine of 1.047197 radians or 60 degrees.	0.5
Cot(Pi()/4)	Returns the cotangent of 0.785398... radians or 45 degrees.	1
Sin(Pi()/2)	Returns the sine of 1.570796... radians or 90 degrees.	1
Tan(Radians(60))	Returns the tangent of 1.047197... radians or 60 degrees.	1.732050...
Acos(0.5)	Returns the arccosine of 0.5, in radians.	1.047197...
Acot(1)	Returns the arccotangent of 1, in radians.	0.785398...
Asin(1)	Returns the arcsine of 1, in radians.	1.570796...
Atan(1.732050)	Returns the arctangent of 1.732050, in radians.	1.047197...
Atan2(5, 3)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (5,3), which is approximately 31 degrees.	0.540419...
Atan2(4, 4)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (4,4), which is exactly π/4 radians or 45 degrees.	0.785398...
Degrees(1.047197)	Returns the equivalent number of degrees for 1.047197 radians.	60
Pi()	Returns the transcendental number π.	3.141592...
Radians(15)	Returns the equivalent number of radians for 15 degrees.	0.261799...

Single-column table

The examples in this section use a data source that's named **ValueTable** and that contains the following data. The last record in the table is π/2 radians or 90 degrees.

Expand table

Value
0.5
-2
1.570796...

Expand table

Formula	Description	Result
Cos(ValueTable)	Returns the cosine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.877582..., -0.416146..., 0
Cot(ValueTable)	Returns the cotangent of each number in the table.	A single-column table with a `Value` column containing the following values: 1.830487..., 0.457657..., 0
Sin(ValueTable)	Returns the sine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.479425, -0.909297..., 1
Tan(ValueTable)	Returns the tangent of each number in the table.	A single-column table with a `Value` column containing the following values: 0.546302..., 2.185039..., 3060023.306952...
Acos(ValueTable)	Returns the arccosine of each number in the table.	A single-column table with a `Value` column containing the following values: 1.047197..., Blank(), Blank()
Acot(ValueTable)	Returns the arccotangent of each number in the table.	A single-column table with a `Value` column containing the following values: 1.107138..., 2.677945..., 0.566911...
Asin(ValueTable)	Returns the arcsine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.523598..., Blank(), Blank()
Atan(ValueTable)	Returns the arctangent of each number in the table.	A single-column table with a `Value` column containing the following values: 0.463647..., -1.107148..., 1.00388...
Degrees(ValueTable)	Returns the equivalent number of degrees for each number in the table, assumed to be angles in radians.	A single-column table with a `Value` column containing the following values: 28.647889..., -114.591559..., 90
Radians(ValueTable)	Returns the equivalent number of radians for each number in the table, assumed to be angles in degrees.	A single-column table with a `Value` column containing the following values: 0.008726..., -0.034906..., 0.027415...

Assert function

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

An assertion is a condition or an expression that evaluates to true or false in a test. If the expression returns false, the test case will fail. Assertions are used to validate the expected result of a test or test step, against the actual result and to fail the test if the condition is false. Assertions can be used to validate the state of controls in your app such as label values, list box selections and other control properties.

> ⓘ **Important**
>
> **Assert** function is only available for Test Studio in Power Apps.

Assertion messages, for both passed and failed assertions, are also contained in a Traces table in the TestCaseResult record.

Syntax

Assert(expression, message)

- *Expression* – Required. An expression that evaluates to true or false.
- *Message* – Not Required. A message that describes the assertion failure.

Examples

```
Assert(lblResult.Text = "Success", "lblResult value Expected : Success , Actual : " & lblResult.Text)
```

```
Assert(ListBox1.Selected.Value = "Success", "ListBox1 selection Expected : Success, Actual : " & ListBox1.Selected.Value)
```

```
Assert(kudosAfterTest = kudosBeforeTest + 1, "Kudos count. Expected : " & kudosBeforeTest + 1 & " Actual :" & kudosAfterTest)
```

AsType and IsType functions

06/19/2025

Expand table

Function	Applies to
AsType	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
IsType	✅ Canvas apps ✅ Copilot Studio ✅ Model-driven apps ✅ Dataverse functions ✅ Power Pages

Checks if a record reference is a specific table type (**IsType**) and treats the reference as that type (**AsType**).

> ⓘ **Note**
>
> PAC CLI pac power-fx commands don't support **IsType**.

Description

The **AsType** and **IsType** functions can be used to convert record references (for example polymorphic lookups in Dataverse) and dynamic values to typed values that can be used directly.

Record References

Read Understand record references and polymorphic lookups for a broader introduction and more details.

A lookup field usually refers to records in a particular table. Because the table type is well established, access the fields of the lookup using simple dot notation. For example, **First(Accounts).'Primary Contact'.'Full Name'** walks from the **Accounts** table to the **Primary Contact** record in the **Contacts** table and extracts the **Full Name** field.

Microsoft Dataverse also supports polymorphic lookup fields, which can refer to records from a set of tables, as in these examples.

Expand table

Lookup field	Can refer to
Owner	**Users** or **Teams**
Customer	**Accounts** or **Contacts**
Regarding	**Accounts**, **Contacts**, **Knowledge Articles**, etc.

In canvas-app formulas, use record references to work with polymorphic lookups. Because a record reference can refer to different tables, you can't know which fields are available at runtime when you write a formula. The *Record.Field* notation isn't available. These formulas need to adapt to the records that the app encounters when it runs.

The **IsType** function checks if a record reference refers to a specific table type. The function returns a Boolean TRUE or FALSE.

The **AsType** function treats a record reference as a specific table type, also called *casting*. You use the result as if it's a record of the table and use the *Record.Field* notation to access all the fields of that record. If the reference isn't of the specific type, an error occurs.

Use these functions together to first check the table type of a record and then treat it as a record of that type so the fields are available:

Power Fx

```
If( IsType( First( Accounts ).Owner, Users ),
    AsType( First( Accounts ).Owner, Users ).'Full Name',
    AsType( First( Accounts ).Owner, Teams ).'Team Name'
)
```

You need these functions only if you access the fields of a record reference. For example, you use record references in the **Filter** function without **IsType** or **AsType**:

Power Fx

```
Filter( Accounts, Owner = First( Users ) )
```

Similarly, you can use record references with the **Patch** function:

Power Fx

```
Patch( Accounts, First( Accounts ), { Owner: First( Teams ) } )
```

When you use these functions in a record context, such as within a **Gallery** or **Edit form** control, you might need the global disambiguation operator to reference the table type. For

example, this formula works for a gallery that displays a list of contacts where **Company Name** is a **Customer** lookup:

```
Power Fx
```

```
If( IsType( ThisItem.'Company Name', Accounts ),
    AsType( ThisItem.'Company Name', Accounts ).'Account Name',
    AsType( ThisItem.'Company Name', Contacts ).'Full Name'
)
```

For both functions, specify the type by using the name of the data source connected to the table. For the formula to work, add a data source to the app for any types you want to check or cast. For example, add the **Users** table as a data source if you want to use **IsType** and **AsType** with an **Owner** lookup and records from that table. Add only the data sources you use in your app; you don't need to add all the tables that a lookup could reference.

If the record reference is *blank*, **IsType** returns FALSE, and **AsType** returns *blank*. All fields of a *blank* record are also *blank*.

Dynamic values

> **Important**
>
> - Using **AsType** and **IsType** with **Dynamic** values is an experimental feature.
> - Experimental features aren't meant for production use and might not be complete. These features are available before an official release so that you can get early access and provide feedback. More information: Understand experimental, preview, and retired features in canvas apps
> - The behavior that this article describes is available only when the **User-defined types** experimental feature in Settings > Upcoming features > Experimental is turned on (it's off by default).
> - Your feedback is valuable to us. Let us know what you think in the Power Apps experimental features community forum.

A **Dynamic** value from a web API or the [**ParseJSON** function] needs to be converted to a specific typed value before you can use it in Power Fx. Here are some options:

1. Implicitly type the field at the point you use it. For example, an object converts to a number if you use it with the `+` operator, if it can be converted to a number. This option can cause unexpected conversions and can't convert records and tables as a whole.

2. Explicitly type each field individually with the **Decimal**, **Text**, **DateTime**, **GUID**, and other type constructor functions. This option is the most invasive to your formulas because you need to do each field separately.
3. Explicitly type JSON with the second argument to the **ParseJSON** function. This option is easy and avoids needing the **Dynamic** value.
4. Explicitly type a **Dynamic** value using the **AsType** function. You can also check the type before you try the conversion with the **IsType** function.

Syntax

AsType(*RecordReference*, *TableType*)

- *RecordReference* - Required. A record reference, often a lookup field that refers to a record in any of several tables.
- *TableType* - Required. The specific table to cast the record to.

AsType(*DynamicValue*, *TypeSpecification*)

- *DynamicValue* - Required. A dynamic value from the **ParseJSON** function or API call.
- *TypeSpecification* - Required. A type name or type specification you define with the **Type** function.

IsType(*RecordReference*, *TableType*)

- *RecordReference* - Required. A record reference, often a lookup field that can refer to a record in any of multiple tables.
- *TableType* - Required. The specific table to test for.

IsType(*DynamicValue*, *TypeSpecification*)

- *DynamicValue* - Required. A dynamic value from the **ParseJSON** function or an API call.
- *TypeSpecification* - Required. A type name or type specification defined with the **Type** function.

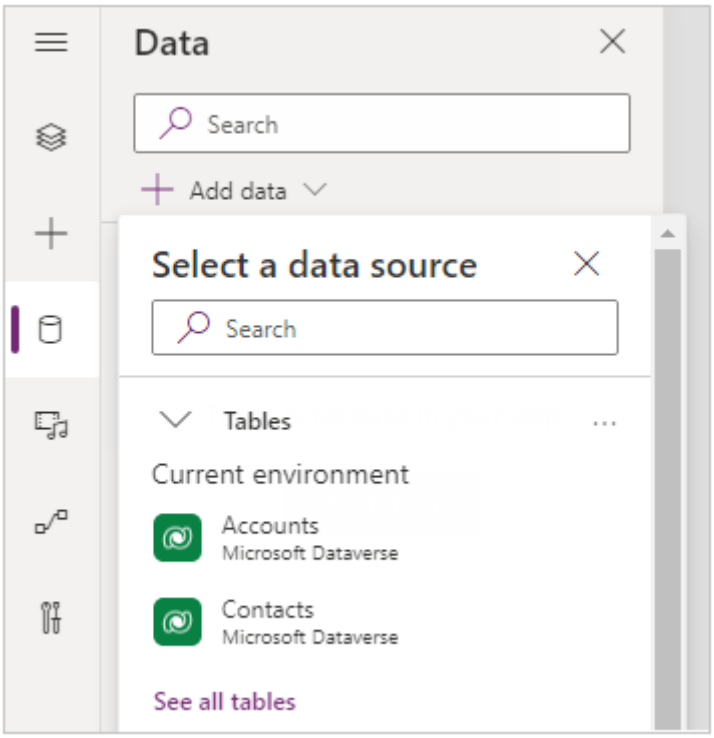
Examples

Record References

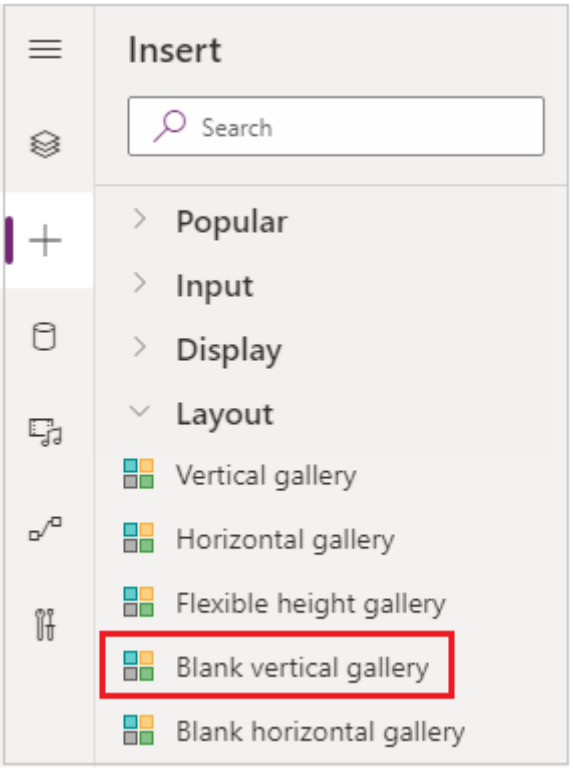
Understand record references and polymorphic lookups contains extensive examples.

1. Create a blank canvas app for tablets.

2. On the left pane, select **Data** > **Add data**, and then add **Accounts** and **Contacts** tables.

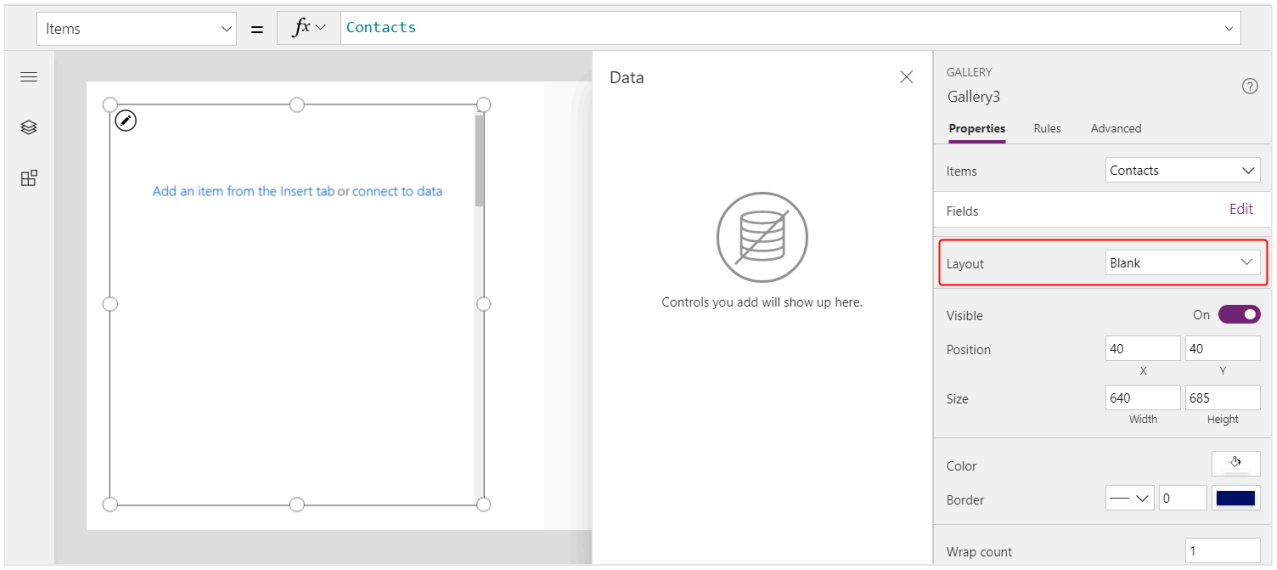


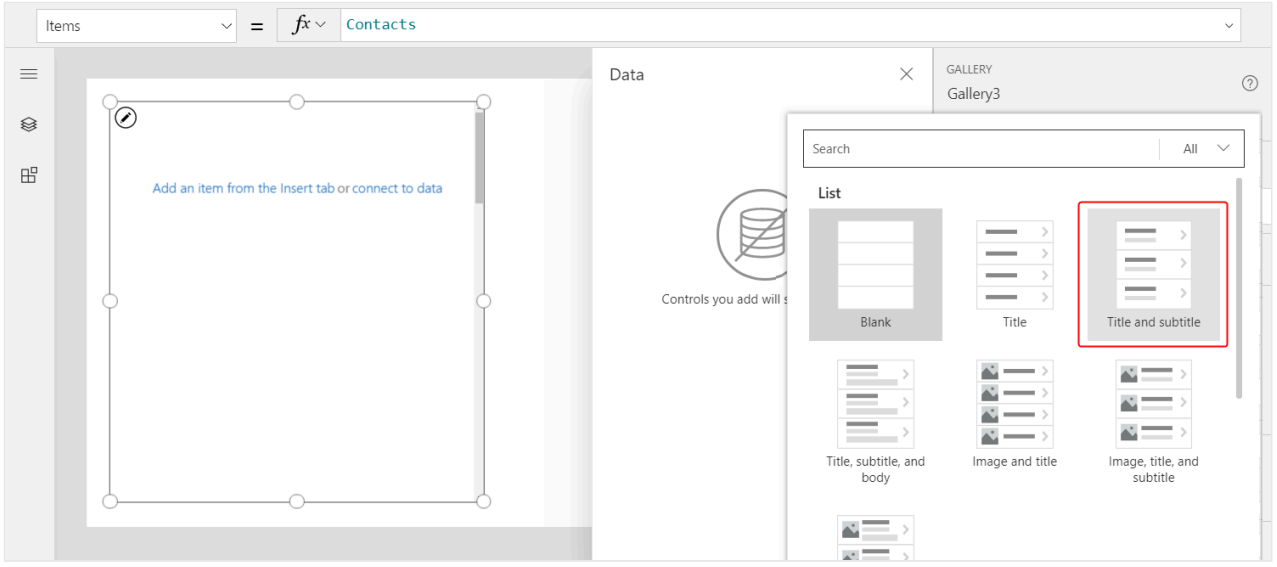
3. On the left pane, select + (Insert) > **Layout** > **Blank vertical gallery**.



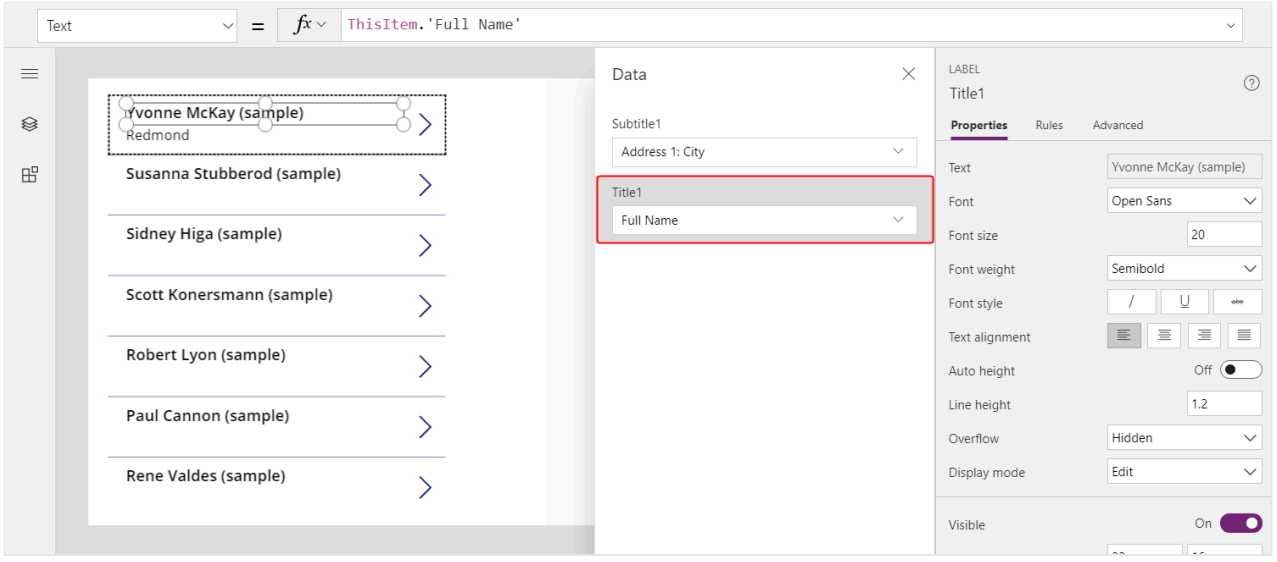
4. Select **Connect to data**, and then select **Contacts** as the data source.

5. Set the gallery layout to **Title and subtitle**.

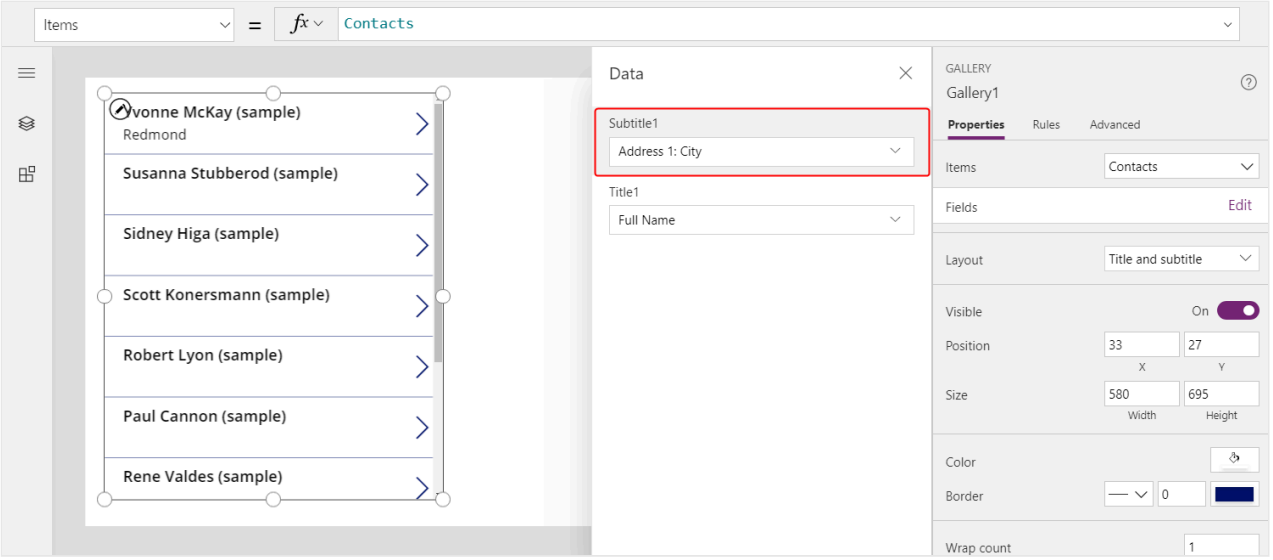




6. In the **Data** pane, open the **Title1** list, and then select **Full Name**.



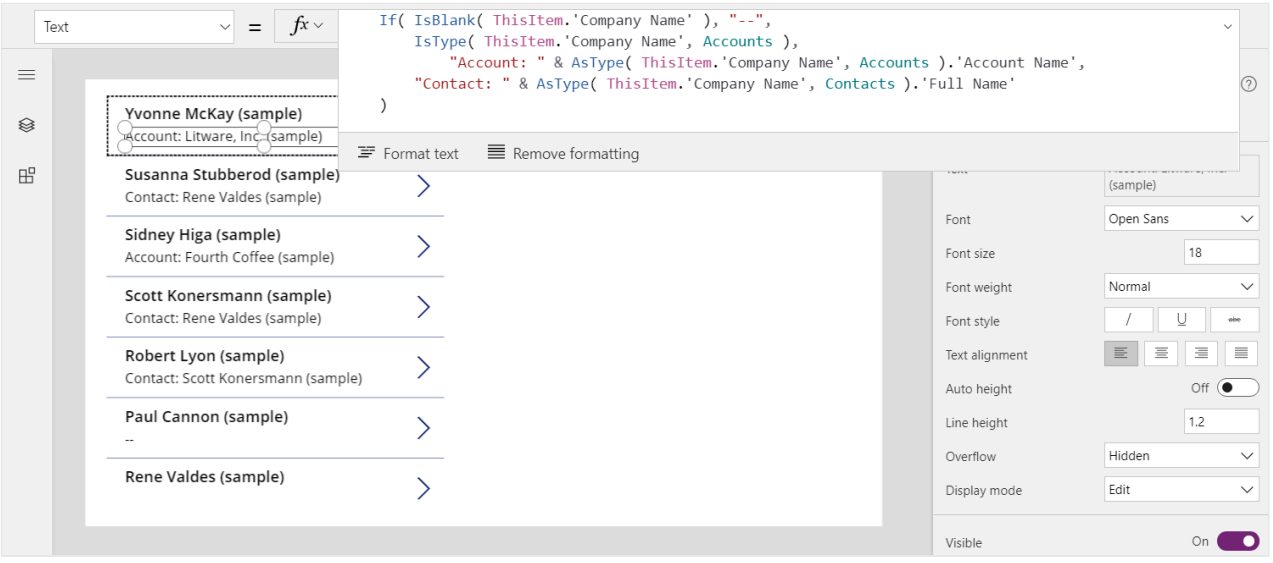
7. Select the **Subtitle1** label control.



8. Set the **Text** property of **Subtitle1** to this formula:

Power Fx

```
If( IsBlank( ThisItem.'Company Name' ), "--",
    IsType( ThisItem.'Company Name', Accounts ),
        "Account: " & AsType( ThisItem.'Company Name', Accounts ).'Account
Name',
    "Contact: " & AsType( ThisItem.'Company Name', Contacts ).'Full Name'
)
```



The subtitle in the gallery shows these values:

- "--" if the '**Company Name**' is *blank*.
- "Account: " and the **Account Name** field from the **Accounts** table if the **Company Name** field refers to an account.
- "Contact: " and the **Full Name** field from the **Contacts** table if the **Company Name** field refers to a contact.

Your results can differ because the sample data can be modified to show more types of results.

Dynamic values

The following examples show a simple JSON record interpreted in various ways by **ParseJSON**, **AsType**, and **IsType** in the Pac CLI Power Fx REPL.

In this first example, no type information is provided to **ParseJSON**, so it returns a dynamic value.

Power Apps

```
>> Set( rec, ParseJSON( "{""a"":1}" ) )
rec: <Dynamic: Use Value, Text, Boolean, or other functions to establish the type>
```

The field is implicitly converted to a number when used in a numerical context.

Power Apps

```
>> 1 + rec.a
2
```

As an alternative, this example explicitly converts the record to a typed Power Fx record with the second argument to **ParseJSON**.

Power Apps

```
>> ParseJSON( "{""a"":1}", Type( {a: Number} ) )
{a:1}
```

And another alternative, this example explicitly converts the record to a typed Power Fx record using **AsType**.

Power Apps

```
>> AsType( ParseJSON( "{""a"":1}" ), Type( {a: Number} ) )
{a:1}
```

Finally, if you aren't sure, this example tests the type before converting it with the **IsType** function.

Power Apps

```
>> IsType( ParseJSON( "{""a"":1}" ), Type( {a: Number} ) )
true
```

Acos, Acot, Asin, Atan, Atan2, Cos, Cot, Degrees, Pi, Radians, Sin, and Tan functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Calculates trigonometric values.

Description

Primary functions

The **Cos** function returns the cosine of its argument, an angle specified in radians.

The **Cot** function returns the cotangent of its argument, an angle specified in radians.

The **Sin** function returns the sine of its argument, an angle specified in radians.

The **Tan** function returns the tangent of its argument, an angle specified in radians.

Inverse functions

The **Acos** function returns the arccosine, or inverse cosine, of its argument. The arccosine is the angle whose cosine is the argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Acot** function returns the principal value of the arccotangent, or inverse cotangent, of its argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Asin** function returns the arcsine, or inverse sine, of its argument. The arcsine is the angle whose sine is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan** function returns the arctangent, or inverse tangent, of its argument. The arctangent is the angle whose tangent is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan2** function returns the arctangent, or inverse tangent, of the specified *x* and *y* coordinates as arguments. The arctangent is the angle from the *x*-axis to a line that contains the origin (0, 0) and a point with coordinates (*x*, *y*). The angle is given in radians between -π and π, excluding -π. A positive result represents a counterclockwise angle from the *x*-axis; a negative result represents a clockwise angle. **Atan2(*a*, *b*)** equals **Atan(*b*/*a*)**, except that ***a*** can equal 0 (zero) with the **Atan2** function.

Helper functions

The **Degrees** function converts radians to degrees. π radians equals 180 degrees.

The **Pi** function returns the transcendental number π, which begins 3.141592...

The **Radians** function converts degrees to radians.

Notes

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results with a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined value, the result is *blank*. This can happen, for example, when using inverse functions with arguments that are out of range.

Syntax

Primary Functions

Cos(*Radians*)
Cot(*Radians*)
Sin(*Radians*)
Tan(*Radians*)

- *Radians* - Required. Angle to operate on.

Cos(*SingleColumnTable*)
Cot(*SingleColumnTable*)
Sin(*SingleColumnTable*)
Tan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of angles to operate on.

Inverse Functions

Acos(*Number*)
Acot(*Number*)
Asin(*Number*)
Atan(*Number*)

- *Number* - Required. Number to operate on.

Acos(*SingleColumnTable*)
Acot(*SingleColumnTable*)
Asin(*SingleColumnTable*)
Atan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Atan2(*X*, *Y*)

- *X* - Required. *X*-axis coordinate.
- *Y* - Required. *Y*-axis coordinate.

Helper Functions

Degrees(*Radians*)

- *Radians* - Required. Angle in radians to convert to degrees.

Pi()

Radians(*Degrees*)

- *Degrees* - Required. Angle in degrees to convert to radians.

Examples

Single number

Expand table

Formula	Description	Result
Cos(1.047197)	Returns the cosine of 1.047197 radians or 60 degrees.	0.5
Cot(Pi()/4)	Returns the cotangent of 0.785398... radians or 45 degrees.	1
Sin(Pi()/2)	Returns the sine of 1.570796... radians or 90 degrees.	1
Tan(Radians(60))	Returns the tangent of 1.047197... radians or 60 degrees.	1.732050...
Acos(0.5)	Returns the arccosine of 0.5, in radians.	1.047197...
Acot(1)	Returns the arccotangent of 1, in radians.	0.785398...
Asin(1)	Returns the arcsine of 1, in radians.	1.570796...
Atan(1.732050)	Returns the arctangent of 1.732050, in radians.	1.047197...
Atan2(5, 3)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (5,3), which is approximately 31 degrees.	0.540419...
Atan2(4, 4)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (4,4), which is exactly π/4 radians or 45 degrees.	0.785398...
Degrees(1.047197)	Returns the equivalent number of degrees for 1.047197 radians.	60
Pi()	Returns the transcendental number π.	3.141592...
Radians(15)	Returns the equivalent number of radians for 15 degrees.	0.261799...

Average, Max, Min, StdevP, Sum, and VarP functions

Article • 04/20/2025

Expand table

Functions	Applies to
Average **Max** **Min** **Sum**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
StdevP **VarP**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Aggregate functions that summarize a set of numbers.

Description

The **Average** function calculates the average, or arithmetic mean, of its arguments.

The **Max** function finds the maximum value.

The **Min** function finds the minimum value.

The **Sum** function calculates the sum of its arguments.

The **StdevP** function calculates the standard deviation of its arguments.

The **VarP** function calculates the variance of its arguments.

You can supply the values for these functions as:

- Separate arguments. For example, **Sum(1, 2, 3)** returns 6.
- A table and a formula to operate over that table. The aggregate will be calculated on the values of the formula for each record.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

These functions operate on numeric values only. Other types of values, such as strings or records, are ignored. Use the **Value** function to convert a string into a number.

The **Average**, **Max**, **Min**, and **Sum** functions can be delegated when used with a data source that supports delegation for these functions. However, **StdevP** and **VarP** can't be delegated for any data sources. If delegation is not supported, only the first portion of the data will be retrieved and then the function applied locally. The result may not represent the complete story. A delegation warning will appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

Syntax

Average(*NumericalFormula1*, [*NumericalFormula2*, ...])
Max(*NumericalFormula1*, [*NumericalFormula2*, ...])
Min(*NumericalFormula1*, [*NumericalFormula2*, ...])
Sum(*NumericalFormula1*, [*NumericalFormula2*, ...])
StdevP(*NumericalFormula1*, [*NumericalFormula2*, ...])
VarP(*NumericalFormula1*, [*NumericalFormula2*, ...])

- *NumericalFormula(s)* - Required. Numeric values to operate on.

Average(*Table*, *NumericalFormula*)
Max(*Table*, *NumericalFormula*)
Min(*Table*, *NumericalFormula*)
Sum(*Table*, *NumericalFormula*)
StdevP(*Table*, *NumericalFormula*)
VarP(*Table*, *NumericalFormula*)

- *Table* - Required. Table to operate on.
- *NumericalFormula* - Required. Formula to evaluate for each record. The result of this formula is used for the aggregation. You can use columns of the table in the formula.

Examples

Step by step

Let's say that you had a data source named **Sales** that contained a **CostPerUnit** column and a **UnitsSold** column, and you set the **Text** property of a label to this function:
Sum(Sales, CostPerUnit * UnitsSold)

The label would show total sales by multiplying the values in those columns for each record and then adding the results from all records together:

Units sold	Cost per unit
30	$150
45	$125
20	$175

Total sales:

$13625

As a different example, let's say that you had sliders that were named **Slider1**, **Slider2**, and **Slider3** and a label with its **Text** property set to this formula:

Sum(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the sum of all values to which the sliders were set.

Average(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the average of all values to which the sliders were set.

Max(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the maximum of all values to which the sliders were set.

Min(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the minimum of all values to which the sliders were set.

StdevP(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the standard deviation of all values to which the sliders were set.

VarP(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the variance of all values to which the sliders were set.

Back and Navigate functions

Article • 03/22/2024

Changes which screen is displayed.

Overview

Most apps contain multiple screens. Use the **Back** and **Navigate** function to change which screen is displayed. For example, set the **OnSelect** property of a button to a formula that includes a **Navigate** function if you want to show a different screen when a user selects that button. In that formula, you can specify a visual transition, such as **Fade**, to control how one screen changes to another.

Back and **Navigate** change only which screen is displayed. Screens that aren't currently displayed continue to operate behind the scenes. You can build formulas that refer to properties of controls on other screens. For example, a user can change the value of a slider on one screen, navigate to a different screen that uses that value in a formula, and determine how it affects what happens in the new screen. The user can then navigate back to the original screen and confirm that the slider has kept its value.

Context variables are also preserved when a user navigates between screens. You can use **Navigate** to set one or more context variables for the screen that the formula will display, which is the only way to set a context variable from outside the screen. You can use this approach to pass parameters to a screen. If you've used another programming tool, this approach is similar to passing parameters to procedures.

Use the **App** object's **StartScreen** property to control the first screen to be displayed.

You can use either function only within a behavior formula.

Navigate

Applies to: ✅ Canvas apps ✅ Model-driven apps

In the first argument, specify the name of the screen to display.

In the second argument, specify how the old screen changes to the new screen:

Expand table

Transition Argument	Description	Demonstration
ScreenTransition.Cover	The new screen slides into view, moving right to left, to cover the current screen.	ScreenTransition.CoverRight	The new screen slides into view, moving left to right, to cover the current screen.	ScreenTransition.Fade	The current screen fades away to reveal the new screen.	ScreenTransition.None (Default)	The new screen quickly replaces the current screen.	ScreenTransition.UnCover	The current screen slides out of view, moving right to left, to uncover the new screen.	ScreenTransition.UnCoverRight	The current screen slides out of view, moving left to right, to uncover the new screen.	
You can use **Navigate** to create or update context variables of the new screen. As an optional third argument, pass a record that contains the context-variable name as a column name and the new value for the context variable. This record is the same as the record that you use with the **UpdateContext** function.

Set the **OnHidden** property of the old screen, the **OnVisible** property of the new screen, or both to make additional changes during the transition. The **App.ActiveScreen** property will be updated to reflect the change.

Navigate normally returns **true** but will return **false** if an error is encountered.

Context variables for navigation are explained in the article navigate between screens.

Back

Applies to: Canvas apps

The **Back** function returns to the screen that was most recently displayed.

For each **Navigate** call, the app tracks the screen that appeared and the transition. You can use successive **Back** calls to return all the way to the screen that appeared when the user started the app.

When the **Back** function runs, the inverse transition is used by default. For example, if a screen appeared through the **CoverRight** transition, **Back** uses **UnCover** (which is to the left) to return. **Fade** and **None** are their own inverses. Pass an optional argument to **Back** to force a specific transition.

Back normally returns **true** but returns **false** if the user hasn't navigated to another screen since starting the app.

Syntax

Back([*Transition*])

- *Transition* - Optional. The visual transition to use between the current screen and the previous screen. Refer to the list of valid values for this argument earlier in this article. By default, the transition through which a screen returns is the inverse of the transition through which it appeared.

Navigate(*Screen* [, *Transition* [, *UpdateContextRecord*]])

- *Screen* - Required. The screen to display. In place of *Screen*, you can also use a control that is on the screen you wish to navigate to.
- *Transition* - Optional. The visual transition to use between the current screen and the next screen. See the list of valid values for this argument earlier in this article. The default value is **None**.
- *UpdateContextRecord* - Optional. A record that contains the name of at least one column and a value for each column. This record updates the context variables of the new screen as if passed to the **UpdateContext** function.

Examples

Expand table

Formula	Description	Result
Navigate(Details)	Displays the **Details** screen with no transition or change in value for a context variable.	The **Details** screen appears quickly.
Navigate(Details, ScreenTransition.Fade)	Displays the **Details** screen with a **Fade** transition. No value of a context variable is changed.	The current screen fades away to show the **Details** screen.
Navigate(Details, ScreenTransition.Fade, { ID: 12 })	Displays the **Details** screen with a **Fade** transition, and updates the value of the **ID** context variable to **12**.	The current screen fades away to show the **Details** screen, and the context variable **ID** on that screen is set to **12**.
Navigate(Details, ScreenTransition.Fade, { ID: 12 , Shade: Color.Red })	Displays the **Details** screen with a **Fade** transition. Updates the value of the **ID** context variable to **12**, and updates the value of the **Shade** context variable to **Color.Red**.	The current screen fades away to show the **Details** screen. The context variable **ID** on the **Details** screen is set to **12**, and the context variable **Shade** is set to **Color.Red**. If you set the **Fill** property of a control on the **Details** screen to **Shade**, that control would display as red.
Back()	Displays the previous screen with the default return transition.	Displays the previous screen through the inverse transition of the transition through which the current screen appeared.
Back(ScreenTransition.Cover)	Displays the previous screen with the **Cover** transition.	Displays the previous screen through the **Cover** transition, regardless of the transition through which the current screen appeared.

Step-by-step

1. Create a blank app.
2. Add a second screen to it.

   The app contains two blank screens: **Screen1** and **Screen2**.
3. Set the **Fill** property of **Screen2** to the value `Gray`.

4. On **Screen2**, add a button, and set its **OnSelect** property to this formula:

```
Power Apps
Navigate( Screen1, ScreenTransition.Cover )
```

5. While holding down the **Alt** key, select the button.

   Screen1 appears with a white background through a transition that covers to the left.

6. On **Screen1**, add a button, and set its **OnSelect** property to this formula:

```
Power Apps
Back()
```

7. While holding down the **Alt** key, select the button.

   The second screen appears with a gray background through a transition that uncovers to the right (the inverse of **Cover**).

8. Select the button on each screen repeatedly to bounce back and forth.

Blank, Coalesce, IsBlank, and IsEmpty functions

06/19/2025

Expand table

Functions	Applies to
Blank	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions
Coalesce **IsEmpty**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
IsBlank	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Tests whether a value is blank or a table contains no records, and provides a way to create *blank* values.

Overview

Blank is a placeholder for "no value" or "unknown value." For example, a **Combo box** control's **Selected** property is *blank* if the user hasn't made a selection. Many data sources can store and return NULL values, which are represented in Power Apps as *blank*.

Any property or calculated value in Power Apps can be *blank*. For example, a Boolean value normally has one of two values: **true** or **false**. But in addition to these two, it can also be *blank* indicating that the state is not known. This is similar to Microsoft Excel, where a worksheet cell starts out as blank with no contents but can hold the values **TRUE** or **FALSE** (among others). At any time, the contents of the cell can again be cleared, returning it to a *blank* state.

Empty string refers to a string that contains no characters. The **Len** function returns zero for such a string and it can be written in a formulas as two double quotes with nothing in between `""`. Some controls and data sources use an empty string to indicate a "no value" condition. To simplify app creation, the **IsBlank** and **Coalesce** functions test for both *blank* values or empty strings.

In the context of the **IsEmpty** function, *empty* is specific to tables that contain no records. The table structure may be intact, complete with column names, but no data is in the table. A table

may start as empty, take on records and no longer be empty, and then have the records removed and again be empty.

Blank

The **Blank** function returns a *blank* value. Use this to store a NULL value in a data source that supports these values, effectively removing any value from the field.

IsBlank

The **IsBlank** function tests for a *blank* value or an empty string. The test includes empty strings to ease app creation since some data sources and controls use an empty string when there is no value present. To test specifically for a *blank* value use `if( Value = Blank(), ...` instead of **IsBlank**. The **IsBlank** function considers empty tables as not blank, and **IsEmpty** should be used to test a table.

When enabling error handling for existing apps, consider replacing **IsBlank** with IsBlankOrError to preserve existing app behavior. Prior to the addition of error handling, a *blank* value was used to represent both null values from databases and error values. Error handling separates these two interpretations of *blank* which could change the behavior of existing apps that continue to use **IsBlank**.

The return value for **IsBlank** is a boolean **true** or **false**.

Coalesce

The **Coalesce** function evaluates its arguments in order and returns the first value that isn't *blank* or an empty string. Use this function to replace a *blank* value or empty string with a different value but leave non-*blank* and non-empty string values unchanged. If all the arguments are *blank* or empty strings then the function returns *blank*, making **Coalesce** a good way to convert empty strings to *blank* values.

`Coalesce( value1, value2 )` is the more concise equivalent of `If( Not IsBlank( value1 ), value1, Not IsBlank( value2 ), value2 )` and doesn't require **value1** and **value2** to be evaluated twice. The **If** function returns *blank* if there is no "else" formula as is the case here.

All arguments to **Coalesce** must be of the same type; for example, you can't mix numbers with text strings. The return value from **Coalesce** is of this common type.

IsEmpty

The **IsEmpty** function tests whether a table contains any records. It's equivalent to using the CountRows function and checking for zero. You can check for data-source errors by combining **IsEmpty** with the Errors function.

The return value for **IsEmpty** is a Boolean **true** or **false**.

Syntax

Blank()

Coalesce(*Value1* [, *Value2*, ...])

- *Value(s)* – Required. Values to test. Each value is evaluated in order until a value that is not *blank* and not an empty string is found. Values after this point are not evaluated.

IsBlank(*Value*)

- *Value* – Required. Value to test for a *blank* value or empty string.

IsEmpty(*Table*)

- *Table* - Required. Table to test for records.

Examples

Blank

1. Create an app from scratch, and add a **Button** control.
2. Set the button's OnSelect property to this formula:

   ```
   Power Fx
   ClearCollect( Cities, { Name: "Seattle", Weather: "Rainy" } )
   ```

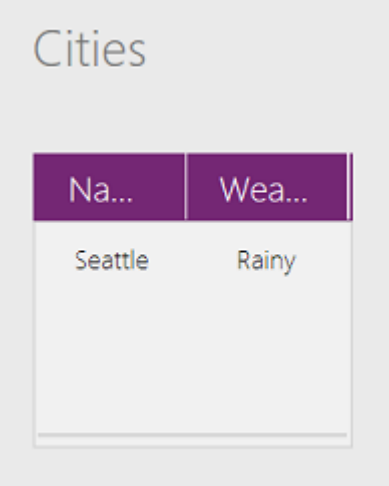
3. Preview your app, click or tap the button that you added, and then close Preview.
4. On the **File** menu, click or tap **Collections**.

   The **Cities** collection appears, showing one record with "Seattle" and "Rainy":



5. Click or tap the back arrow to return to the default workspace.

6. Add a **Label** control, and set its **Text** property to this formula:

```
Power Fx
IsBlank( First( Cities ).Weather )
```

   The label shows **false** because the **Weather** field contains a value ("Rainy").

7. Add a second button, and set its **OnSelect** property to this formula:

```
Power Fx
Patch( Cities, First( Cities ), { Weather: Blank() } )
```

8. Preview your app, click or tap the button that you added, and then close Preview.

   The **Weather** field of the first record in **Cities** is replaced with a *blank*, removing the "Rainy" that was there previously.

   The label shows **true** because the **Weather** field no longer contains a value.

Coalesce

Expand table

Formula	Description	Result
Coalesce(Blank(), 1)	Tests the return value from the **Blank** function, which always returns a *blank* value. Because the first argument is *blank*, evaluation continues with the next argument until a non-*blank* value and non-empty string is found.	**1**
Coalesce("", "2")	Tests the first argument which is an empty string. Because the first argument is an empty string, evaluation continues with the next argument until a non-*blank* value and non-empty string is found.	**2**
Coalesce(Blank(), "", Blank(), "", "3", "4")	**Coalesce** starts at the beginning of the argument list and evaluates each argument in turn until a non-*blank* value and non-empty string is found. In this case, the first four arguments all return *blank* or an empty string, so evaluation continues to the fifth argument. The fifth argument is non-*blank* and non-empty string, so evaluation stops here. The value of the fifth argument is returned, and the sixth argument isn't evaluated.	**3**
Coalesce("")	Tests the first argument which is an empty string. Because the first argument is an empty string, and there are no more arguments, the function returns *blank*.	*blank*

IsBlank

1. Create an app from scratch, add a text-input control, and name it **FirstName**.
2. Add a label, and set its **Text** property to this formula:

   ```
   Power Fx
   ```

   ```
   If( IsBlank( FirstName.Text ), "First Name is a required field." )
   ```

   By default, the **Text** property of a text-input control is set to **"Text input"**. Because the property contains a value, it isn't blank, and the label doesn't display any message.
3. Remove all the characters from the text-input control, including any spaces.

   Because the **Text** property no longer contains any characters, it's an empty string, and **IsBlank(FirstName.Text)** will be **true**. The required field message is displayed.

For information about how to perform validation by using other tools, see the **Validate** function and working with data sources.

Other examples:

Expand table

Formula	Description	Result
IsBlank(Blank())	Tests the return value from the **Blank** function, which always returns a *blank* value.	**true**
IsBlank("")	A string that contains no characters.	**true**
IsBlank("Hello")	A string that contains one or more characters.	**false**
IsBlank(*AnyCollection*)	Because the collection exists, it isn't blank, even if it doesn't contain any records. To check for an empty collection, use **IsEmpty** instead.	**false**
IsBlank(Mid("Hello", 17, 2))	The starting character for **Mid** is beyond the end of the string. The result is an empty string.	**true**
IsBlank(If(false, false))	An **If** function with no *ElseResult*. Because the condition is always **false**, this **If** always returns *blank*.	**true**

IsEmpty

1. Create an app from scratch, and add a **Button** control.
2. Set the button's **OnSelect** property to this formula:

   Collect(IceCream, { Flavor: "Strawberry", Quantity: 300 }, { Flavor: "Chocolate", Quantity: 100 })
3. Preview your app, click or tap the button that you added, and then close Preview.

   A collection named **IceCream** is created and contains this data:

Flavor	Quantity
"Strawberry"	300
"Chocolate"	100

   This collection has two records and isn't empty. **IsEmpty(IceCream)** returns **false**, and **CountRows(IceCream)** returns **2**.
4. Add a second button, and set its **OnSelect** property to this formula:

   Clear(IceCream)
5. Preview your app, click or tap the second button, and then close Preview.

The collection is now empty:

Flavor	Quantity

The Clear function removes all the records from a collection, resulting in an empty collection. **IsEmpty(IceCream)** returns **true**, and **CountRows(IceCream)** returns **0**.

You can also use **IsEmpty** to test whether a calculated table is empty, as these examples show:

Expand table

Formula	Description	Result
IsEmpty([1, 2, 3])	The single-column table contains three records and, therefore, isn't empty.	**false**
IsEmpty([ ])	The single-column table contains no records and is empty.	**true**
IsEmpty(Filter([1, 2, 3], Value > 5))	The single-column table contains no values that are greater than 5. The result from the filter doesn't contain any records and is empty.	**true**

Calendar and Clock functions

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Retrieves calendar and clock information about the current locale.

Description

The **Calendar** and **Clock** functions are a set of functions that retrieve information about the current locale.

You can use these functions to display dates and times in the language of the current user. The single-column tables returned by **Calendar** and **Clock** functions can be used directly with the **Items** property of Dropdown and Listbox controls.

Expand table

Function	Description
Calendar.MonthsLong()	Single-column table containing the full names of each month, starting with "January".
Calendar.MonthsShort()	Single-column table containing the abbreviated names of each month, starting with "Jan" for January.
Calendar.WeekdaysLong()	Single-column table containing the full names of each weekday, starting with "Sunday".
Calendar.WeekdaysShort()	Single-column table containing the full names of each weekday, starting with "Sun" for Sunday.
Clock.AmPm()	Single-column table containing the long uppercase "AM" and "PM" designations. If the language uses a 24-hour clock, the table will be empty.
Clock.AmPmShort()	Single-column table containing the short uppercase "A" and "P" designations. If the language uses a 24-hour clock, the table will be empty.
Clock.IsClock24()	Boolean indicating if a 24-hour clock is used in this locale.

Use the **Text** function to format date and time values using this same information. The **Language** function returns the current language and region code.

Syntax

Calendar.MonthsLong()

Calendar.MonthsShort()

Calendar.WeekdaysLong()

Calendar.WeekdaysShort()

Clock.AmPm()

Clock.AmPmShort()

Clock.IsClock24()

Examples

1. Insert a Dropdown control.
2. Set the formula for the **Items** property to:
    - **Calendar.MonthsLong()**
3. Users of your app can now select a month in their own language. **MonthsLong** can be replaced with any of the single-column tables that are returned by **Calendar** to create weekday and time selectors.

In the United States, with **Language** returning "en-US", the following is returned by the **Calendar** functions:

Expand table

Formula	Description	Result
Calendar.MonthsLong()	The return value contains the full name of each month, starting with "January".	["January", "February", "March", "April", "May", "June", "July", "August", "September", "October", "November", "December"]
Calendar.MonthsShort()	The return value contains the abbreviated name of each month, starting with "January".	["Jan", "Feb", "Mar", "Apr", "May", "Jun", "Jul", "Aug", "Sep", "Oct", "Nov", "Dec"]
Calendar.WeekdaysLong()	The return value contains the full name of each day, starting	["Sunday", "Monday", "Tuesday", "Wednesday", "Thursday",

Formula	Description	Result
	with "Sunday".	"Friday", "Saturday"]
Calendar.WeekdaysShort()	The return value contains the abbreviated name of each day, starting with "Sunday".	["Sun", "Mon", "Tue", "Wed", "Thu", "Fri", "Sat"]
Clock.AmPm()	This language uses a 12-hour clock. The return value contains the uppercase versions of the full AM and PM designations.	["AM", "PM"]
Clock.AmPmShort()	This language uses a 12-hour clock. The return value contains the uppercase versions of the short AM and PM designations.	["A", "P"]
Clock.IsClock24()	This language uses a 12-hour clock.	**false**

Char and UniChar functions

Article • 04/20/2025

Expand table

Function	Applies to
Char	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
UniChar	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Translates a character code into a string.

Description

The **Char** function translates a number into a string with the corresponding ASCII character.

The **UniChar** function translates a number into a string with the corresponding Unicode character.

If you pass a single number, the return value is the translated string version of that number. If you pass a single-column table that contains numbers, the return value is a single-column table of strings in a **Value** column. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

Syntax

Char(*CharacterCode*)

- *CharacterCode* - Required. ASCII character code to translate.

Char(*CharacterCodeTable*)

- *CharacterCodeTable* - Required. Table of ASCII character codes to translate.

UniChar(*UnicodeCode*)

- *UnicodeCode* - Required. Unicode character code to translate.

UniChar(*UnicodeCodeTable*)

- *UnicodeCodeTable* - Required. Table of Unicode character codes to translate.

Examples

Single number

Expand table

Formula	Description	Result
Char(65)	Returns the character that corresponds to ASCII code 65.	"A"
Char(105)	Returns the character that corresponds to ASCII code 105.	"i"
Char(35)	Returns the character that corresponds to ASCII code 35.	"#"
UniChar(35)	Returns the character that corresponds to Unicode code 35.	"#"
UniChar(233)	Returns the character that corresponds to Unicode code 233.	"á"
UniChar(9829)	Returns the character that corresponds to Unicode code 9829.	"♥"

Single-column table

The example in this section converts numbers from a single-column table.

Expand table

Formula	Result
`Char( [ 65, 105 ] )`	A single-column table with a `Value` column containing the following values: "A", "i"
`Char( [ 35, 52 ] )`	A single-column table with a `Value` column containing the following values: "#", "4"
`UniChar( [ 71, 97, 114, 231, 111, 110 ] )`	A single-column table with a `Value` column containing the following values: "G", "a", "r", "ç", "o", "n"

Display a character map

1. On an empty screen in a tablet app, add a Gallery control with a **Blank Horizontal** layout, and then set these properties:

   - **Items**: `Sequence( 8, 0, 16 ) As HighNibble`
   - **Width**: `Parent.Width`
   - **Height**: `Parent.Height`

- **TemplateSize**: `Parent.Width / 8`
- **TemplatePadding**: 0
- **X**: 0
- **Y**: 0

2. Inside that gallery, add a **Gallery** control with a **Blank Vertical** layout, and then set these properties:

   - **Items**: `Sequence( 16, HighNibble.Value ) As FullCode`
   - **Width**: `Parent.Width / 8`
   - **Height**: `Parent.Height`
   - **TemplateSize**: `Parent.Height / 16`
   - **TemplatePadding**: 0
   - **X**: 0
   - **Y**: 0

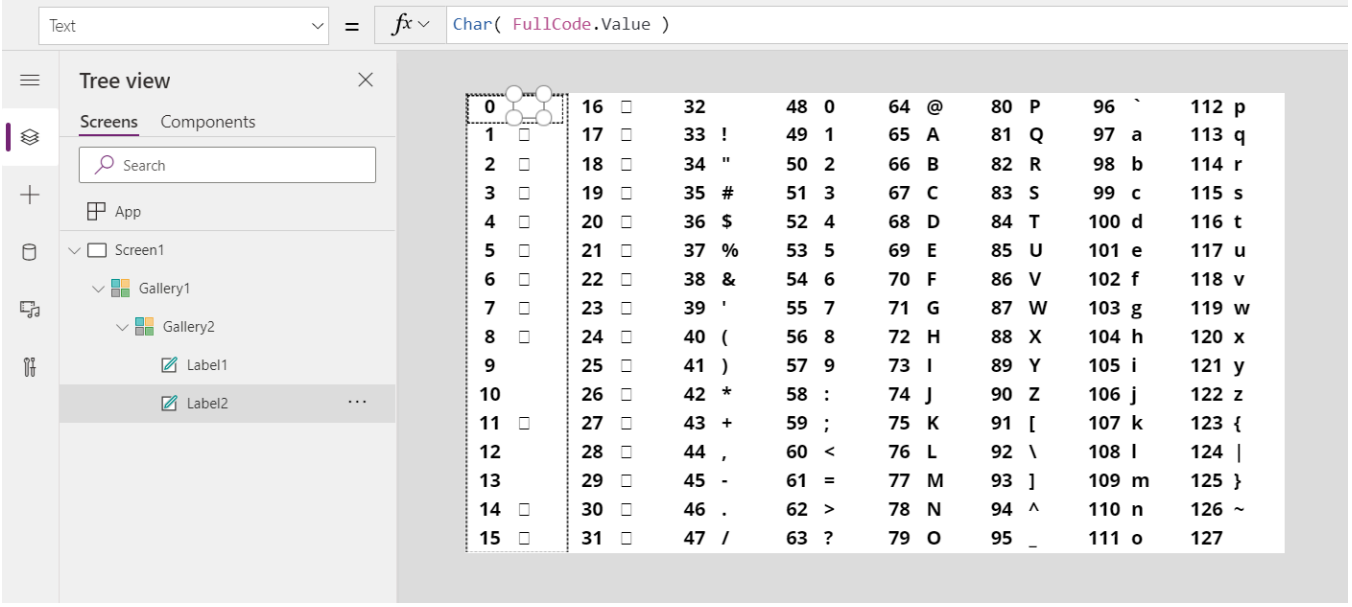
3. Inside the second (vertical) gallery, add a **Label** control, and set these properties:

   - **Text**: `FullCode.Value`
   - **Width**: `Parent.Width / 2`
   - **X**: 0
   - **Y**: 0
   - **Align**: `Center`
   - **FontWeight**: `Bold`
   - **Size**: 24

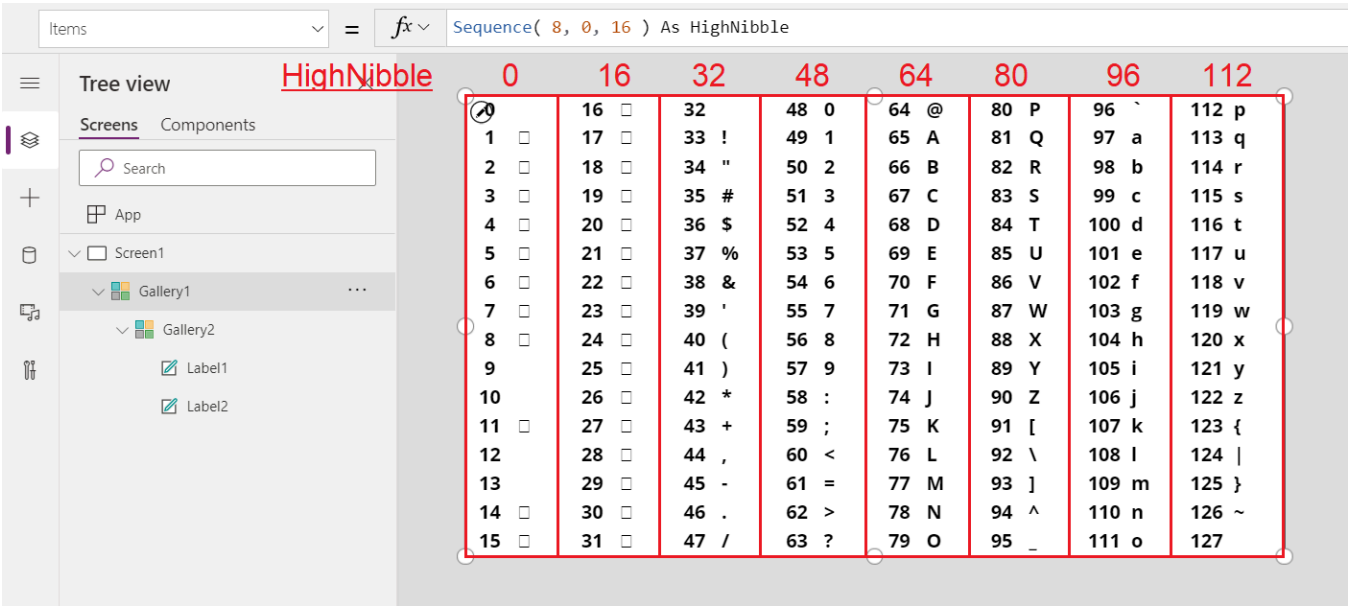
4. Inside the second (vertical) gallery, add another **Label** control, and set these properties:

   - **Text**: `Char( FullCode.Value )`
   - **Width**: `Parent.Width / 2`
   - **X**: `Parent.Width / 2`
   - **Y**: 0
   - **FontWeight**: `Bold`
   - **Size**: 24

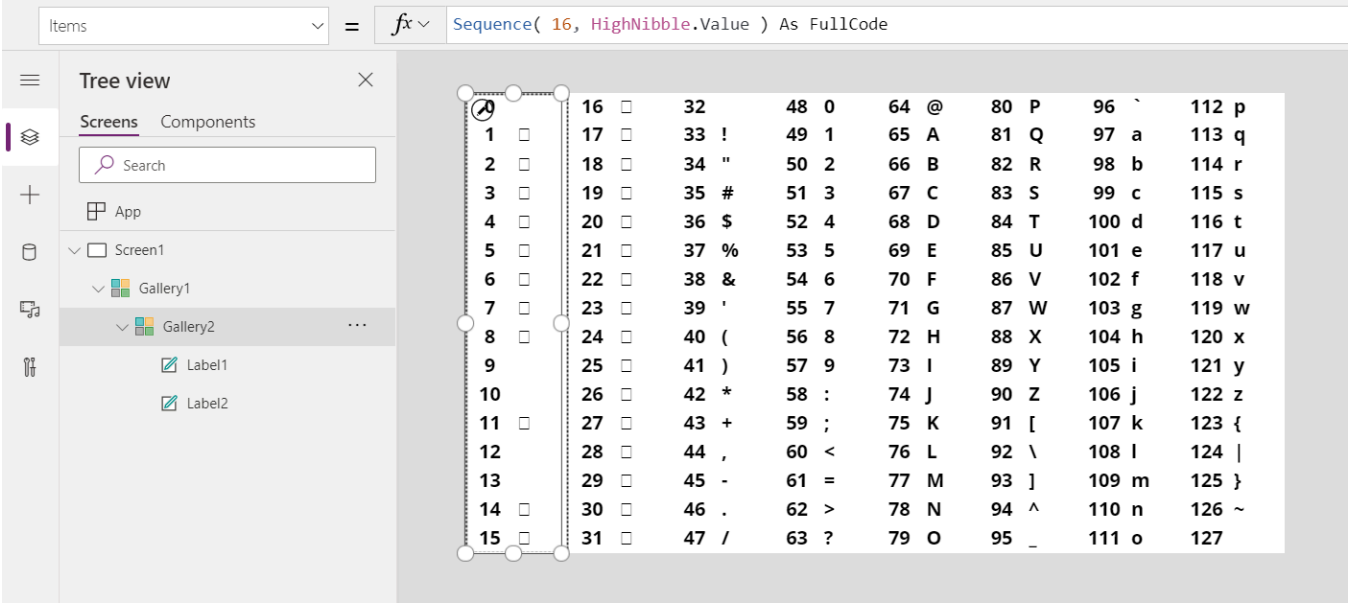
You've created a chart of the first 128 ASCII characters. Characters that appear as a small square can't be printed.



If you want to see how **FullCode.Value** gets its values. Let's begin with the outer horizontal gallery. Its **Items** property uses the **Sequence** function to create 8 columns, starting with 0 with increments of 16:

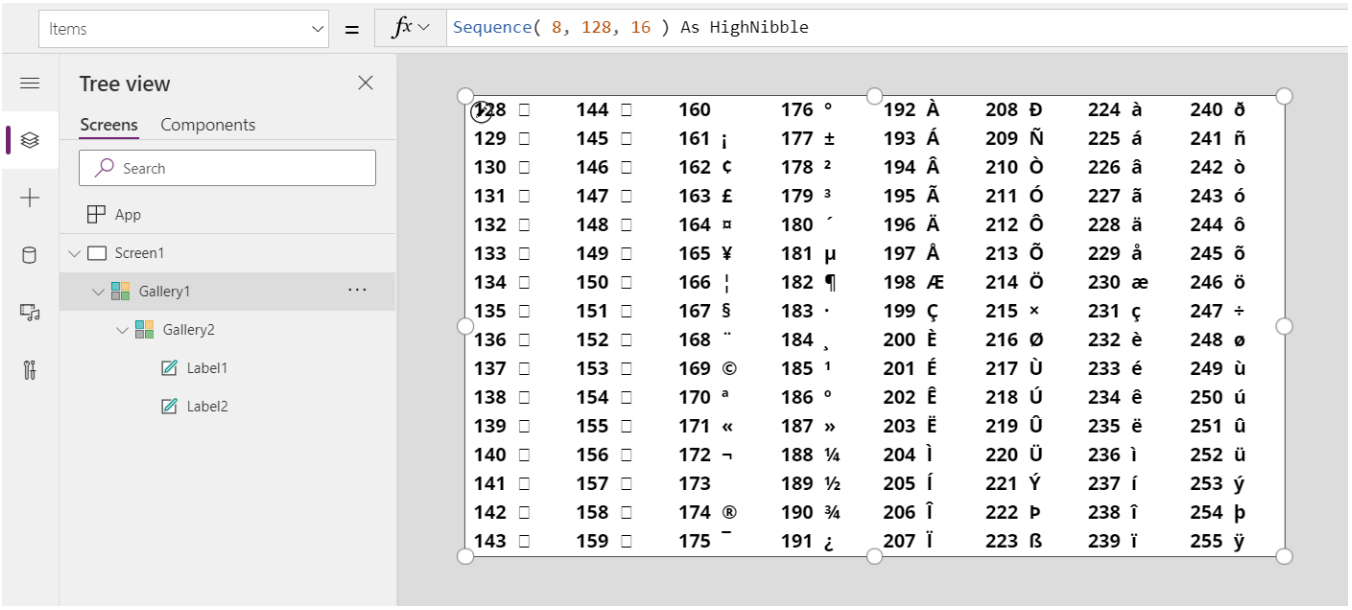


Nested within this gallery is another vertical gallery. Its **Items** property fills in the gap left by the increment of 16 from the outer gallery:



To show the extended ASCII characters, it is a simple matter of changing the starting point for the chart, set in the Sequence function for the outer gallery:

```
Sequence( 8, 128, 16 ) As HighNibble
```



Finally, to show the characters in a different font, set the **Font** property of the second label to a value such as '**Dancing Script**'.

Choices function

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

Returns a table of the possible values for a lookup column.

Description

The **Choices** function returns a table of the possible values for a lookup column.

Use the **Choices** function to provide a list of choices for your user to select from. This function is commonly used with the **Combo box** control in edit forms.

For a lookup, the table that **Choices** returns matches the foreign table that's associated with the lookup. By using **Choices**, you eliminate the need to add the foreign table as an additional data source. **Choices** returns all columns of the foreign table.

Because **Choices** returns a table, you can use **Filter**, **Sort**, **AddColumns**, and all the other table-manipulation functions to filter, sort, and shape the table.

At this time, you can't delegate **Choices**. If this limitation poses a problem in your app, add the foreign table as a data source, and use it directly.

Choices doesn't require column names to be strings and enclosed in double quotes, unlike the **ShowColumns**, **Search**, and other table functions. Provide the formula as if you were referencing the column directly.

Column references must be direct to the data source. For example, if the data source is **Accounts** and the lookup is **SLA**, the column reference would be **Accounts.SLA**. The reference can't pass through a function, a variable, or a control. Furthering this example, if **Accounts** is fed to a **Gallery** control, use the formula **Gallery.Selected.SLA** to reference the SLA for the selected account. However, this reference has passed through a control, so it can't be passed to the **Columns** function - you must still use **Accounts.SLA**.

At this time, you can use lookup columns only with SharePoint and Microsoft Dataverse.

Syntax

Choices(*column-reference* [, *text-filter*])

- *column-reference* - Required. A lookup column of a data source. Don't enclose the column name in double quotes. The reference must be directly to the column of the data source and not pass through a function or a control.
- *text-filter* - Optional. Filters the list of choices by only returning choices that start with the text specified in *text-filter*. If an empty string is specified, all choices will be returned.

Examples

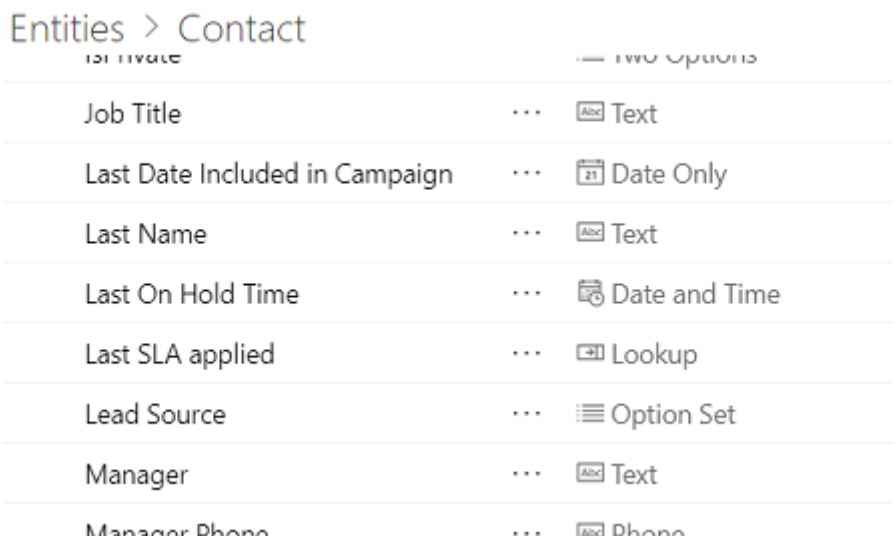
Choices for a lookup

1. Create a database in Dataverse, and select the **Include sample apps and data** box.

   Many tables, such as **Accounts**, are created.

   Note: Table names are singular on make.powerapps.com and plural in Power Apps Studio.

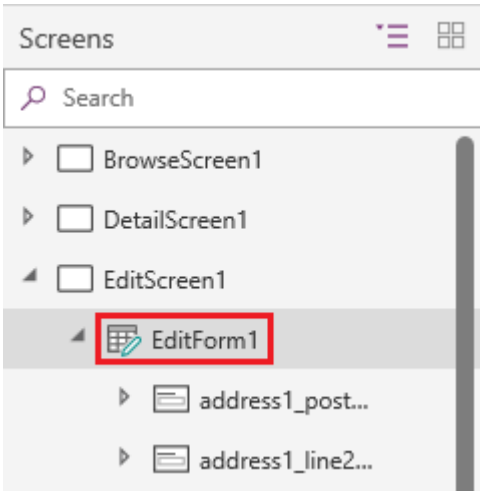
   
   The **Accounts** table has a **Primary Contact** column, which is a lookup to the **Contacts** table.



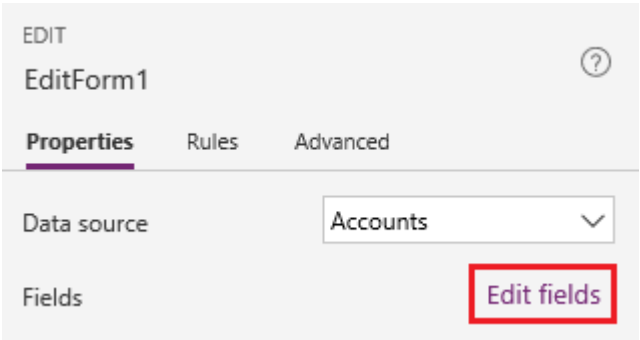
For each account, a contact is designated as the primary contact, or the primary contact is *blank*.

2. Generate an app from the **Accounts** table.

3. In the list of screens and controls near the left edge, scroll down until **EditScreen1** appears, and then select **EditForm1** just under it.

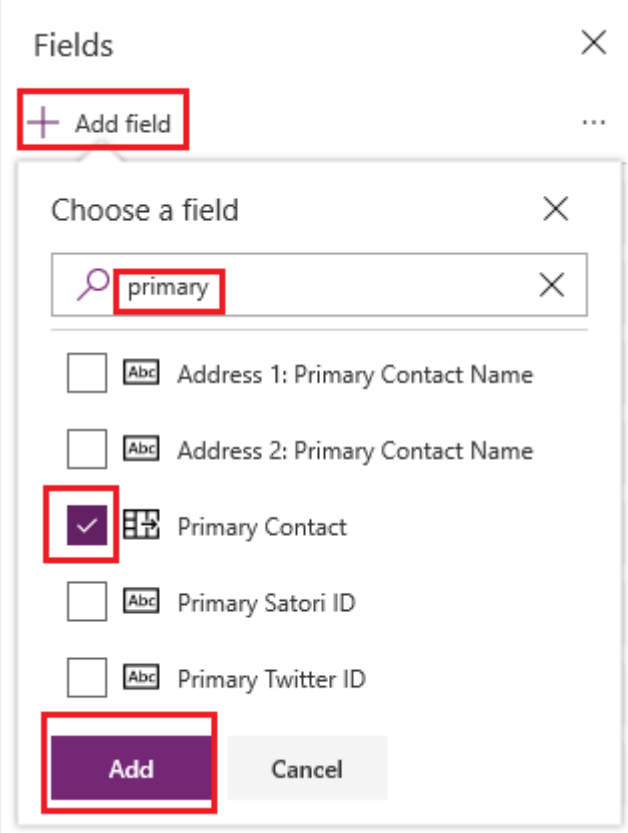


4. On the **Properties** tab of the right pane, select **Edit fields**.



5. In the **Fields** pane, select **Add field**.

6. Search for the **Primary Contact** field, select its check box, and then select **Add**.



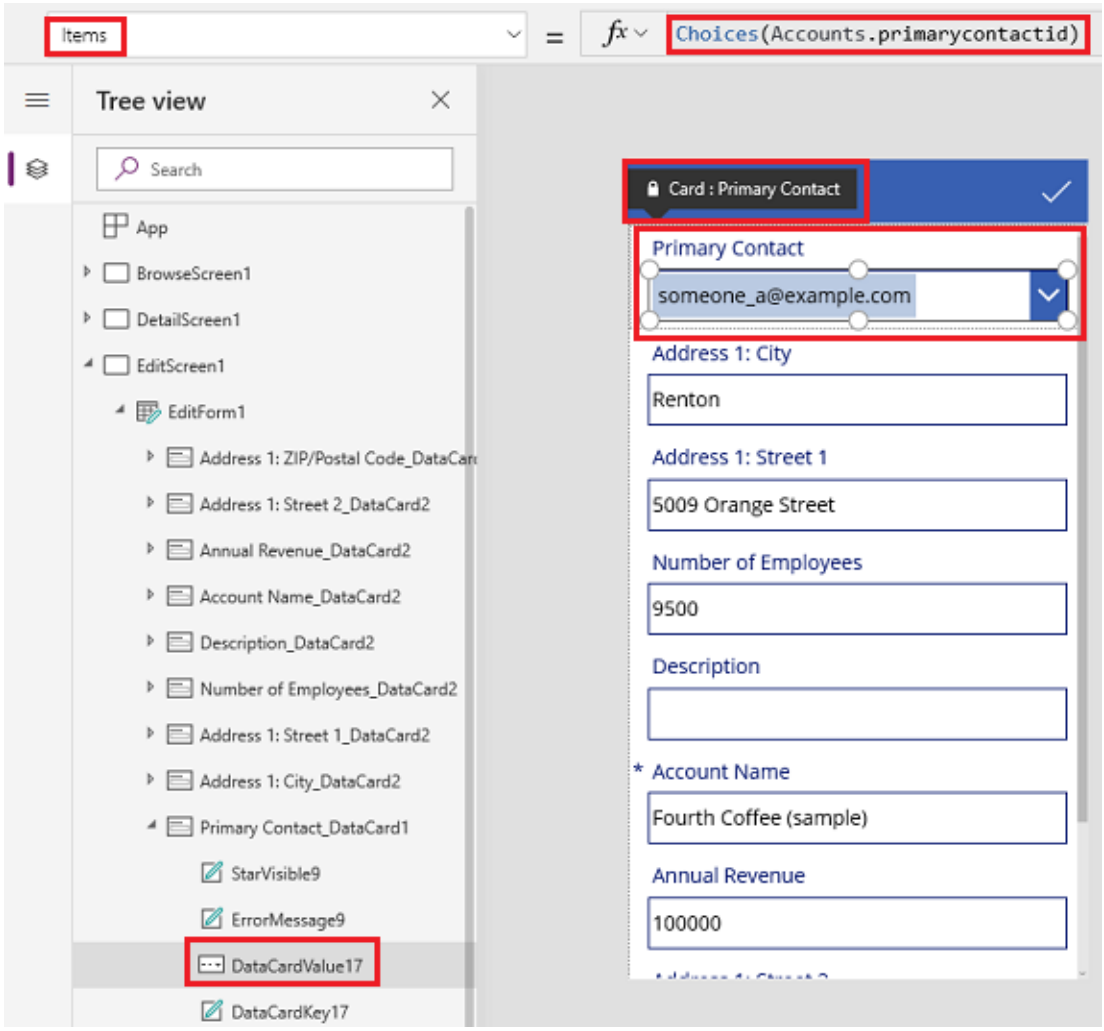
The **Primary Contact** field appears at the bottom of the form. If the field shows an error, select **Data sources** on the **View** tab, select the ellipsis (...) for the **Accounts** data source, and then select **Refresh**.

7. (optional) Drag the **Primary Contact** field from the bottom to the top of the list of fields.

8. In the card for **Primary Contact**, select the **Combo box** control.

   The **Items** property of that control is set to a formula that identifies the column by either its display name, as in the first example, or its logical name, as in the second example:

   - **Choices(Accounts.'Primary Contact')**
   - **Choices(Accounts.primarycontactid)**



9. For illustration purposes, we can view the complete table returned by the **Choices** function in a **Data table** control. On the **Home** tab, select **New screen**, and then select **Blank**.

10. On the **Insert** tab, select **Data table**.

11. Set the **Items** property of the **Data table** control to this formula:

    Choices(Accounts.'Primary Contact')

12. In the middle of the **Data table** control, select the link that starts **Choose the fields...**, and then select the check boxes for the field or fields that you want to show (for example, **firstname** and **lastname**).

Collect, Clear, and ClearCollect functions

Article • 04/11/2024

Creates and clears collections and adds records to any data source.

Collect

Applies to: ✅ Canvas apps ✅ Cards ✅ Dataverse low-code plug-ins ✅ Power Platform CLI ✅ Desktop flows

The **Collect** function adds records to a data source. The items to be added can be:

- A single value: The value is placed in the **Value** field of a new record. All other properties are left blank.
- A record: Each named property is placed in the corresponding property of a new record. All other properties are left blank.
- A table: Each record of the table is added as a separate record of the data source as described above. The table isn't added as a nested table to a record. To do this, wrap the table in a record first.

When used with a collection, additional columns will be created as needed. The columns for other data sources are fixed by the data source and new columns can't be added.

If the data source doesn't already exist, a collection is created.

Collections are sometimes used to hold global variables or make a temporary copy of a data source. Canvas apps are based on formulas that automatically recalculate as the user interacts with an app. Collections don't enjoy this benefit and their use can make your app harder to create and understand. Before using a collection in this manner, review working with variables.

You can also use the **Patch** function to create records in a data source.

Collect returns the modified data source as a table. **Collect** can only be used in a behavior formula.

Clear

Applies to: ✅ Canvas apps

The **Clear** function deletes all the records of a collection. The columns of the collection will remain.

Note that **Clear** only operates on collections and not other data sources. You can use **RemoveIf(*DataSource*, true)** for this purpose. Use caution as this will remove all records from the data source's storage and can affect other users.

You can use the **Remove** function to selectively remove records.

Clear has no return value. It can only be used in a behavior formula.

ClearCollect

Applies to: Canvas apps Model-driven apps

The **ClearCollect** function deletes all the records from a collection. And then adds a different set of records to the same collection. With a single function, **ClearCollect** offers the combination of **Clear** and then **Collect**.

ClearCollect returns the modified collection as a table. **ClearCollect** can only be used in a behavior formula.

Delegation

When used with a data source, these functions can't be delegated. Only the first portion of the data source will be retrieved and then the function applied. The result may not represent the complete story. A warning may appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

Syntax

Collect(*DataSource*, *Item*, ...)

- *DataSource* – Required. The data source that you want to add data to. If it doesn't already exist, a new collection is created.
- *Item(s)* - Required. One or more records or tables to add to the data source.

Clear(*Collection*)

- *Collection* – Required. The collection that you want to clear.

ClearCollect(*Collection*, *Item*, ...)

- *Collection* – Required. The collection that you want to clear and then add data to.
- *Item(s)* - Required. One or more records or tables to add to the data source.

Examples

Clearing and adding records to a data source

In these examples, you'll erase and add to a collection that's named **IceCream**. The data source begins with these contents:

Flavor	Quantity
"Chocolate"	100
"Vanilla"	200

Expand table

Formula	Description	Result
ClearCollect(IceCream, { Flavor: "Strawberry", Quantity: 300 })	Clears all data from the **IceCream** collection and then adds a record that includes a quantity of strawberry ice cream.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Strawberry"</td><td>300</td></tr></table> The **IceCream** collection has also been modified.
Collect(IceCream, { Flavor: "Pistachio", Quantity: 40 }, { Flavor: "Orange", Quantity: 200 })	Adds two records to the **IceCream** collection that includes a quantity of pistachio and orange ice cream.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Strawberry"</td><td>300</td></tr><tr><td>"Pistachio"</td><td>40</td></tr><tr><td>"Orange"</td><td>200</td></tr></table> The **IceCream** collection has also been modified.
Clear(IceCream)	Removes all records from the **IceCream** collection.	<table><tr><th>Flavor</th><th>Quantity</th></tr></table> The **IceCream** collection has also been modified.

For step-by-step examples of how to create a collection, see Create and update a collection.

Records and tables

These examples examine how record and table arguments to **Collect** and **ClearCollect** are handled.

Expand table

Formula	Description	Result
ClearCollect(IceCream, { Flavor: "Chocolate", Quantity: 100 }, { Flavor: "Vanilla", Quantity: 200 })	Clear all data and then adds two records to the **IceCream** collection that includes a quantity of chocolate and vanilla ice cream. The records to be added are provided as individual arguments to the function.	 The **IceCream** collection has also been modified.
ClearCollect(IceCream, Table({ Flavor: "Chocolate", Quantity: 100 }, { Flavor: "Vanilla", Quantity: 200 }))	Same as the previous example except that the records are combined in a table and passed in through a single argument. The contents of the table are extracted record by record before being added to the **IceCream** collection.	 The **IceCream** collection has also been modified.
ClearCollect(IceCream, { MyFavorites: Table({ Flavor: "Chocolate", Quantity: 100 }, { Flavor: "Vanilla", Quantity: 200 }) })	Same as the previous example except that the table is wrapped in a record. The records of the table aren't extracted and instead the entire table is added as a cell of the record.	 The **IceCream** collection has also been modified.

Collect, Clear, and ClearCollect functions

Article • 04/11/2024

Creates and clears collections and adds records to any data source.

Collect

Applies to: ✅ Canvas apps ✅ Cards ✅ Dataverse low-code plug-ins ✅ Power Platform CLI ✅ Desktop flows

The **Collect** function adds records to a data source. The items to be added can be:

- A single value: The value is placed in the **Value** field of a new record. All other properties are left blank.
- A record: Each named property is placed in the corresponding property of a new record. All other properties are left blank.
- A table: Each record of the table is added as a separate record of the data source as described above. The table isn't added as a nested table to a record. To do this, wrap the table in a record first.

When used with a collection, additional columns will be created as needed. The columns for other data sources are fixed by the data source and new columns can't be added.

If the data source doesn't already exist, a collection is created.

Collections are sometimes used to hold global variables or make a temporary copy of a data source. Canvas apps are based on formulas that automatically recalculate as the user interacts with an app. Collections don't enjoy this benefit and their use can make your app harder to create and understand. Before using a collection in this manner, review working with variables.

You can also use the **Patch** function to create records in a data source.

Collect returns the modified data source as a table. **Collect** can only be used in a behavior formula.

Clear

Applies to: ✅ Canvas apps

The **Clear** function deletes all the records of a collection. The columns of the collection will remain.

Note that **Clear** only operates on collections and not other data sources. You can use **RemoveIf(*DataSource*, true)** for this purpose. Use caution as this will remove all records from the data source's storage and can affect other users.

You can use the **Remove** function to selectively remove records.

Clear has no return value. It can only be used in a behavior formula.

ClearCollect

Applies to: Canvas apps Model-driven apps

The **ClearCollect** function deletes all the records from a collection. And then adds a different set of records to the same collection. With a single function, **ClearCollect** offers the combination of **Clear** and then **Collect**.

ClearCollect returns the modified collection as a table. **ClearCollect** can only be used in a behavior formula.

Delegation

When used with a data source, these functions can't be delegated. Only the first portion of the data source will be retrieved and then the function applied. The result may not represent the complete story. A warning may appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. Collect(IceCream, { Flavor: "Pistachio", Quantity: 40 }, { Flavor: "Orange", Quantity: 200 })	Adds two records to the **IceCream** collection that includes a quantity of pistachio and orange ice cream.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Strawberry"</td><td>300</td></tr><tr><td>"Pistachio"</td><td>40</td></tr><tr><td>"Orange"</td><td>200</td></tr></table> The **IceCream** collection has also been modified.
Clear(IceCream)	Removes all records from the **IceCream** collection.	<table><tr><th>Flavor</th><th>Quantity</th></tr></table> The **IceCream** collection has also been modified.

For step-by-step examples of how to create a collection, see Create and update a collection.

Records and tables

These examples examine how record and table arguments to **Collect** and **ClearCollect** are handled.

Expand table

Formula	Description	Result
ClearCollect(IceCream, { Flavor: "Chocolate", Quantity: 100 }, { Flavor: "Vanilla", Quantity: 200 })	Clear all data and then adds two records to the **IceCream** collection that includes a quantity of chocolate and vanilla ice cream. The records to be added are provided as individual arguments to the function.	 The **IceCream** collection has also been modified.
ClearCollect(IceCream, Table({ Flavor: "Chocolate", Quantity: 100 }, { Flavor: "Vanilla", Quantity: 200 }))	Same as the previous example except that the records are combined in a table and passed in through a single argument. The contents of the table are extracted record by record before being added to the **IceCream** collection.	 The **IceCream** collection has also been modified.
ClearCollect(IceCream, { MyFavorites: Table({ Flavor: "Chocolate", Quantity: 100 }, { Flavor: "Vanilla", Quantity: 200 }) })	Same as the previous example except that the table is wrapped in a record. The records of the table aren't extracted and instead the entire table is added as a cell of the record.	 The **IceCream** collection has also been modified.

Calendar and Clock functions

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Retrieves calendar and clock information about the current locale.

Description

The **Calendar** and **Clock** functions are a set of functions that retrieve information about the current locale.

You can use these functions to display dates and times in the language of the current user. The single-column tables returned by **Calendar** and **Clock** functions can be used directly with the **Items** property of Dropdown and Listbox controls.

Expand table

Function	Description
Calendar.MonthsLong()	Single-column table containing the full names of each month, starting with "January".
Calendar.MonthsShort()	Single-column table containing the abbreviated names of each month, starting with "Jan" for January.
Calendar.WeekdaysLong()	Single-column table containing the full names of each weekday, starting with "Sunday".
Calendar.WeekdaysShort()	Single-column table containing the full names of each weekday, starting with "Sun" for Sunday.
Clock.AmPm()	Single-column table containing the long uppercase "AM" and "PM" designations. If the language uses a 24-hour clock, the table will be empty.
Clock.AmPmShort()	Single-column table containing the short uppercase "A" and "P" designations. If the language uses a 24-hour clock, the table will be empty.
Clock.IsClock24()	Boolean indicating if a 24-hour clock is used in this locale.

Use the **Text** function to format date and time values using this same information. The **Language** function returns the current language and region code.

Syntax

Calendar.MonthsLong()

Calendar.MonthsShort()

Calendar.WeekdaysLong()

Calendar.WeekdaysShort()

Clock.AmPm()

Clock.AmPmShort()

Clock.IsClock24()

Examples

1. Insert a Dropdown control.
2. Set the formula for the **Items** property to:
    - **Calendar.MonthsLong()**
3. Users of your app can now select a month in their own language. **MonthsLong** can be replaced with any of the single-column tables that are returned by **Calendar** to create weekday and time selectors.

In the United States, with **Language** returning "en-US", the following is returned by the **Calendar** functions:

Expand table

Formula	Description	Result
Calendar.MonthsLong()	The return value contains the full name of each month, starting with "January".	["January", "February", "March", "April", "May", "June", "July", "August", "September", "October", "November", "December"]
Calendar.MonthsShort()	The return value contains the abbreviated name of each month, starting with "January".	["Jan", "Feb", "Mar", "Apr", "May", "Jun", "Jul", "Aug", "Sep", "Oct", "Nov", "Dec"]
Calendar.WeekdaysLong()	The return value contains the full name of each day, starting	["Sunday", "Monday", "Tuesday", "Wednesday", "Thursday",

Formula	Description	Result
	with "Sunday".	"Friday", "Saturday"]
Calendar.WeekdaysShort()	The return value contains the abbreviated name of each day, starting with "Sunday".	["Sun", "Mon", "Tue", "Wed", "Thu", "Fri", "Sat"]
Clock.AmPm()	This language uses a 12-hour clock. The return value contains the uppercase versions of the full AM and PM designations.	["AM", "PM"]
Clock.AmPmShort()	This language uses a 12-hour clock. The return value contains the uppercase versions of the short AM and PM designations.	["A", "P"]
Clock.IsClock24()	This language uses a 12-hour clock.	**false**

Blank, Coalesce, IsBlank, and IsEmpty functions

06/19/2025

Expand table

Functions	Applies to
Blank	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions
Coalesce **IsEmpty**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
IsBlank	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Tests whether a value is blank or a table contains no records, and provides a way to create *blank* values.

Overview

Blank is a placeholder for "no value" or "unknown value." For example, a **Combo box** control's **Selected** property is *blank* if the user hasn't made a selection. Many data sources can store and return NULL values, which are represented in Power Apps as *blank*.

Any property or calculated value in Power Apps can be *blank*. For example, a Boolean value normally has one of two values: **true** or **false**. But in addition to these two, it can also be *blank* indicating that the state is not known. This is similar to Microsoft Excel, where a worksheet cell starts out as blank with no contents but can hold the values **TRUE** or **FALSE** (among others). At any time, the contents of the cell can again be cleared, returning it to a *blank* state.

Empty string refers to a string that contains no characters. The **Len** function returns zero for such a string and it can be written in a formulas as two double quotes with nothing in between `""`. Some controls and data sources use an empty string to indicate a "no value" condition. To simplify app creation, the **IsBlank** and **Coalesce** functions test for both *blank* values or empty strings.

In the context of the **IsEmpty** function, *empty* is specific to tables that contain no records. The table structure may be intact, complete with column names, but no data is in the table. A table

may start as empty, take on records and no longer be empty, and then have the records removed and again be empty.

Blank

The **Blank** function returns a *blank* value. Use this to store a NULL value in a data source that supports these values, effectively removing any value from the field.

IsBlank

The **IsBlank** function tests for a *blank* value or an empty string. The test includes empty strings to ease app creation since some data sources and controls use an empty string when there is no value present. To test specifically for a *blank* value use `if( Value = Blank(), ...` instead of **IsBlank**. The **IsBlank** function considers empty tables as not blank, and **IsEmpty** should be used to test a table.

When enabling error handling for existing apps, consider replacing **IsBlank** with IsBlankOrError to preserve existing app behavior. Prior to the addition of error handling, a *blank* value was used to represent both null values from databases and error values. Error handling separates these two interpretations of *blank* which could change the behavior of existing apps that continue to use **IsBlank**.

The return value for **IsBlank** is a boolean **true** or **false**.

Coalesce

The **Coalesce** function evaluates its arguments in order and returns the first value that isn't *blank* or an empty string. Use this function to replace a *blank* value or empty string with a different value but leave non-*blank* and non-empty string values unchanged. If all the arguments are *blank* or empty strings then the function returns *blank*, making **Coalesce** a good way to convert empty strings to *blank* values.

`Coalesce( value1, value2 )` is the more concise equivalent of `If( Not IsBlank( value1 ), value1, Not IsBlank( value2 ), value2 )` and doesn't require **value1** and **value2** to be evaluated twice. The **If** function returns *blank* if there is no "else" formula as is the case here.

All arguments to **Coalesce** must be of the same type; for example, you can't mix numbers with text strings. The return value from **Coalesce** is of this common type.

IsEmpty

The **IsEmpty** function tests whether a table contains any records. It's equivalent to using the CountRows function and checking for zero. You can check for data-source errors by combining **IsEmpty** with the Errors function.

The return value for **IsEmpty** is a Boolean **true** or **false**.

Syntax

Blank()

Coalesce(*Value1* [, *Value2*, ...])

- *Value(s)* – Required. Values to test. Each value is evaluated in order until a value that is not *blank* and not an empty string is found. Values after this point are not evaluated.

IsBlank(*Value*)

- *Value* – Required. Value to test for a *blank* value or empty string.

IsEmpty(*Table*)

- *Table* - Required. Table to test for records.

Examples

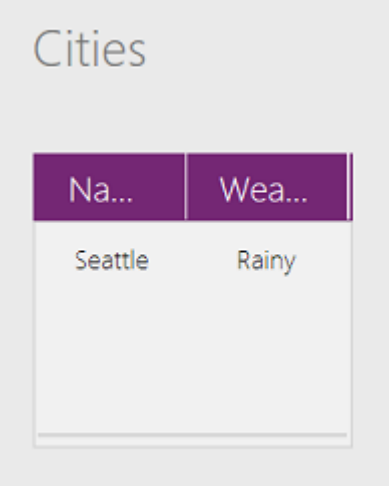
Blank

1. Create an app from scratch, and add a **Button** control.
2. Set the button's OnSelect property to this formula:

   ```
   Power Fx
   ClearCollect( Cities, { Name: "Seattle", Weather: "Rainy" } )
   ```

3. Preview your app, click or tap the button that you added, and then close Preview.
4. On the **File** menu, click or tap **Collections**.

   The **Cities** collection appears, showing one record with "Seattle" and "Rainy":



5. Click or tap the back arrow to return to the default workspace.

6. Add a **Label** control, and set its **Text** property to this formula:

```
Power Fx
IsBlank( First( Cities ).Weather )
```

   The label shows **false** because the **Weather** field contains a value ("Rainy").

7. Add a second button, and set its **OnSelect** property to this formula:

```
Power Fx
Patch( Cities, First( Cities ), { Weather: Blank() } )
```

8. Preview your app, click or tap the button that you added, and then close Preview.

   The **Weather** field of the first record in **Cities** is replaced with a *blank*, removing the "Rainy" that was there previously.

   The label shows **true** because the **Weather** field no longer contains a value.

Coalesce

Expand table

Formula	Description	Result
Coalesce(Blank(), 1)	Tests the return value from the **Blank** function, which always returns a *blank* value. Because the first argument is *blank*, evaluation continues with the next argument until a non-*blank* value and non-empty string is found.	**1**
Coalesce("", "2")	Tests the first argument which is an empty string. Because the first argument is an empty string, evaluation continues with the next argument until a non-*blank* value and non-empty string is found.	**2**
Coalesce(Blank(), "", Blank(), "", "3", "4")	**Coalesce** starts at the beginning of the argument list and evaluates each argument in turn until a non-*blank* value and non-empty string is found. In this case, the first four arguments all return *blank* or an empty string, so evaluation continues to the fifth argument. The fifth argument is non-*blank* and non-empty string, so evaluation stops here. The value of the fifth argument is returned, and the sixth argument isn't evaluated.	**3**
Coalesce("")	Tests the first argument which is an empty string. Because the first argument is an empty string, and there are no more arguments, the function returns *blank*.	*blank*

IsBlank

1. Create an app from scratch, add a text-input control, and name it **FirstName**.
2. Add a label, and set its **Text** property to this formula:

   ```
   Power Fx
   ```

   ```
   If( IsBlank( FirstName.Text ), "First Name is a required field." )
   ```

   By default, the **Text** property of a text-input control is set to **"Text input"**. Because the property contains a value, it isn't blank, and the label doesn't display any message.
3. Remove all the characters from the text-input control, including any spaces.

   Because the **Text** property no longer contains any characters, it's an empty string, and **IsBlank(FirstName.Text)** will be **true**. The required field message is displayed.

For information about how to perform validation by using other tools, see the **Validate** function and working with data sources.

Other examples:

Expand table

Formula	Description	Result
IsBlank(Blank())	Tests the return value from the **Blank** function, which always returns a *blank* value.	**true**
IsBlank("")	A string that contains no characters.	**true**
IsBlank("Hello")	A string that contains one or more characters.	**false**
IsBlank(*AnyCollection*)	Because the collection exists, it isn't blank, even if it doesn't contain any records. To check for an empty collection, use **IsEmpty** instead.	**false**
IsBlank(Mid("Hello", 17, 2))	The starting character for **Mid** is beyond the end of the string. The result is an empty string.	**true**
IsBlank(If(false, false))	An **If** function with no *ElseResult*. Because the condition is always **false**, this **If** always returns *blank*.	**true**

IsEmpty

1. Create an app from scratch, and add a **Button** control.
2. Set the button's **OnSelect** property to this formula:

   Collect(IceCream, { Flavor: "Strawberry", Quantity: 300 }, { Flavor: "Chocolate", Quantity: 100 })
3. Preview your app, click or tap the button that you added, and then close Preview.

   A collection named **IceCream** is created and contains this data:

Flavor	Quantity
"Strawberry"	300
"Chocolate"	100

   This collection has two records and isn't empty. **IsEmpty(IceCream)** returns **false**, and **CountRows(IceCream)** returns **2**.
4. Add a second button, and set its **OnSelect** property to this formula:

   Clear(IceCream)
5. Preview your app, click or tap the second button, and then close Preview.

The collection is now empty:

Flavor	Quantity

The Clear function removes all the records from a collection, resulting in an empty collection. **IsEmpty(IceCream)** returns **true**, and **CountRows(IceCream)** returns **0**.

You can also use **IsEmpty** to test whether a calculated table is empty, as these examples show:

Expand table

Formula	Description	Result
IsEmpty([1, 2, 3])	The single-column table contains three records and, therefore, isn't empty.	**false**
IsEmpty([ ])	The single-column table contains no records and is empty.	**true**
IsEmpty(Filter([1, 2, 3], Value > 5))	The single-column table contains no values that are greater than 5. The result from the filter doesn't contain any records and is empty.	**true**

Collect, Clear, and ClearCollect functions

Article • 04/11/2024

Creates and clears collections and adds records to any data source.

Collect

Applies to: ✅ Canvas apps ✅ Cards ✅ Dataverse low-code plug-ins ✅ Power Platform CLI ✅ Desktop flows

The **Collect** function adds records to a data source. The items to be added can be:

- A single value: The value is placed in the **Value** field of a new record. All other properties are left blank.
- A record: Each named property is placed in the corresponding property of a new record. All other properties are left blank.
- A table: Each record of the table is added as a separate record of the data source as described above. The table isn't added as a nested table to a record. To do this, wrap the table in a record first.

When used with a collection, additional columns will be created as needed. The columns for other data sources are fixed by the data source and new columns can't be added.

If the data source doesn't already exist, a collection is created.

Collections are sometimes used to hold global variables or make a temporary copy of a data source. Canvas apps are based on formulas that automatically recalculate as the user interacts with an app. Collections don't enjoy this benefit and their use can make your app harder to create and understand. Before using a collection in this manner, review working with variables.

You can also use the **Patch** function to create records in a data source.

Collect returns the modified data source as a table. **Collect** can only be used in a behavior formula.

Clear

Applies to: ✅ Canvas apps

The **Clear** function deletes all the records of a collection. The columns of the collection will remain.

Note that **Clear** only operates on collections and not other data sources. You can use **RemoveIf(*DataSource*, true)** for this purpose. Use caution as this will remove all records from the data source's storage and can affect other users.

You can use the **Remove** function to selectively remove records.

Clear has no return value. It can only be used in a behavior formula.

ClearCollect

Applies to: Canvas apps Model-driven apps

The **ClearCollect** function deletes all the records from a collection. And then adds a different set of records to the same collection. With a single function, **ClearCollect** offers the combination of **Clear** and then **Collect**.

ClearCollect returns the modified collection as a table. **ClearCollect** can only be used in a behavior formula.

Delegation

When used with a data source, these functions can't be delegated. Only the first portion of the data source will be retrieved and then the function applied. The result may not represent the complete story. A warning may appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

Syntax

Collect(*DataSource*, *Item*, ...)

- *DataSource* – Required. The data source that you want to add data to. If it doesn't already exist, a new collection is created.
- *Item(s)* - Required. One or more records or tables to add to the data source.

Clear(*Collection*)

- *Collection* – Required. The collection that you want to clear.

ClearCollect(*Collection*, *Item*, ...)

- *Collection* – Required. The collection that you want to clear and then add data to.
- *Item(s)* - Required. One or more records or tables to add to the data source.

Examples

Clearing and adding records to a data source

In these examples, you'll erase and add to a collection that's named **IceCream**. The data source begins with these contents:

Flavor	Quantity
"Chocolate"	100
"Vanilla"	200

Expand table

Formula	Description	Result
ClearCollect(IceCream, { Flavor: "Strawberry", Quantity: 300 })	Clears all data from the **IceCream** collection and then adds a record that includes a quantity of strawberry ice cream.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Strawberry"</td><td>300</td></tr></table> The **IceCream** collection has also been modified.
Collect(IceCream, { Flavor: "Pistachio", Quantity: 40 }, { Flavor: "Orange", Quantity: 200 })	Adds two records to the **IceCream** collection that includes a quantity of pistachio and orange ice cream.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Strawberry"</td><td>300</td></tr><tr><td>"Pistachio"</td><td>40</td></tr><tr><td>"Orange"</td><td>200</td></tr></table> The **IceCream** collection has also been modified.
Clear(IceCream)	Removes all records from the **IceCream** collection.	<table><tr><th>Flavor</th><th>Quantity</th></tr></table> The **IceCream** collection has also been modified.

For step-by-step examples of how to create a collection, see Create and update a collection.

Records and tables

These examples examine how record and table arguments to **Collect** and **ClearCollect** are handled.

Expand table

Formula	Description	Result
ClearCollect(IceCream, { Flavor: "Chocolate", Quantity: 100 }, { Flavor: "Vanilla", Quantity: 200 })	Clear all data and then adds two records to the **IceCream** collection that includes a quantity of chocolate and vanilla ice cream. The records to be added are provided as individual arguments to the function.	 The **IceCream** collection has also been modified.
ClearCollect(IceCream, Table({ Flavor: "Chocolate", Quantity: 100 }, { Flavor: "Vanilla", Quantity: 200 }))	Same as the previous example except that the records are combined in a table and passed in through a single argument. The contents of the table are extracted record by record before being added to the **IceCream** collection.	 The **IceCream** collection has also been modified.
ClearCollect(IceCream, { MyFavorites: Table({ Flavor: "Chocolate", Quantity: 100 }, { Flavor: "Vanilla", Quantity: 200 }) })	Same as the previous example except that the table is wrapped in a record. The records of the table aren't extracted and instead the entire table is added as a cell of the record.	 The **IceCream** collection has also been modified.

Color enumeration and ColorFade, ColorValue, and RGBA functions

06/19/2025

Expand table

Functions	Applies to
Color	✅ Model-driven apps
ColorFade **ColorValue**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions
RGBA	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Use built-in color values, define custom colors, and use the alpha channel to control transparency.

> ⓘ Note
>
> PAC CLI pac power-fx commands don't support the **Color** enumeration.

Description

Use the **Color** enumeration to access colors defined by HTML's Cascading Style Sheets (CSS). For example, **Color.Red** returns pure red. A list of these colors appears at the end of this article.

The **ColorValue** function returns a color based on a CSS color string. The string can be in any of these forms:

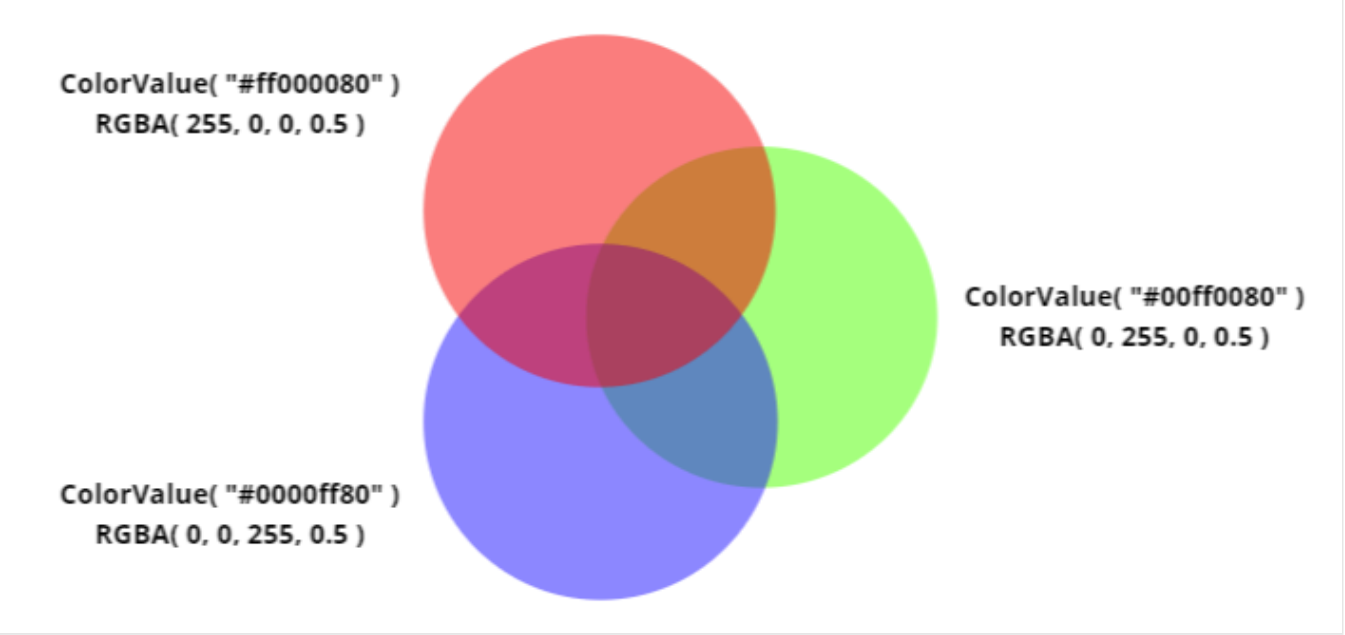
- **CSS color name:** **"RoxyBrown"** and **"OliveDrab"** are examples. These names don't include spaces. The list of supported colors appears later in this article.
- **6-digit hex value:** For example, **"#ffd700"** is the same as **"Gold"**. The string uses the format "*#rrggbb*", where *rr* is the red portion in two hexadecimal digits, *gg* is the green, and *bb* is the blue.
- **8-digit hex value:** For example, **"#ff7f5080"** is the same as **"Coral"** with a 50% alpha channel. The string uses the format "*#rrggbbaa*", where *rr*, *gg*, and *bb* are identical to the 6-digit form. The alpha channel is represented by *aa*: **00** means fully transparent, and **ff** means fully opaque.

The **RGBA** function returns a color based on red, green, and blue components. The function also includes an alpha channel for mixing colors of controls layered in front of each other. The alpha channel ranges from 0% or 0% (fully transparent and invisible) to 1% or 100% (fully opaque and completely blocks any layers behind a control).

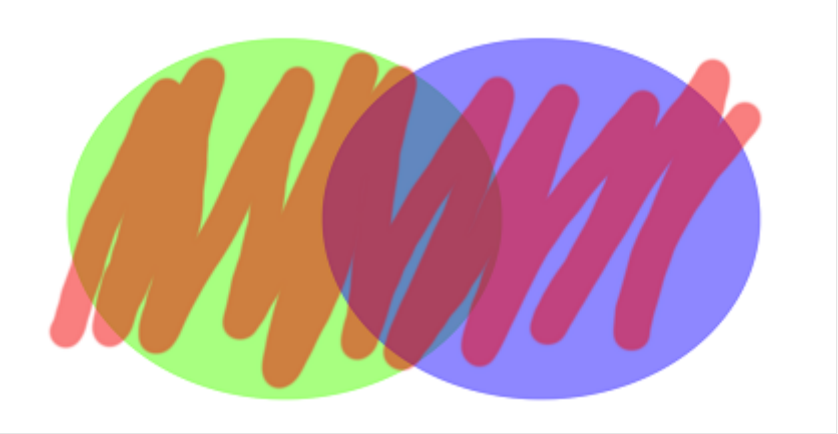
The **ColorFade** function returns a brighter or darker version of a color. The amount of fade ranges from -1 (fully darkens a color to black), to 0 (doesn't affect the color), to 1 (fully brightens a color to white).

Alpha channel

In a canvas app, you layer controls in front of one another and set the transparency of a control to any controls behind it. As a result, colors blend through the layers. For example, this diagram shows how the three primary colors mix with an alpha setting of 50 percent:



You can also blend images in file formats that support alpha channels. For example, you can't blend .jpeg files, but you can blend .png files. The next graphic shows the same red, green, and blue colors from the previous example, but the red color appears as a squiggle (instead of a circle) in a .png file with a 50 percent alpha channel:



If you specify a **Color** enumeration value or build a **ColorValue** formula with a color name or a 6-digit hexadecimal value, the alpha setting is 100 percent, which is fully opaque.

Syntax

Color.*ColorName*

- *ColorName* - Required. A Cascading Style Sheet (CSS) color name. The list of possible enumeration values is at the end of this article.

ColorValue(*CSSColor*)

- *CSSColor* - Required. A Cascading Style Sheet (CSS) color definition. S name, OliveDralike a hex value, like **#6b8e23** olikeffd420**. Hex values can use either #_rrggbb__usgormat. format

ColorValue(*Dynamic*)

- *Dynamic* - Required. A **Dynamic** value with a string that represents a Cascading Style Sheet (CSS) color definition.

RGBA(*Red*, *Green*, *Blue*, *Alpha*)

- *Red*, *Green*, *Blue* - Required. Color component values that range from 0 (no saturation) to 255 (full saturation).
- *Alpha* - Required. Alpha component that ranges from 0 (fully transparent) to 1 (fully opaque). You can also use a percentage, 0% to 100%.

ColorFade(*Color*, *FadeAmount*)

- *Color* - Required. A color value like **Color.Red** or the output from **ColorValue** or **RGBA**.
- *FadeAmount* - Required. A number between -1 and 1. -1 fully darkens a color to black, 0 doesn't affect the color, and 1 fully brightens a color to white. You can also use a percentage, from -100% to 100%.

Color enumeration and ColorFade, ColorValue, and RGBA functions

06/19/2025

Expand table

Functions	Applies to
Color	✅ Model-driven apps
ColorFade **ColorValue**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions
RGBA	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Use built-in color values, define custom colors, and use the alpha channel to control transparency.

> ⓘ Note
>
> PAC CLI pac power-fx commands don't support the **Color** enumeration.

Description

Use the **Color** enumeration to access colors defined by HTML's Cascading Style Sheets (CSS). For example, **Color.Red** returns pure red. A list of these colors appears at the end of this article.

The **ColorValue** function returns a color based on a CSS color string. The string can be in any of these forms:

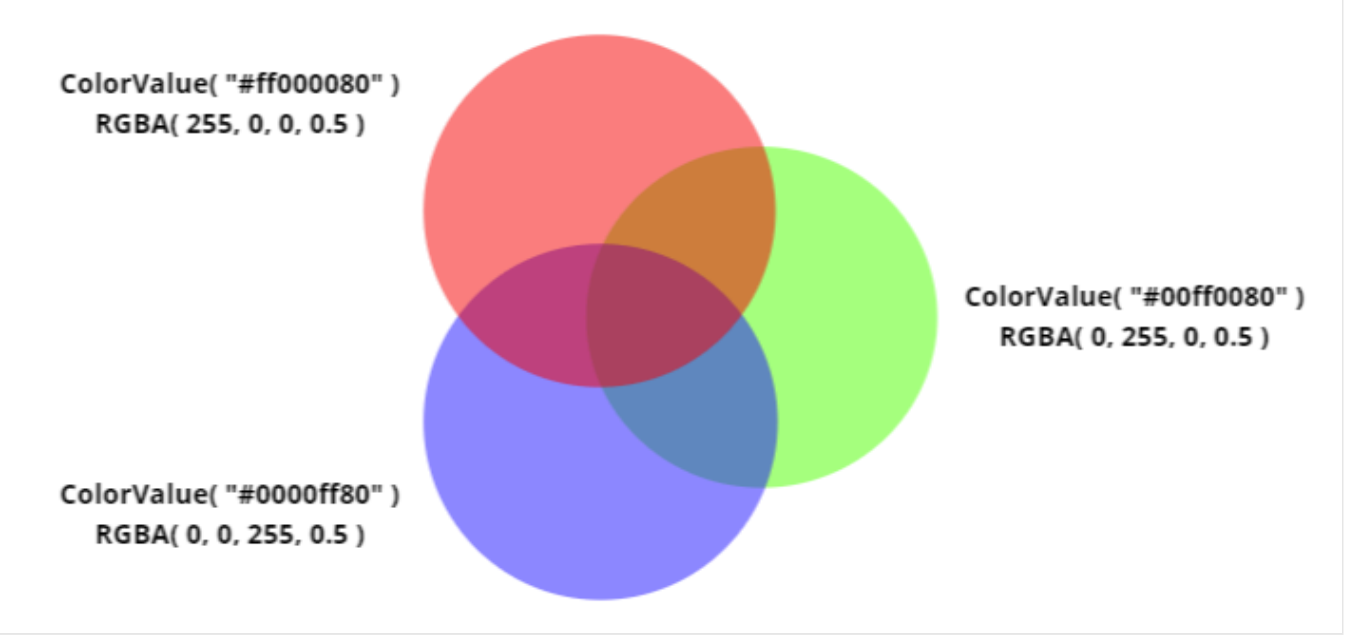
- **CSS color name:** **"RoxyBrown"** and **"OliveDrab"** are examples. These names don't include spaces. The list of supported colors appears later in this article.
- **6-digit hex value:** For example, **"#ffd700"** is the same as **"Gold"**. The string uses the format "*#rrggbb*", where *rr* is the red portion in two hexadecimal digits, *gg* is the green, and *bb* is the blue.
- **8-digit hex value:** For example, **"#ff7f5080"** is the same as **"Coral"** with a 50% alpha channel. The string uses the format "*#rrggbbaa*", where *rr*, *gg*, and *bb* are identical to the 6-digit form. The alpha channel is represented by *aa*: **00** means fully transparent, and **ff** means fully opaque.

The **RGBA** function returns a color based on red, green, and blue components. The function also includes an alpha channel for mixing colors of controls layered in front of each other. The alpha channel ranges from 0% or 0% (fully transparent and invisible) to 1% or 100% (fully opaque and completely blocks any layers behind a control).

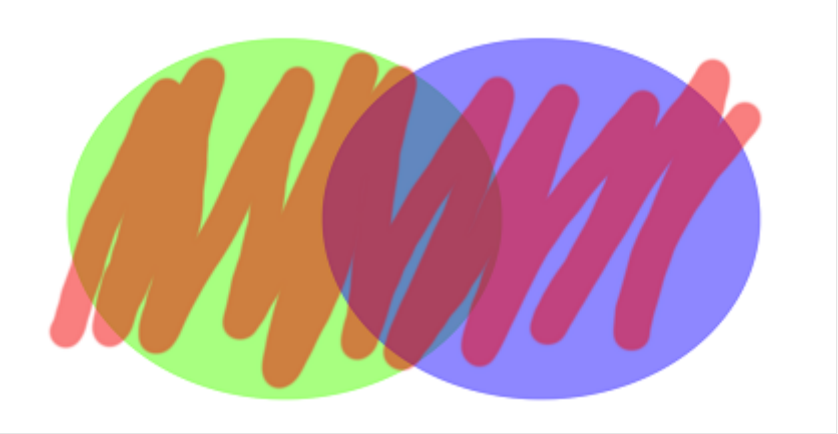
The **ColorFade** function returns a brighter or darker version of a color. The amount of fade ranges from -1 (fully darkens a color to black), to 0 (doesn't affect the color), to 1 (fully brightens a color to white).

Alpha channel

In a canvas app, you layer controls in front of one another and set the transparency of a control to any controls behind it. As a result, colors blend through the layers. For example, this diagram shows how the three primary colors mix with an alpha setting of 50 percent:



You can also blend images in file formats that support alpha channels. For example, you can't blend .jpeg files, but you can blend .png files. The next graphic shows the same red, green, and blue colors from the previous example, but the red color appears as a squiggle (instead of a circle) in a .png file with a 50 percent alpha channel:



If you specify a **Color** enumeration value or build a **ColorValue** formula with a color name or a 6-digit hexadecimal value, the alpha setting is 100 percent, which is fully opaque.

Syntax

Color.*ColorName*

- *ColorName* - Required. A Cascading Style Sheet (CSS) color name. The list of possible enumeration values is at the end of this article.

ColorValue(*CSSColor*)

- *CSSColor* - Required. A Cascading Style Sheet (CSS) color definition. S name, OliveDralike a hex value, like **#6b8e23** olikeffd420**. Hex values can use either #_rrggbb__usgormat. format

ColorValue(*Dynamic*)

- *Dynamic* - Required. A **Dynamic** value with a string that represents a Cascading Style Sheet (CSS) color definition.

RGBA(*Red*, *Green*, *Blue*, *Alpha*)

- *Red*, *Green*, *Blue* - Required. Color component values that range from 0 (no saturation) to 255 (full saturation).
- *Alpha* - Required. Alpha component that ranges from 0 (fully transparent) to 1 (fully opaque). You can also use a percentage, 0% to 100%.

ColorFade(*Color*, *FadeAmount*)

- *Color* - Required. A color value like **Color.Red** or the output from **ColorValue** or **RGBA**.
- *FadeAmount* - Required. A number between -1 and 1. -1 fully darkens a color to black, 0 doesn't affect the color, and 1 fully brightens a color to white. You can also use a percentage, from -100% to 100%.

Color enumeration and ColorFade, ColorValue, and RGBA functions

06/19/2025

Expand table

Functions	Applies to
Color	✅ Model-driven apps
ColorFade **ColorValue**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions
RGBA	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Use built-in color values, define custom colors, and use the alpha channel to control transparency.

> ⓘ Note
>
> PAC CLI pac power-fx commands don't support the **Color** enumeration.

Description

Use the **Color** enumeration to access colors defined by HTML's Cascading Style Sheets (CSS). For example, **Color.Red** returns pure red. A list of these colors appears at the end of this article.

The **ColorValue** function returns a color based on a CSS color string. The string can be in any of these forms:

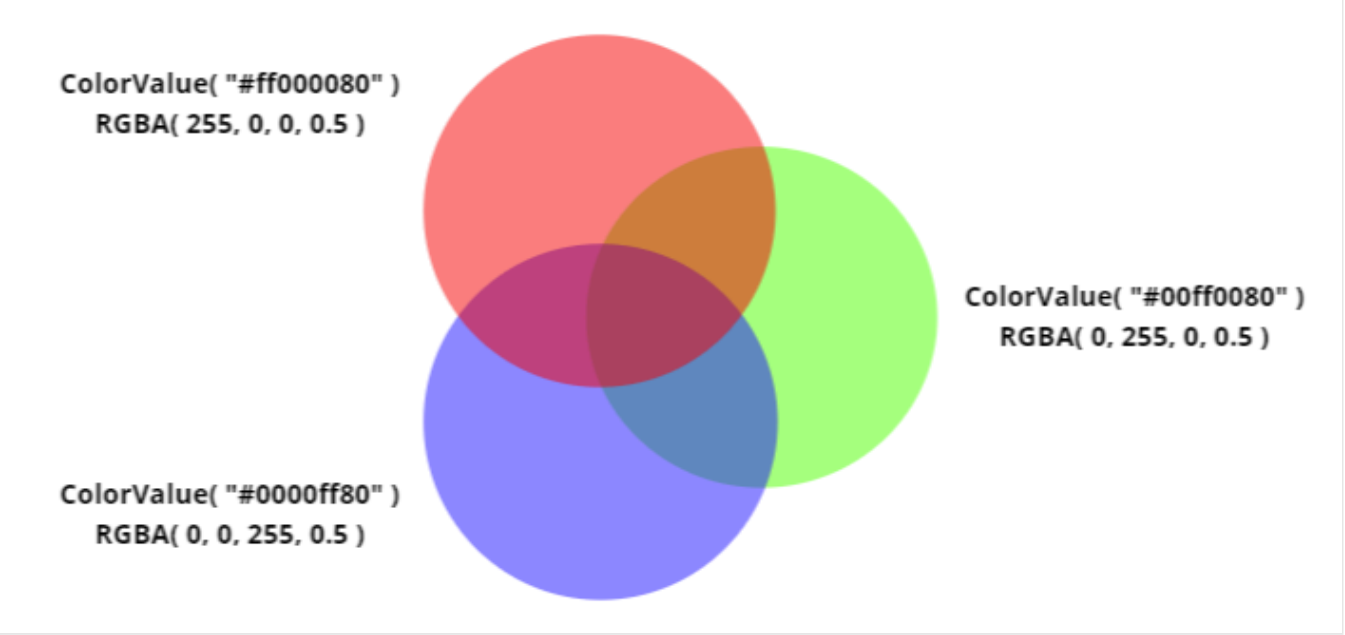
- **CSS color name:** **"RoxyBrown"** and **"OliveDrab"** are examples. These names don't include spaces. The list of supported colors appears later in this article.
- **6-digit hex value:** For example, **"#ffd700"** is the same as **"Gold"**. The string uses the format "*#rrggbb*", where *rr* is the red portion in two hexadecimal digits, *gg* is the green, and *bb* is the blue.
- **8-digit hex value:** For example, **"#ff7f5080"** is the same as **"Coral"** with a 50% alpha channel. The string uses the format "*#rrggbbaa*", where *rr*, *gg*, and *bb* are identical to the 6-digit form. The alpha channel is represented by *aa*: **00** means fully transparent, and **ff** means fully opaque.

The **RGBA** function returns a color based on red, green, and blue components. The function also includes an alpha channel for mixing colors of controls layered in front of each other. The alpha channel ranges from 0% or 0% (fully transparent and invisible) to 1% or 100% (fully opaque and completely blocks any layers behind a control).

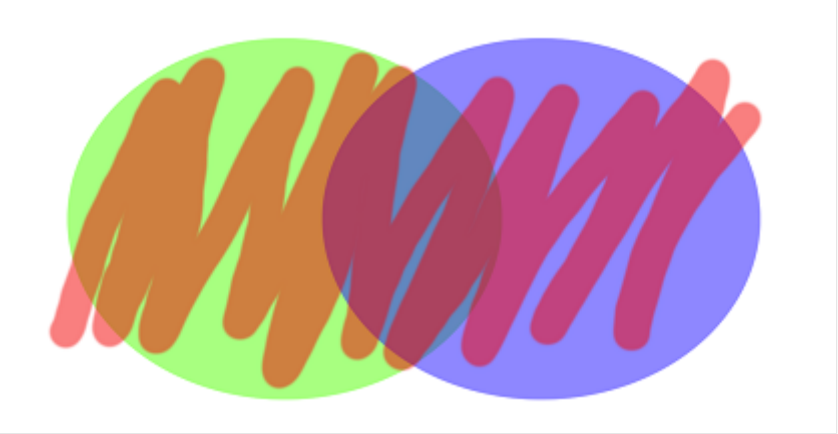
The **ColorFade** function returns a brighter or darker version of a color. The amount of fade ranges from -1 (fully darkens a color to black), to 0 (doesn't affect the color), to 1 (fully brightens a color to white).

Alpha channel

In a canvas app, you layer controls in front of one another and set the transparency of a control to any controls behind it. As a result, colors blend through the layers. For example, this diagram shows how the three primary colors mix with an alpha setting of 50 percent:



You can also blend images in file formats that support alpha channels. For example, you can't blend .jpeg files, but you can blend .png files. The next graphic shows the same red, green, and blue colors from the previous example, but the red color appears as a squiggle (instead of a circle) in a .png file with a 50 percent alpha channel:



If you specify a **Color** enumeration value or build a **ColorValue** formula with a color name or a 6-digit hexadecimal value, the alpha setting is 100 percent, which is fully opaque.

Syntax

Color.*ColorName*

- *ColorName* - Required. A Cascading Style Sheet (CSS) color name. The list of possible enumeration values is at the end of this article.

ColorValue(*CSSColor*)

- *CSSColor* - Required. A Cascading Style Sheet (CSS) color definition. S name, OliveDralike a hex value, like **#6b8e23** olikeffd420**. Hex values can use either #_rrggbb__usgormat. format

ColorValue(*Dynamic*)

- *Dynamic* - Required. A **Dynamic** value with a string that represents a Cascading Style Sheet (CSS) color definition.

RGBA(*Red*, *Green*, *Blue*, *Alpha*)

- *Red*, *Green*, *Blue* - Required. Color component values that range from 0 (no saturation) to 255 (full saturation).
- *Alpha* - Required. Alpha component that ranges from 0 (fully transparent) to 1 (fully opaque). You can also use a percentage, 0% to 100%.

ColorFade(*Color*, *FadeAmount*)

- *Color* - Required. A color value like **Color.Red** or the output from **ColorValue** or **RGBA**.
- *FadeAmount* - Required. A number between -1 and 1. -1 fully darkens a color to black, 0 doesn't affect the color, and 1 fully brightens a color to white. You can also use a percentage, from -100% to 100%.

Acceleration, App, Compass, Connection, and Location signals in Power Apps

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

Returns information about the app's environment, such as where the user is located in the world and which screen is displayed.

Description and syntax

Signals are values that can change at any time, independent of how the user may be interacting with the app. Formulas that are based on signals automatically recalculate as these values change.

Signals typically return a record of information. You can use and store this information as a record, or you can extract individual properties by using the . operator.

> **Note**
>
> The **Acceleration** and **Compass** functions return accurate values in a native player such as on iOS or Android, but those functions return zero values as you create or modify an app in the browser.

Acceleration

The **Acceleration** signal returns the device's acceleration in three dimensions relative to the device's screen. Acceleration is measured in *g* units of 9.81 m/second^2 or 32.2 ft/second^2 (the acceleration that the Earth imparts to objects at its surface due to gravity).

Expand table

Property	Description
Acceleration.X	Right and left. Right is a positive number.
Acceleration.Y	Forward and back. Forward is a positive number.

Property	Description
Acceleration.Z	Up and down. Up is a positive number.

App

Among other properties, the **App** object includes a signal that indicates which screen is showing.

Expand table

Property	Description
App.ActiveScreen	Screen that's showing. Returns a screen object, which you can use to reference properties of the screen or compare to another screen to determine which screen is showing. You can use the **Back** or **Navigate** function to change the screen that's showing.

More information: **App** object documentation.

Compass

The **Compass** signal returns the compass heading of the top of the screen. The heading is based on magnetic north.

Expand table

Property	Description
Compass.Heading	Heading in degrees. Returns a number 0 to 360, and 0 is north.

Connection

The **Connection** signal returns the information about the network connection. When on a metered connection, you may want to limit how much data you send or receive over the network. Or, if your app is enabled for offline, you may want to display different information depending on the current sync state.

Expand table

Property	Description
Connection.Connected	Returns a Boolean **true** or **false** value that indicates whether the device is connected to a network.
Connection.Metered	Returns a Boolean **true** or **false** value that indicates whether the connection is metered.
Connection.Sync	Returns an enum named **ConnectionSync** which holds the current synchronization state for an app that is enabled for offline.

Below are the enums values available for Connection.Sync.

Expand table

Enum value	Description
Connected	Your device is connected to the network and your app is ready to work offline
ConnectedWithWarning	Your device is connected with a warning.
ConnectedPendingUpsync	Some data on your device must be synchronized with the service.
ConnectedError	There was an error on the last synchronization attempt.
ConnectedRefresh	Your app is currently synchronizing data with the service.
NotConnected	Your device isn't connected to the service.
NotConnectedWithWarning	The last synchronization warning.
NotConnectedPendingUpsync	There are updates on your device waiting to be synchronized.
NotConnectedSyncError	The last synchronization error.

Location

The **Location** signal returns the location of the device based on the Global Positioning System (GPS) and other device information, such as cell-tower communications and IP address.

When a user accesses the location information for the first time, the device may prompt that user to allow access to this information.

As the location changes, dependencies on the location will continuously recalculate, which will consume power from the device's battery. To conserve battery life, you can

use the **Enable** and **Disable** functions to turn location updates on and off. Location is automatically turned off if the displayed screen doesn't depend on location information.

Expand table

Property	Description
Location.Altitude	Returns a number that indicates the altitude, measured in meters, above sea level.
Location.Latitude	Returns a number, from –90 to 90, that indicates the latitude, as measured in degrees from the equator. A positive number indicates a location that's north of the equator.
Location.Longitude	Returns a number, from –180 to 180, that indicates the longitude, as measured in degrees from Greenwich, England. A positive number indicates a location that's east of Greenwich.

Examples

In a baseball field, a pitcher throws a phone from the pitcher's mound to a catcher at home plate. The phone is lying flat with respect to the ground, the top of the screen is pointed at the catcher, and the pitcher adds no spin. At this location, the phone has cellular network service that's metered but no WiFi. The **PlayBall** screen is displayed. The app is enabled for offline and is connected to the service.

Expand table

Formula	Description	Result
Location.Latitude	Returns the latitude of the current location. The field is located at map coordinates 47.591 N, 122.333 W.	47.591 The latitude will change continuously as the ball moves between the pitcher and the catcher.
Location.Longitude	Returns the longitude of the current location.	122.333 The longitude will change continuously as the ball moves between the pitcher and the catcher.
Location	Returns the latitude and longitude of the current location, as a record.	{ Latitude: 47.591, Longitude: 122.333 }

Formula	Description	Result
Compass.Heading	Returns the compass heading of the top of the screen. At this field, home plate is roughly southwest from the pitcher's mound.	230.25
Acceleration.X	Returns the acceleration of the device side to side. The pitcher is throwing the phone straight ahead with respect to the screen's top, so the device isn't accelerating side to side.	0
Acceleration.Y	Returns the acceleration of the device front to back. The pitcher initially gives the device a large acceleration when throwing the device, going from 0 to 90 miles per hour (132 feet per second) in half a second. After the device is in the air, ignoring air friction, the device doesn't accelerate further. The device decelerates when the catcher catches it, bringing it to a stop.	8.2, while the pitcher throws the device. 0, while the device is in the air. -8.2, as the catcher catches the device.
Acceleration.Z	Returns the acceleration of the device top to bottom. While in the air, the device experiences the effects of gravity.	0, before the pitcher throws the device. 1, while the device is in the air. 0, after the catcher catches the device.
Acceleration	Returns the acceleration as a record.	{ X: 0, Y: 264, Z: 0 } as the pitcher throws the device.
Connection.Connected	Returns a Boolean value that indicates whether the device is connected to a network	**true**
Connection.Metered	Returns a Boolean value that indicates whether the connection is metered	**true**
Connection.Sync	Returns an enum value that indicates current sync state.	**ConnectionSync.Connected**
App.ActiveScreen = PlayBall	Returns a Boolean value that indicates whether **PlayBall** is	**true**

Formula	Description	Result
	displayed.	
App.ActiveScreen.Fill	Returns the background color for the displayed screen.	**Color.Green**

Concat and Concatenate functions

06/20/2025

Expand table

Function	Applies to
Concat	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Concatenate	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Concatenates individual strings of text and strings in tables.

Description

The **Concatenate** function concatenates a mix of individual strings and a single-column table of strings. When you use this function with individual strings, it's equivalent to using the **&** operator.

The **Concat** function concatenates the result of a formula applied across all the records of a table, resulting in a single string. Use this function to summarize the strings of a table, just as the **Sum** function does for numbers.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

Use the **Split** or **MatchAll** function to split a string into a table of substrings.

Syntax

Concat(*Table*, *Formula*, *separator*)

- *Table* - Required. Table to operate on.
- *Formula* - Required. Formula to apply across the records of the table.
- *Separator* - Optional. A text value to be inserted between concatenated rows of the table.

Concatenate(*String1* [, *String2*, ...])

- *String(s)* - Required. Mix of individual strings or a single-column table of strings.

Examples

The examples in this section use these global variables:

- **FirstName** = "Jane"
- **LastName** = "Doe"
- **Products** =

Name	Type
"Violin"	"String"
"Cello"	"String"
"Trumpet"	"Wind"

To create these global variables in an app, insert a **Button** control, and set its **OnSelect** property to this formula:

Power Fx

```
Set( FirstName, "Jane" ); Set( LastName, "Doe" );
Set( Products,
    Table(
        { Name: "Violin", Type: "String" },
        { Name: "Cello", Type: "String" },
        { Name: "Trumpet", Type: "Wind" }
    )
)
```

Select the button (by clicking it while you hold down the Alt key).

Concatenate function and the & operator

For these examples, set the **Text** property of a **Label** control to a formula from the first column of the next table.

Expand table

Formula	Description	Result
Concatenate(LastName, ", ", FirstName)	Concatenates the value in **LastName**, the string ", " (a comma followed by a space), and the value in **FirstName**.	"Doe, Jane"
LastName & ", " & FirstName	Same as the previous example except using the **&** operator instead of the function.	"Doe, Jane"

Formula	Description	Result
Concatenate(FirstName, " ", LastName)	Concatenates the value in **FirstName**, the string " " (a single space), and the value in **LastName**.	"Jane Doe"
FirstName & " " & LastName	Same as the previous example, using the **&** operator instead of the function.	"Jane Doe"

Concatenate with a single-column table

For this example, add a blank, vertical Gallery control, set its **Items** property to the formula in the next table, and then add a label in the gallery template.

Expand table

Formula	Description	Result
Concatenate("Name: ", Products.Name, ", Type: ", Products.Type)	For each record in the **Products** table, concatenates the string **"Name: "**, the name of the product, the string **", Type: "** and the type of the product.	A single-column table with a `Value` column containing the following values: "Name: Violin, Type: String", "Name: "Cello, Type: String", "Name: Trumpet, Type: Wind"

Concat function

For these examples, set the **Text** property of a label to a formula from the first column of the next table.

Expand table

Formula	Description	Result
Concat(Products, Name, ", ")	Evaluates the expression **Name** for each record of **Products** and concatenates the results together into a single text string separated by **", "**.	"Violin, Cello, Trumpet"
Concat(Products, "'" & Name & "'", ", ")	Evaluates the expression **"'" & Name & "'"** for each record of **Products** and concatenates the results together into a single text string separated by **", "**.	"'Violin', 'Cello', 'Trumpet'"

Formula	Description	Result
Concat(**Filter(Products, Type = "String"),** **Name, ", ")**	Evaluates the formula **Name** for each record of **Products** that satisfies the filter **Type** = "**String**", and concatenates the results into a single text string separated by **", "**.	"Violin, Cello"

Split and MatchAll

If you used **Concat** with a separator, you can reverse the operation by using the **Split** function.

For these examples, add a blank, vertical gallery, set its **Items** property to a formula in the next table, and then add a label in the gallery template.

Expand table

Formula	Description	Result
Split(**Concat(Products, Name, ", "), ", "** **)**	Splits the text string with the separator **", "**.	A single-column table with a `Value` column containing the following values: "Violin", "Cello", "Trumpet"

Concatenates individual strings of text and strings in tables.

Description

The **Concatenate** function concatenates a mix of individual strings and a single-column table of strings. When you use this function with individual strings, it's equivalent to using the **&** operator.

The **Concat** function concatenates the result of a formula applied across all the records of a table, resulting in a single string. Use this function to summarize the strings of a table, just as the **Sum** function does for numbers.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

Use the **Split** or **MatchAll** function to split a string into a table of substrings.

Syntax

Concat(*Table*, *Formula*, *separator*)

- *Table* - Required. Table to operate on.
- *Formula* - Required. Formula to apply across the records of the table.
- *Separator* - Optional. A text value to be inserted between concatenated rows of the table.

Concatenate(*String1* [, *String2*, ...])

- *String(s)* - Required. Mix of individual strings or a single-column table of strings.

Examples

The examples in this section use these global variables:

- **FirstName** = "Jane"
- **LastName** = "Doe"
- **Products** =

Name	Type
"Violin"	"String"
"Cello"	"String"
"Trumpet"	"Wind"

To create these global variables in an app, insert a **Button** control, and set its **OnSelect** property to this formula:

Power Fx

```
Set( FirstName, "Jane" ); Set( LastName, "Doe" );
Set( Products,
    Table(
        { Name: "Violin", Type: "String" },
        { Name: "Cello", Type: "String" },
        { Name: "Trumpet", Type: "Wind" }
    )
)
```

Select the button (by clicking it while you hold down the Alt key).

Concatenate function and the & operator

For these examples, set the **Text** property of a **Label** control to a formula from the first column of the next table.

Expand table

Formula	Description	Result
Concatenate(LastName, ", ", FirstName)	Concatenates the value in **LastName**, the string ", " (a comma followed by a space), and the value in **FirstName**.	"Doe, Jane"
LastName & ", " & FirstName	Same as the previous example except using the **&** operator instead of the function.	"Doe, Jane"

Formula	Description	Result
Concatenate(FirstName, " ", LastName)	Concatenates the value in **FirstName**, the string " " (a single space), and the value in **LastName**.	"Jane Doe"
FirstName & " " & LastName	Same as the previous example, using the **&** operator instead of the function.	"Jane Doe"

Concatenate with a single-column table

For this example, add a blank, vertical Gallery control, set its **Items** property to the formula in the next table, and then add a label in the gallery template.

Expand table

Formula	Description	Result
Concatenate("Name: ", Products.Name, ", Type: ", Products.Type)	For each record in the **Products** table, concatenates the string **"Name: "**, the name of the product, the string **", Type: "** and the type of the product.	A single-column table with a `Value` column containing the following values: "Name: Violin, Type: String", "Name: "Cello, Type: String", "Name: Trumpet, Type: Wind"

Concat function

For these examples, set the **Text** property of a label to a formula from the first column of the next table.

Expand table

Formula	Description	Result
Concat(Products, Name, ", ")	Evaluates the expression **Name** for each record of **Products** and concatenates the results together into a single text string separated by **", "**.	"Violin, Cello, Trumpet"
Concat(Products, "'" & Name & "'", ", ")	Evaluates the expression **"'" & Name & "'"** for each record of **Products** and concatenates the results together into a single text string separated by **", "**.	"'Violin', 'Cello', 'Trumpet'"

Formula	Description	Result
Concat(**Filter(Products, Type = "String"),** **Name, ", ")**	Evaluates the formula **Name** for each record of **Products** that satisfies the filter **Type** = "**String**", and concatenates the results into a single text string separated by **", "**.	"Violin, Cello"

Split and MatchAll

If you used **Concat** with a separator, you can reverse the operation by using the **Split** function.

For these examples, add a blank, vertical gallery, set its **Items** property to a formula in the next table, and then add a label in the gallery template.

Expand table

Formula	Description	Result
Split(**Concat(Products, Name, ", "), ", "** **)**	Splits the text string with the separator **", "**.	A single-column table with a `Value` column containing the following values: "Violin", "Cello", "Trumpet"

Concurrent function

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

Evaluates multiple formulas concurrently with one another.

Description

The **Concurrent** function allows multiple formulas specified within the same property to be evaluated at the same time if they have connector or Dataverse calls. Normally, multiple formulas are evaluated by chaining them together with the ; (semi-colon) operator, which evaluates each formula sequentially. With the Concurrent function, the app will evaluate all formulas within a property concurrently even after using the ; operator. This concurrency will help users wait less for the same result.

In the OnStart property of your app, use **Concurrent** to improve performance when the app loads data. When data calls don't start until the previous calls finish, the app must wait for the sum of all request times. If data calls start at the same time, the app needs to wait only for the longest request time. Web browsers often improve performance by performing network calls concurrently.

You can't predict the order in which formulas within the **Concurrent** function start and end evaluation. Formulas within the **Concurrent** function shouldn't contain dependencies on other formulas within the same **Concurrent** function, and Power Apps shows an error if you try. From within, you can safely take dependencies on formulas outside the **Concurrent** function because they will complete before the **Concurrent** function starts. Formulas after the **Concurrent** function can safely take dependencies on formulas within: they'll all complete before the **Concurrent** function finishes and moves on to the next formula in a chain (if you use the **;** operator). Watch out for subtle order dependencies if you're calling functions or service methods that have side effects.

You can chain formulas together with the **;** operator within an argument to **Concurrent**. For example, **Concurrent(Set(a, 1); Set(b, a+1), Set(x, 2); Set(y, x+2))** evaluates **Set(a, 1); Set(b, a+1)** concurrently with **Set(x, 2); Set(y, x+2)**. In this case, the dependencies within the formulas are fine: **a** will be set before **b**, and **x** will be set before **y**.

Depending on the device or browser in which the app is running, only a handful of formulas might actually be evaluated concurrently. **Concurrent** uses the available capabilities and won't finish until all formulas have been evaluated.

If you enable **Formula-level error management** (in advanced settings), the first error encountered in argument order is returned from **Concurrent**; otherwise, *blank* is returned. If all formulas are successful, *true* is returned. If one formula fails, the rest of that formula stops, but other formulas continue evaluating.

You can use **Concurrent** only in behavior formulas.

Syntax

Concurrent(*Formula1*, *Formula2* [, ...])

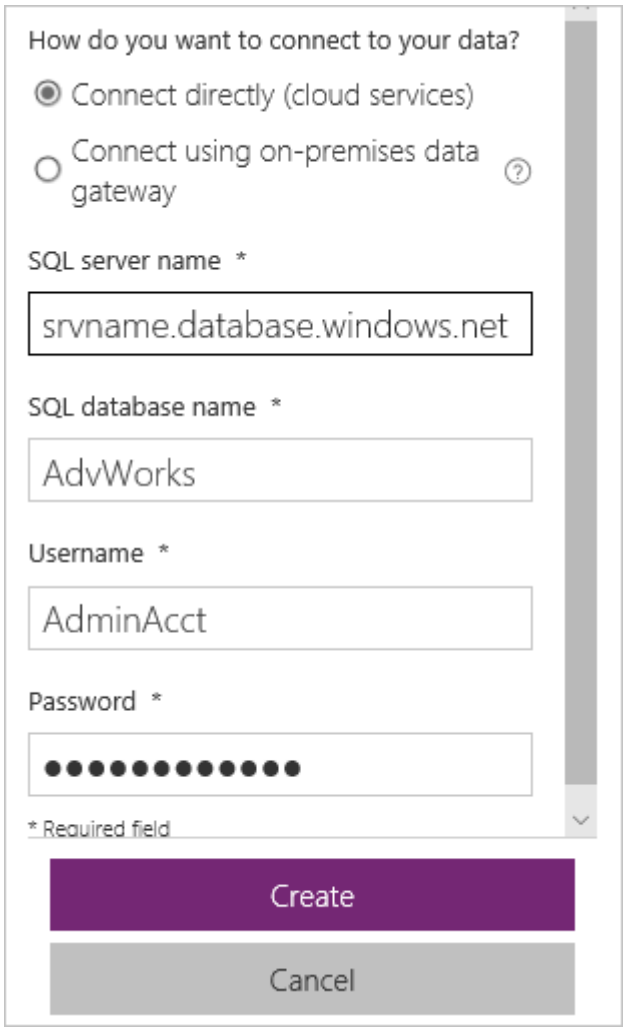
- *Formula(s)* – Required. Formulas to evaluate concurrently. You must supply at least two formulas.

Examples

Loading data faster

1. Create an app, and add four data sources from Microsoft Dataverse, SQL Server, or SharePoint.

   This example uses four tables from the sample Adventure Works database on SQL Azure. After you create the database, connect to it from Power Apps using the fully qualified server name (for example, srvname.database.windows.net):



2. Add a **Button** control, and set its **OnSelect** property to this formula:

Power Apps

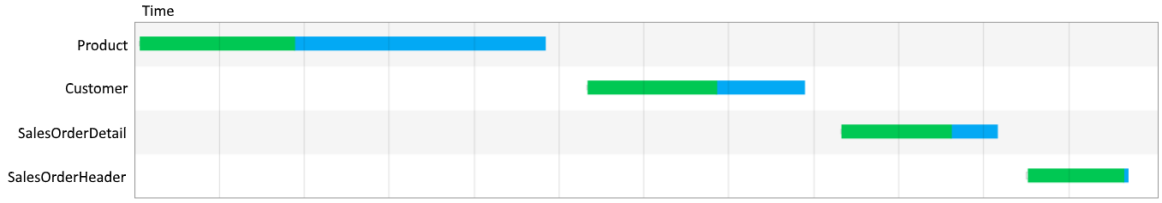
```
ClearCollect( Product, '[SalesLT].[Product]' );
ClearCollect( Customer, '[SalesLT].[Customer]' );
ClearCollect( SalesOrderDetail, '[SalesLT].[SalesOrderDetail]' );
ClearCollect( SalesOrderHeader, '[SalesLT].[SalesOrderHeader]' )
```

3. In Microsoft Edge or Google Chrome, turn on developer tools to monitor network traffic while your app is running.

4. (optional) Turn on network throttling to exaggerate the effects of this comparison.

5. While holding down the Alt key, select the button, and then watch the network traffic.

   The tools show four requests performed in series, similar to this example. Actual times have been removed as they will vary wildly. The graph shows that each call starts after the last has finished:



6. Save, close, and reopen the app.

   Power Apps caches data, so selecting the button again won't necessarily cause four new requests. Each time you want to test performance, close and reopen your app. If you turned network throttling on, you may want to turn it off until you're ready for another test.

7. Add a second **Button** control, and set its **OnSelect** property to this formula:

   Power Apps

   ```
   Concurrent(
       ClearCollect( Product, '[SalesLT].[Product]' ),
       ClearCollect( Customer, '[SalesLT].[Customer]' ),
       ClearCollect( SalesOrderDetail, '[SalesLT].[SalesOrderDetail]' ),
       ClearCollect( SalesOrderHeader, '[SalesLT].[SalesOrderHeader]' )
   )
   ```

   Note that you added the same **ClearCollect** calls to the first button, but they're wrapped in a **Concurrent** function and separated by commas this time.

8. Clear the network monitor in the browser.

9. If you were using network throttling before, turn it on again.

10. While holding down the Alt key, select the second button, and then watch the network traffic.

    The tools show four requests performed concurrently, similar to this example. Again, actual times have been removed as they will vary wildly. The graph shows that all the calls start at about the same time and do not wait for the previous one to finish:

    These graphs are based on the same scale. By using **Concurrent**, you halved the total amount of time these operations took to finish.

11. Save, close, and reopen the app.

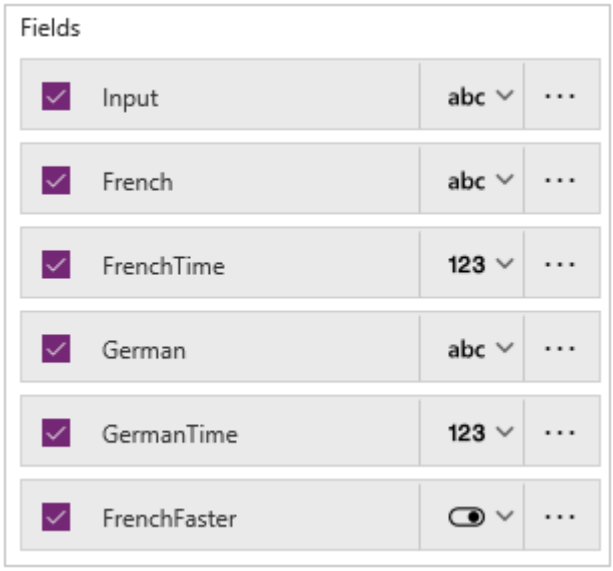
Race condition

1. Add a connection to the Microsoft Translator service to your app.
2. Add a **Text input** control, and rename it **TextInput1** if it has a different name.
3. Add a **Button** control, and set its **OnSelect** property to this formula:

```
Power Apps
```

```
Set( StartTime, Value( Now() ) );
Concurrent(
    Set( FRTrans, MicrosoftTranslator.Translate( TextInput1.Text, "fr"
) );
        Set( FRTransTime, Value( Now() ) ),
    Set( DETrans, MicrosoftTranslator.Translate( TextInput1.Text, "de"
) );
        Set( DETransTime, Value( Now() ) )
);
Collect( Results,
    {
        Input: TextInput1.Text,
        French: FRTrans, FrenchTime: FRTransTime - StartTime,
        German: DETrans, GermanTime: DETransTime - StartTime,
        FrenchFaster: FRTransTime < DETransTime
    }
)
```

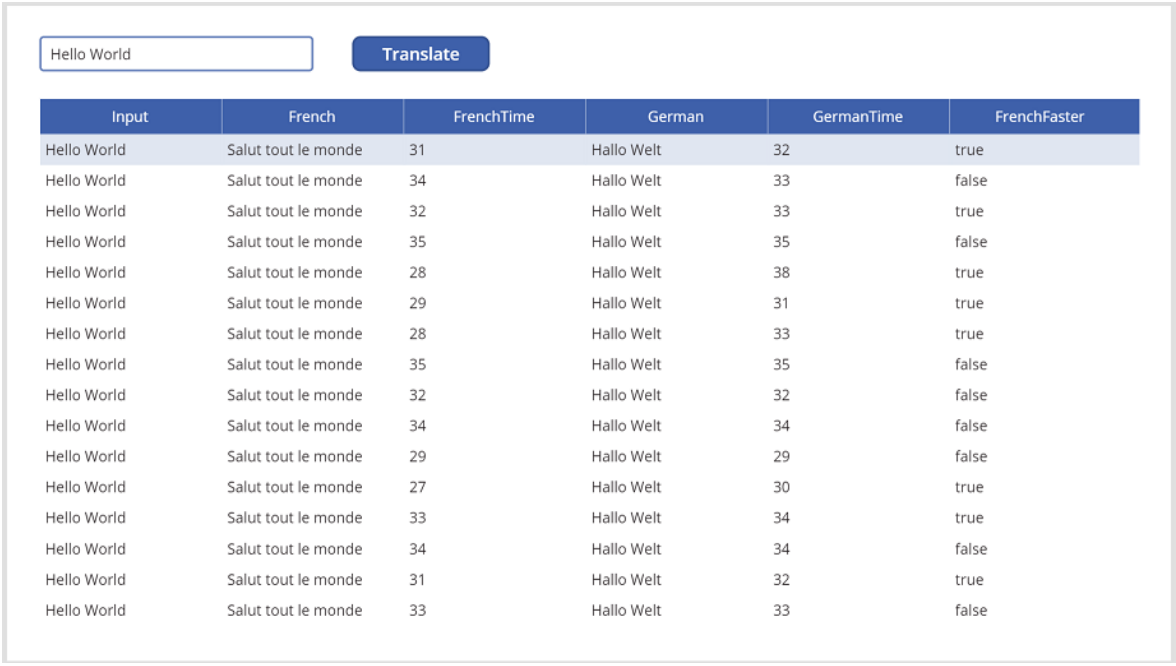
4. Add a **Data table** control, and set its **Items** property to **Results**.
5. On the **Properties** tab of the right pane, select **Edit fields** to open the **Fields** pane.
6. In the list of fields, select the check box for each field to show them all in the data table.
7. (optional) Drag the **Input** field to the top of the list, and drag the **FrenchFaster** field to the bottom of the list.



8. In the **Text input** control, type or paste a phrase to translate.

9. While holding down the Alt key, select the button multiple times to fill the table.

   The times are shown in milliseconds.



Input	French	FrenchTime	German	GermanTime	FrenchFaster
Hello World	Salut tout le monde	31	Hallo Welt	32	true
Hello World	Salut tout le monde	34	Hallo Welt	33	false
Hello World	Salut tout le monde	32	Hallo Welt	33	true
Hello World	Salut tout le monde	35	Hallo Welt	35	false
Hello World	Salut tout le monde	28	Hallo Welt	38	true
Hello World	Salut tout le monde	29	Hallo Welt	31	true
Hello World	Salut tout le monde	28	Hallo Welt	33	true
Hello World	Salut tout le monde	35	Hallo Welt	35	false
Hello World	Salut tout le monde	32	Hallo Welt	32	false
Hello World	Salut tout le monde	34	Hallo Welt	34	false
Hello World	Salut tout le monde	29	Hallo Welt	29	false
Hello World	Salut tout le monde	27	Hallo Welt	30	true
Hello World	Salut tout le monde	33	Hallo Welt	34	true
Hello World	Salut tout le monde	34	Hallo Welt	34	false
Hello World	Salut tout le monde	31	Hallo Welt	32	true
Hello World	Salut tout le monde	33	Hallo Welt	33	false

In some cases, the French translation is faster than the German translation, and vice versa. Both start at the same time, but one returns before the other for a variety of reasons, including network latency and server-side processing.

A race condition would occur if the app depended on one translation ending first. Fortunately, Power Apps flags most timing dependencies that it can detect.

Acceleration, App, Compass, Connection, and Location signals in Power Apps

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

Returns information about the app's environment, such as where the user is located in the world and which screen is displayed.

Description and syntax

Signals are values that can change at any time, independent of how the user may be interacting with the app. Formulas that are based on signals automatically recalculate as these values change.

Signals typically return a record of information. You can use and store this information as a record, or you can extract individual properties by using the . operator.

> **Note**
>
> The **Acceleration** and **Compass** functions return accurate values in a native player such as on iOS or Android, but those functions return zero values as you create or modify an app in the browser.

Acceleration

The **Acceleration** signal returns the device's acceleration in three dimensions relative to the device's screen. Acceleration is measured in *g* units of 9.81 m/second^2 or 32.2 ft/second^2 (the acceleration that the Earth imparts to objects at its surface due to gravity).

Expand table

Property	Description
Acceleration.X	Right and left. Right is a positive number.
Acceleration.Y	Forward and back. Forward is a positive number.

Property	Description
Acceleration.Z	Up and down. Up is a positive number.

App

Among other properties, the **App** object includes a signal that indicates which screen is showing.

Expand table

Property	Description
App.ActiveScreen	Screen that's showing. Returns a screen object, which you can use to reference properties of the screen or compare to another screen to determine which screen is showing. You can use the **Back** or **Navigate** function to change the screen that's showing.

More information: **App** object documentation.

Compass

The **Compass** signal returns the compass heading of the top of the screen. The heading is based on magnetic north.

Expand table

Property	Description
Compass.Heading	Heading in degrees. Returns a number 0 to 360, and 0 is north.

Connection

The **Connection** signal returns the information about the network connection. When on a metered connection, you may want to limit how much data you send or receive over the network. Or, if your app is enabled for offline, you may want to display different information depending on the current sync state.

Expand table

Property	Description
Connection.Connected	Returns a Boolean **true** or **false** value that indicates whether the device is connected to a network.
Connection.Metered	Returns a Boolean **true** or **false** value that indicates whether the connection is metered.
Connection.Sync	Returns an enum named **ConnectionSync** which holds the current synchronization state for an app that is enabled for offline.

Below are the enums values available for Connection.Sync.

Expand table

Enum value	Description
Connected	Your device is connected to the network and your app is ready to work offline
ConnectedWithWarning	Your device is connected with a warning.
ConnectedPendingUpsync	Some data on your device must be synchronized with the service.
ConnectedError	There was an error on the last synchronization attempt.
ConnectedRefresh	Your app is currently synchronizing data with the service.
NotConnected	Your device isn't connected to the service.
NotConnectedWithWarning	The last synchronization warning.
NotConnectedPendingUpsync	There are updates on your device waiting to be synchronized.
NotConnectedSyncError	The last synchronization error.

Location

The **Location** signal returns the location of the device based on the Global Positioning System (GPS) and other device information, such as cell-tower communications and IP address.

When a user accesses the location information for the first time, the device may prompt that user to allow access to this information.

As the location changes, dependencies on the location will continuously recalculate, which will consume power from the device's battery. To conserve battery life, you can

use the **Enable** and **Disable** functions to turn location updates on and off. Location is automatically turned off if the displayed screen doesn't depend on location information.

Expand table

Property	Description
Location.Altitude	Returns a number that indicates the altitude, measured in meters, above sea level.
Location.Latitude	Returns a number, from –90 to 90, that indicates the latitude, as measured in degrees from the equator. A positive number indicates a location that's north of the equator.
Location.Longitude	Returns a number, from –180 to 180, that indicates the longitude, as measured in degrees from Greenwich, England. A positive number indicates a location that's east of Greenwich.

Examples

In a baseball field, a pitcher throws a phone from the pitcher's mound to a catcher at home plate. The phone is lying flat with respect to the ground, the top of the screen is pointed at the catcher, and the pitcher adds no spin. At this location, the phone has cellular network service that's metered but no WiFi. The **PlayBall** screen is displayed. The app is enabled for offline and is connected to the service.

Expand table

Formula	Description	Result
Location.Latitude	Returns the latitude of the current location. The field is located at map coordinates 47.591 N, 122.333 W.	47.591 The latitude will change continuously as the ball moves between the pitcher and the catcher.
Location.Longitude	Returns the longitude of the current location.	122.333 The longitude will change continuously as the ball moves between the pitcher and the catcher.
Location	Returns the latitude and longitude of the current location, as a record.	{ Latitude: 47.591, Longitude: 122.333 }

Formula	Description	Result
Compass.Heading	Returns the compass heading of the top of the screen. At this field, home plate is roughly southwest from the pitcher's mound.	230.25
Acceleration.X	Returns the acceleration of the device side to side. The pitcher is throwing the phone straight ahead with respect to the screen's top, so the device isn't accelerating side to side.	0
Acceleration.Y	Returns the acceleration of the device front to back. The pitcher initially gives the device a large acceleration when throwing the device, going from 0 to 90 miles per hour (132 feet per second) in half a second. After the device is in the air, ignoring air friction, the device doesn't accelerate further. The device decelerates when the catcher catches it, bringing it to a stop.	8.2, while the pitcher throws the device. 0, while the device is in the air. -8.2, as the catcher catches the device.
Acceleration.Z	Returns the acceleration of the device top to bottom. While in the air, the device experiences the effects of gravity.	0, before the pitcher throws the device. 1, while the device is in the air. 0, after the catcher catches the device.
Acceleration	Returns the acceleration as a record.	{ X: 0, Y: 264, Z: 0 } as the pitcher throws the device.
Connection.Connected	Returns a Boolean value that indicates whether the device is connected to a network	**true**
Connection.Metered	Returns a Boolean value that indicates whether the connection is metered	**true**
Connection.Sync	Returns an enum value that indicates current sync state.	**ConnectionSync.Connected**
App.ActiveScreen = PlayBall	Returns a Boolean value that indicates whether **PlayBall** is	**true**

Formula	Description	Result
	displayed.	
App.ActiveScreen.Fill	Returns the background color for the displayed screen.	**Color.Green**

Count, CountA, CountIf, and CountRows functions

Article • 04/20/2025

Applies to: Canvas apps Cards Copilot Studio Desktop flows Model-driven apps Power Platform CLI Dataverse functions Power Pages

Counts all records in a table, or counts all records that satisfy a condition.

Description

The **Count** function counts the number of records that contain a number in a single-column table.

The **CountA** function counts the number of records that aren't *blank* in a single-column table. This function includes empty text ("") in the count.

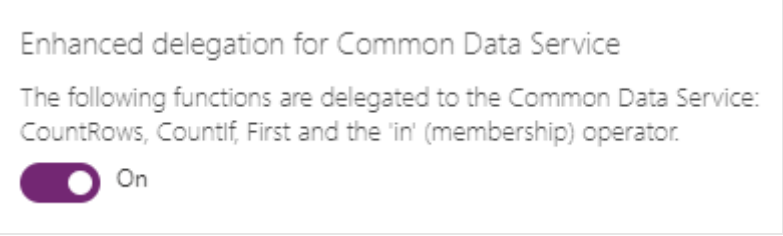
The **CountIf** function counts the number of records in a table that are **true** for a logical formula. The formula can reference columns of the table.

The **CountRows** function counts the number of records in a table.

Each of these functions returns a number.

You need to enable the **Enhanced delegation for Microsoft Dataverse** option in the advance settings to make **CountIf** and **CountRows** functions delegation to work. To enable the option:

1. Open the app where you want to use the functions.
2. Select **Settings** > **Upcoming features** > **Preview**.
3. Turn on the **Enhanced delegation for Microsoft Dataverse** option.



> **Important**
>
> - There is a 50K delegation limit if you use `CountRows` and `CountIf` functions with filters. There is no hard limit on the `CountRows` function when extracted directly from

the data source because of the cached count that Dataverse keeps.

- If the `CountRows(<Data Source>)` function is used without filtering, the count might not be 100% accurate, because the cached count updates periodically. If you need precise count and expect the result to be under the aggregate limit, you can bypass the cached count via `CountIf(<Data Source>, True)`.

Syntax

Count(*SingleColumnTable*)
CountA(*SingleColumnTable*)

- *SingleColumnTable* - Required. Column of records to count.

CountIf(*Table*, *LogicalFormula*)

- *Table* - Required. Table of records to count.
- *LogicalFormula* - Required. Formula to evaluate for each record of the table. Records that return **true** for this formula are counted. The formula can reference columns of the table.

CountRows(*Table*)

- *Table* - Required. Table of records to count.

Example

1. Import or create a collection named **Inventory**, as the first subprocedure in Show images and text in a gallery describes.

2. Add a label, and set its **Text** property to this formula:

   CountIf(Inventory, UnitsInStock < 30)

   The label shows **2** because two products (Ganymede and Callisto) have fewer than 30 units in stock.

3. Add another label, and set its **Text** property to this formula:

   CountA(Inventory.UnitsInStock)

   The label shows **5**, the number of non-empty cells in the **UnitsInStock** column.

4. Add another label, and set its **Text** property to this formula:

CountRows(Inventory)

The label shows **5** because the collection contains five rows.

Acos, Acot, Asin, Atan, Atan2, Cos, Cot, Degrees, Pi, Radians, Sin, and Tan functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Calculates trigonometric values.

Description

Primary functions

The **Cos** function returns the cosine of its argument, an angle specified in radians.

The **Cot** function returns the cotangent of its argument, an angle specified in radians.

The **Sin** function returns the sine of its argument, an angle specified in radians.

The **Tan** function returns the tangent of its argument, an angle specified in radians.

Inverse functions

The **Acos** function returns the arccosine, or inverse cosine, of its argument. The arccosine is the angle whose cosine is the argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Acot** function returns the principal value of the arccotangent, or inverse cotangent, of its argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Asin** function returns the arcsine, or inverse sine, of its argument. The arcsine is the angle whose sine is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan** function returns the arctangent, or inverse tangent, of its argument. The arctangent is the angle whose tangent is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan2** function returns the arctangent, or inverse tangent, of the specified *x* and *y* coordinates as arguments. The arctangent is the angle from the *x*-axis to a line that contains the origin (0, 0) and a point with coordinates (*x*, *y*). The angle is given in radians between -π and π, excluding -π. A positive result represents a counterclockwise angle from the *x*-axis; a negative result represents a clockwise angle. **Atan2(*a*, *b*)** equals **Atan(*b*/*a*)**, except that ***a*** can equal 0 (zero) with the **Atan2** function.

Helper functions

The **Degrees** function converts radians to degrees. π radians equals 180 degrees.

The **Pi** function returns the transcendental number π, which begins 3.141592...

The **Radians** function converts degrees to radians.

Notes

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results with a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined value, the result is *blank*. This can happen, for example, when using inverse functions with arguments that are out of range.

Syntax

Primary Functions

Cos(*Radians*)
Cot(*Radians*)
Sin(*Radians*)
Tan(*Radians*)

- *Radians* - Required. Angle to operate on.

Cos(*SingleColumnTable*)
Cot(*SingleColumnTable*)
Sin(*SingleColumnTable*)
Tan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of angles to operate on.

Inverse Functions

Acos(*Number*)
Acot(*Number*)
Asin(*Number*)
Atan(*Number*)

- *Number* - Required. Number to operate on.

Acos(*SingleColumnTable*)
Acot(*SingleColumnTable*)
Asin(*SingleColumnTable*)
Atan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Atan2(*X*, *Y*)

- *X* - Required. *X*-axis coordinate.
- *Y* - Required. *Y*-axis coordinate.

Helper Functions

Degrees(*Radians*)

- *Radians* - Required. Angle in radians to convert to degrees.

Pi()

Radians(*Degrees*)

- *Degrees* - Required. Angle in degrees to convert to radians.

Examples

Single number

Calculates trigonometric values.

Description

Primary functions

The **Cos** function returns the cosine of its argument, an angle specified in radians.

The **Cot** function returns the cotangent of its argument, an angle specified in radians.

The **Sin** function returns the sine of its argument, an angle specified in radians.

The **Tan** function returns the tangent of its argument, an angle specified in radians.

Inverse functions

The **Acos** function returns the arccosine, or inverse cosine, of its argument. The arccosine is the angle whose cosine is the argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Acot** function returns the principal value of the arccotangent, or inverse cotangent, of its argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Asin** function returns the arcsine, or inverse sine, of its argument. The arcsine is the angle whose sine is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan** function returns the arctangent, or inverse tangent, of its argument. The arctangent is the angle whose tangent is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan2** function returns the arctangent, or inverse tangent, of the specified *x* and *y* coordinates as arguments. The arctangent is the angle from the *x*-axis to a line that contains the origin (0, 0) and a point with coordinates (*x*, *y*). The angle is given in radians between -π and π, excluding -π. A positive result represents a counterclockwise angle from the *x*-axis; a negative result represents a clockwise angle. **Atan2(*a*, *b*)** equals **Atan(*b*/*a*)**, except that ***a*** can equal 0 (zero) with the **Atan2** function.

Helper functions

The **Degrees** function converts radians to degrees. π radians equals 180 degrees.

The **Pi** function returns the transcendental number π, which begins 3.141592...

The **Radians** function converts degrees to radians.

Notes

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results with a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined value, the result is *blank*. This can happen, for example, when using inverse functions with arguments that are out of range.

Count, CountA, CountIf, and CountRows functions

Article • 04/20/2025

Applies to: Canvas apps Cards Copilot Studio Desktop flows Model-driven apps Power Platform CLI Dataverse functions Power Pages

Counts all records in a table, or counts all records that satisfy a condition.

Description

The **Count** function counts the number of records that contain a number in a single-column table.

The **CountA** function counts the number of records that aren't *blank* in a single-column table. This function includes empty text ("") in the count.

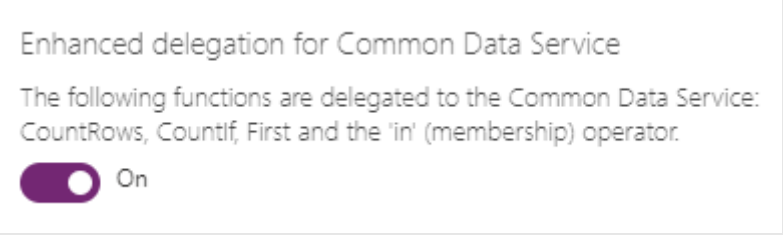
The **CountIf** function counts the number of records in a table that are **true** for a logical formula. The formula can reference columns of the table.

The **CountRows** function counts the number of records in a table.

Each of these functions returns a number.

You need to enable the **Enhanced delegation for Microsoft Dataverse** option in the advance settings to make **CountIf** and **CountRows** functions delegation to work. To enable the option:

1. Open the app where you want to use the functions.
2. Select **Settings** > **Upcoming features** > **Preview**.
3. Turn on the **Enhanced delegation for Microsoft Dataverse** option.



> **Important**
>
> - There is a 50K delegation limit if you use `CountRows` and `CountIf` functions with filters. There is no hard limit on the `CountRows` function when extracted directly from

the data source because of the cached count that Dataverse keeps.

- If the `CountRows(<Data Source>)` function is used without filtering, the count might not be 100% accurate, because the cached count updates periodically. If you need precise count and expect the result to be under the aggregate limit, you can bypass the cached count via `CountIf(<Data Source>, True)`.

Syntax

Count(*SingleColumnTable*)
CountA(*SingleColumnTable*)

- *SingleColumnTable* - Required. Column of records to count.

CountIf(*Table*, *LogicalFormula*)

- *Table* - Required. Table of records to count.
- *LogicalFormula* - Required. Formula to evaluate for each record of the table. Records that return **true** for this formula are counted. The formula can reference columns of the table.

CountRows(*Table*)

- *Table* - Required. Table of records to count.

Example

1. Import or create a collection named **Inventory**, as the first subprocedure in Show images and text in a gallery describes.

2. Add a label, and set its **Text** property to this formula:

   CountIf(Inventory, UnitsInStock < 30)

   The label shows **2** because two products (Ganymede and Callisto) have fewer than 30 units in stock.

3. Add another label, and set its **Text** property to this formula:

   CountA(Inventory.UnitsInStock)

   The label shows **5**, the number of non-empty cells in the **UnitsInStock** column.

4. Add another label, and set its **Text** property to this formula:

CountRows(Inventory)

The label shows **5** because the collection contains five rows.

   CountA(Inventory.UnitsInStock)

   The label shows **5**, the number of non-empty cells in the **UnitsInStock** column.

4. Add another label, and set its **Text** property to this formula:

CountRows(Inventory)

The label shows **5** because the collection contains five rows.

Data types

06/19/2025

Information flows through Power Fx in small, discrete values, like the cells of a spreadsheet. For example, data in a **Birthday** field and an **Anniversary** field both flow through as a **Date** value that includes the year, month, and day. Power Fx formats these values, constrains input to what's appropriate for each, and shares the values with a database. Birthdays and anniversaries might differ to people, but the system handles them in the same way. In this case, **Date** is an example of a data type.

This article explains each data type in Power Fx, how they work, and how they map to external data sources.

Expand table

Data type	Description	Examples
Boolean	A *true* or *false* value. You can use it directly in **If**, **Filter**, and other functions without a comparison.	*true*
Choice	A choice from a set of options, backed by a number. This data type combines a localizable text label with a numeric value. The label appears in the app, and the numeric value is stored and used for comparisons. The **Type** function supports this data type if you use an instance of a **Choice** field by name.	**ThisItem.OrderStatus**
Color	A color specification that includes an alpha channel.	**Color.Red** **ColorValue("#102030")** **RGBA(255, 128, 0, 0.5)**
Currency	A currency value stored in a floating-point number. Currency values are the same as number values with currency-formatting options. The **Type** function doesn't support the **Currency** data type.	**123** **4.56**
Date	A date without a time, in the app user's time zone.	**Date(2019, 5, 16)**
DateTime	A date with a time, in the app user's time zone.	**DateTimeValue("May 16, 2019 1:23:09 PM")**

Data type	Description	Examples
Decimal	A number with high precision, base 10 operations, and a limited range.	**123** **Decimal("1.2345")**
Dynamic (formerly **UntypedObject**)	The value's type is dynamic and can vary at runtime. A Dynamic value could be any existing type, and can be converted into compatible types using functions such as Boolean(), Value(), Table(), etc. For more information, see Dynamic values and Working with JSON.	**ParseJSON("{ ""Field"" : 1234 }").Field**
Float	A number with standard precision, base 2 operations, and a wide range.	**123** **8.903e121** **1.234e-200**
GUID	A globally unique identifier.	**GUID()** **GUID("123e4567-e89b-12d3-a456-426655440000")**
Hyperlink	A text string that contains a hyperlink.	**"https://powerapps.microsoft.com"**
Image	A universal resource identifier (URI) text string to an image in .jpeg, .png, .svg, .gif, or another common web-image format. The **Type** function doesn't support the **Image** data type.	**MyImage** added as an app resource **"https://northwindtraders.com/logo.jpg"** **"appres://blobmanager/7b12ffa2..."**
Media	A URI text string to a video or audio recording. The **Type** function doesn't support the **Media** data type.	**MyVideo** added as an app resource **"https://northwindtraders.com/intro.mp4"** **"appres://blobmanager/3ba411c..."**
Number	An alias for **Decimal** (most Power Fx hosts) or **Float** (Canvas apps). If you can use either variety of number for a situation, use **Number** for maximum compatibility.	**123** **0.0123** **1e4**
Record	A record of data values. This compound data type contains instances of other data types listed in this article. For more information, see Working with tables. The **Type** function supports this data type if you use an instance of a **Record**.	**{ Company: "Northwind Traders",** **Staff: 35,** **NonProfit: false }**
Record reference	A reference to a record in a table. These references are often used with polymorphic lookups. For more	**First(Accounts).Owner**

Data type	Description	Examples
	information, see Working with references. The **Type** function doesn't support this data type.	
Table	A table of records. All records must have the same field names and data types, and omitted fields are treated as *blank*. This compound data type contains instances of other data types listed in this article. For more information, see Working with tables. The **Type** function supports this data type if you use an instance of a **Table**.	**Table({ FirstName: "Sidney", LastName: "Higa" }, { FirstName: "Nancy", LastName: "Anderson" })**
Text	A Unicode text string.	**"Hello, World"**
Time	A time without a date, in the app user's time zone.	**Time(11, 23, 45)**
Void	Used only by behavior user defined functions, it indicates that a function doesn't have a return type. The **Type** function doesn't support this data type. Even though a function doesn't have a return type or value, it can always return an error.	**Hi(): Void = { Notify("Hello!") }**
Yes/No	A choice from a set of two options, backed by a boolean value. This data type combines a localizable text label with a boolean value. The label appears in the app, and the boolean value is stored and used for comparisons. The **Type** function supports this data type if you use an instance of a **Yes/No** field by name.	**ThisItem.Taxable**

Many of these data types are similar and have the same underlying representation, like a **Hyperlink** field being treated as **Text**. The extra data types give better default experiences in forms and other controls.

Blank

All data types can have a value of *blank* (no value). The term "null" is often used in databases for this concept.

Use the **Blank** function with the **Set** or **Patch** function to set a variable or field to *blank*. For example, **Set(x, Blank())** removes the value in the global variable **x**.

Test for a *blank* value with the **IsBlank** function. Replace possible *blank* values with non-*blank* values by using the **Coalesce** function.

Because all data types support *blank*, the **Boolean** and **Two option** data types have three possible values.

Text, Hyperlink, Image, and Media

All four of these data types are based on a Unicode text string.

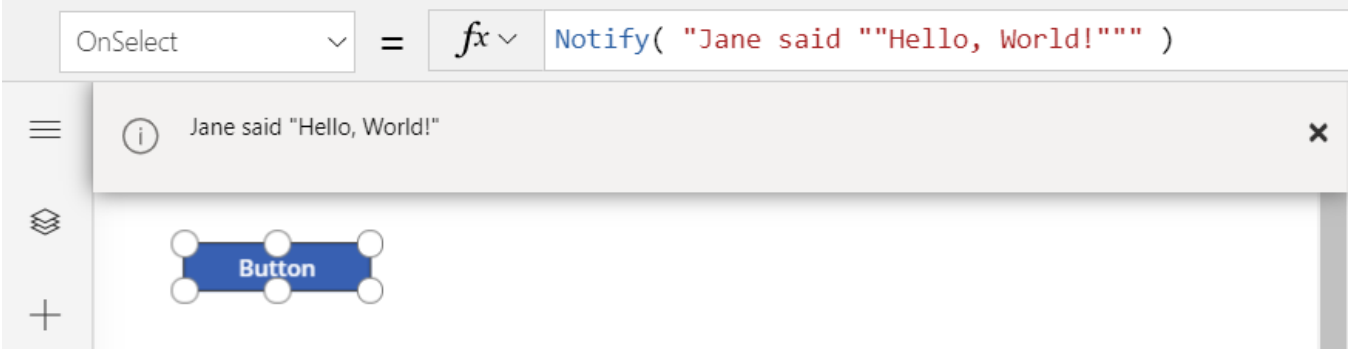
Embedded text

Embedded text strings in a formula are enclosed in double quotation marks. Use two double quotes together to represent a single double quote in the text string. For example, using the following formula in the **OnSelect** property of a **Button** control:

```
Power Fx

Notify( "Jane said ""Hello, World!""" )
```

Results in a banner when the button is pressed, where the first and last double quotes are omitted (as they delimit the text string) and the repeated double quotes around **Hello, World!** are replaced with a single double quote:



Single quotation marks are used for identifier names that contain special characters and have no special significance within a text string.

String interpolation

Use string interpolation to embed formulas within a text string. This approach is often easier to work with and visualize the output than using the **Concatenate** function or **&** operator.

Prefix the text string with a dollar sign **$** and enclose the formula to be embedded with curly braces **{ }**. To include a curly brace in the text string, use repeated curly braces: **{{** or **}}**. String interpolation can be used anywhere a standard text string can be used.

For example, consider this formula with global variables **Apples** set to 3 and **Bananas** set to 4:

```
Power Fx
```

```
$"We have {Apples} apples, {Bananas} bananas, yielding {Apples+Bananas} fruit
total."
```

This formula returns the text string **We have 3 apples, 4 bananas, yielding 7 fruit total.** The variables **Apples** and **Bananas** are inserted in the text replacing the curly braces, along with the result of the mathematical formula **Apples+Bananas**. Spaces and other characters around the curly braces are preserved as they are.

Embedded formulas can include any functions or operators. All that is required is that the result of the formula can be coerced to a text string. For example, this formula inserts **NickName** if it's supplied, or the **FirstName** if not, in a greeting:

```
Power Fx
```

```
$"Welcome {Coalesce( NickName, FirstName )}, it's great to meet you!"
```

If **NickName** is set to "Joe", then this formula produces the text string **Welcome Joe, it's great to meet you!**. But if **NickName** is *blank* and **FirstName** is "Joseph", then this formula produces **Dear Joseph, great to meet you!** instead.

String interpolation can include standard text strings in the embedded formula. For example, if neither **NickName** nor **FirstName** were supplied, we could still provide **"Friend"** as a substitute:

```
Power Fx
```

```
$"Welcome {Coalesce( NickName, FirstName, "Friend" )}!"
```

String interpolations can even be nested. Consider this example where **First**, **Middle**, and **Last** names are combined into a greeting. Even if one or two of these values are *blank*, the correct number of spaces are maintained between the name parts. If none of the parts are provided, the inner string interpolation will collapse to an empty string, and be replaced by the **Coalesce** function by "Friend".

```
Power Fx
```

```
$"Welcome {Coalesce( Trim( $"{First} {Middle} {Last}"}), "Friend" )}!"
```

Expand table

First	Middle	Last	Result
John	Qunicy	Doe	`Welcome John Quincy Doe!`
John	*blank*	Doe	`Welcome John Doe!`
blank	*blank*	Doe	`Welcome Doe!`
blank	*blank*	*blank*	`Welcome Friend!`

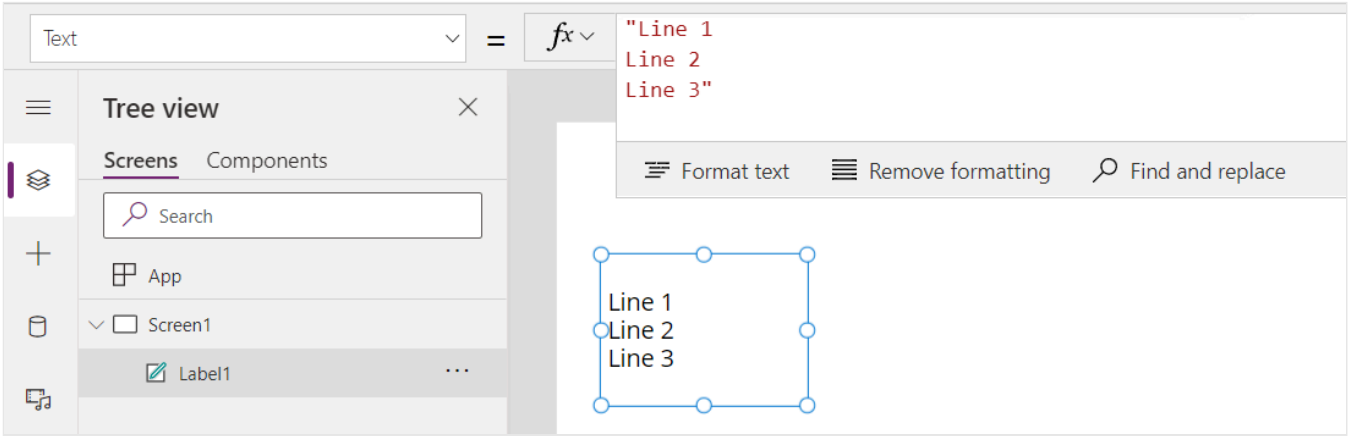
Newlines

Embedded text strings can contain newlines. For example, consider setting the **Text** property of a **Label** control to the following:

Power Fx

```
"Line 1
Line 2
Line 3"
```

This formula results in three lines shown in the label control:



Newlines are also supported with string interpolation:

Power Fx

```
$"Line {1}
Line {1+1}
Line {1+1+1}"
```

Which results in the same output:

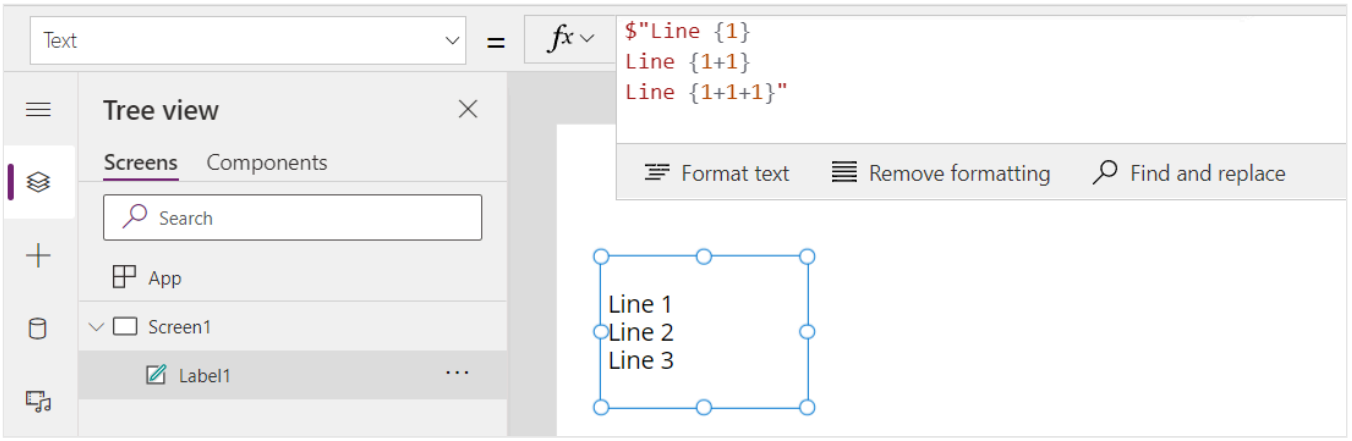


Image and Media resources

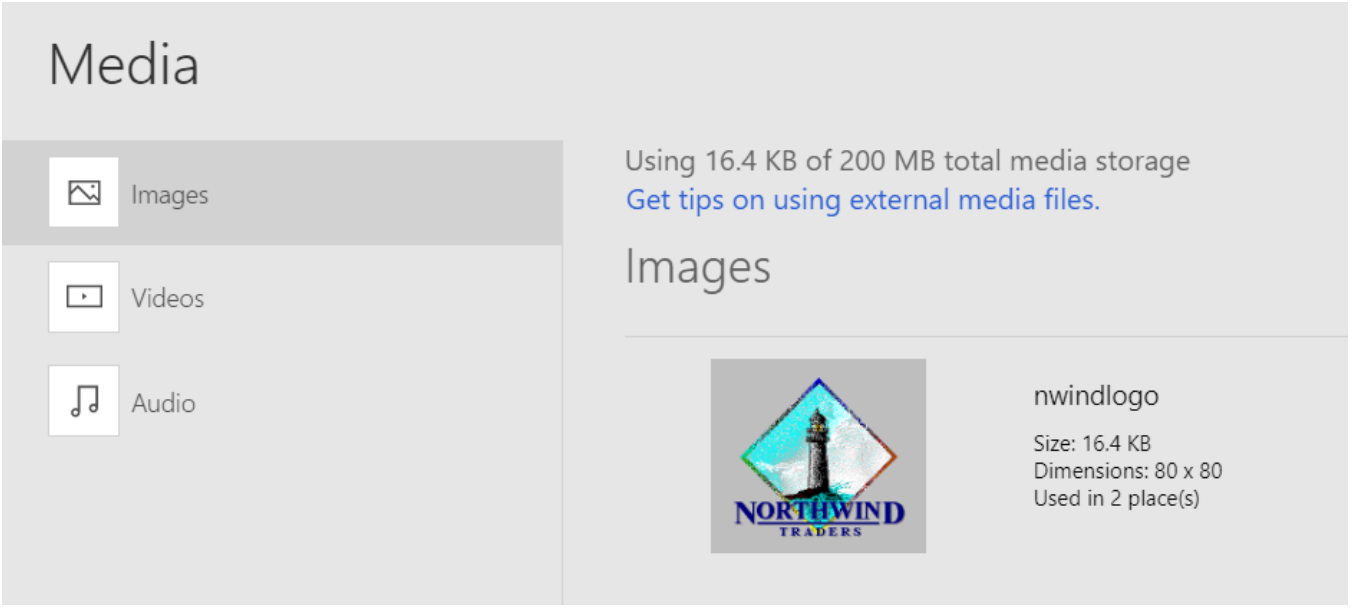
Through the **File** menu, you can add image, video, and audio files as app resources. The name of the imported file becomes the resource name in the app. In this graphic, the Northwind Traders logo, which is named **nwindlogo**, has been added to the app:



To use this resource in an app, specify it in the **Image** property of an **Image** control:

URIs for images and other media

You can dig a little deeper into that last example by setting the **Text** property of a **Label** control to **nwindlogo**. The label shows a text string:

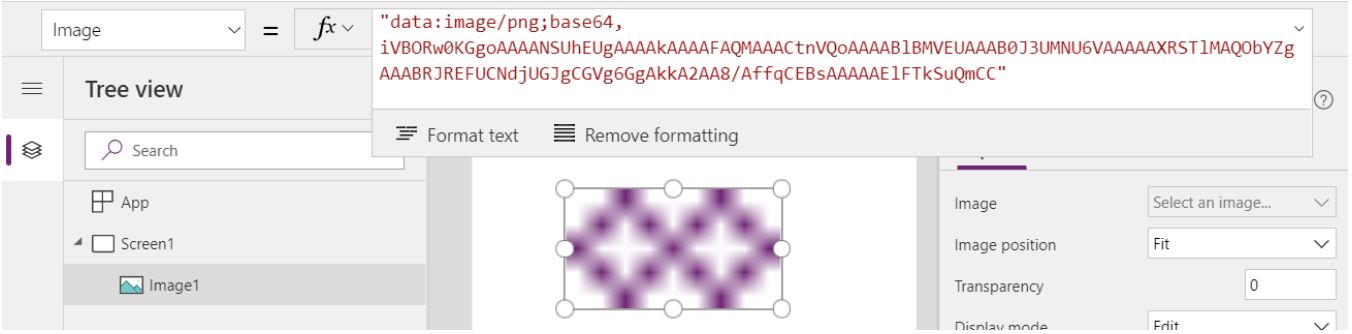
Canvas apps reference each image or other media file, whether it's in the cloud or added as an app resource, by a URI text string.

For example, the **Image** property of an image control accepts not only app resources but also links to images on the web, such as "https://northwindtraders.com/logo.jpg". The property also accepts inline images that use the data URI scheme, as in this example:

Power Fx

```
""
```

That URI displays a scaled-up version of two purple diamonds:



You can show the most recent image captured in a **Camera** control if you set the **Image** property of an image control to the **Photo** property of the camera control. The app holds the image in memory, and the **Photo** property of the camera control returns a URI reference to the image. For example, you might take a picture, and the camera's **Photo** property could return **"appres://blobmanager/7b12ffa2ea4547e5b3812cb1c7b0a2a0/1"**.

You use a URI to reference an image or another media file stored in a database. That way, the app doesn't retrieve the actual data until it's needed. For example, an attachment in a Microsoft Dataverse table might return **"appres://datasources/Contacts/table/..."** As in the camera example, you can display this image by setting the **Image** property of an image control to this reference, which retrieves the binary data.

When you save a media data type, such as an image, to a database, the app sends the actual image or media data, not the URI reference.

Size limits

As text strings and URIs, these data types have no preset limit on their length.

The binary data that these data types reference also has no preset limit on size. For example, an image captured through the camera control that's referenced as **"appres://..."** can be as large and high resolution as the device's camera can muster. The resolution, frame rate, and other attributes of media files aren't limited by the data type, but specific controls for playing and capturing media may have their own limitations.

However, all data sizes are subject to the amount of available memory in the app. Browsers running on a desktop computer typically support more than 100 megabytes of data. However, the amount of available memory on a device such as a phone might be far lower, typically in the range 30-70 megabytes. To determine whether your app runs within these limits, test common scenarios on all devices on which it should run.

As a best practice, hold data in memory only as long as necessary. Upload images to a database as soon as you can; download images only when the app's user requests them.

Numbers

> **Note**
>
> Power Apps only supports **Float** today and it's the type of all numbers. **Decimal** support will be added soon.

Power Fx supports two kinds of numbers: **Decimal** and **Float** (with synonyms **Number** and **Currency**).

Decimal is best for most business calculations. It can accurately represent numbers in base 10 meaning that `0.1` can be exactly represented and will avoid rounding errors during calculations. It has a large enough range for any business need, up to 10^{28} with up to 28 digits

of precision. **Decimal** is the default numeric data type for most Power Fx hosts, used if one simply writes `2*2`.

Float is best for scientific calculations. It can represent numbers in a larger range, up to 10^{308}. Precision is limited to 15 decimal places and math is based on base 2 so it can't represent some common decimal values precisely. **Float** also has higher performance and is favored if that is a factor and precision isn't critical.

Decimal numbers

The **Decimal** data type most often uses the .NET decimal data type. Some hosts, such as Dataverse formula columns that are run in SQL Server, use the SQL Server decimal data type.

Decimal does math the way you learned in school, using base 10 digits, important to avoid rounding errors from very small differences that can accumulate when using base 2 math (as used by **Float**).

The range is from positive 79,228,162,514,264,337,593,543,950,335 to negative 79,228,162,514,264,337,593,543,950,335. The decimal separator can be placed anywhere within these numbers, providing up to 28 digits of precision, and still be precisely represented. For example, 79,228,162,514,264.337593543950335 can be exactly represented, as can 7.9228162514264337593543950335.

Floating point numbers

The **Float** data type, also known as **Number** or **Currency**, uses the IEEE 754 double-precision floating-point standard. This standard provides a very large range of numbers in which to work, from -1.79769×10^{308} to 1.79769×10^{308}. The smallest value that can be represented is 5×10^{-324}.

Float can exactly represent whole numbers (or integers) between –9,007,199,254,740,991 ($-(2^{53} - 1)$) and 9,007,199,254,740,991 ($2^{53} - 1$), inclusive. This range is larger than the 32-bit (or 4-byte) integer data types that databases commonly use. However, canvas apps can't represent 64-bit (or 8-byte) integer data types. You might want to store the number in a text field or use a calculated column to make a copy of the number in a text field, so that it maps into a **Text** data type in the canvas app. In this manner, you can hold, display, and enter these values, and comparing them to determine whether they're equal; however, you can't perform numerical calculations on them in this form.

Floating-point arithmetic is approximate, so it can sometimes give unexpected results with many documented examples. You might expect the formula **55 / 100 * 100** to return exactly 55 and **(55 / 100 * 100) - 55** to return exactly zero. However, the latter formula returns $7.1054 \times 10^{-}$

^{15}, which is very small but not zero. That tiny difference doesn't normally cause a problem, and the app rounds it away when showing the result. However, small differences can compound in subsequent calculations and appear to give the wrong answer.

Database systems often store currencies and perform calculations by using decimal math, which offers a smaller range but greater control over the precision. By default, canvas apps map currencies in and out of floating-point values; therefore, the result might differ from calculations that are done in a native decimal data type. Depending on the precision needs of your app, you might want to work with these values as **Text**, as described for large integers earlier.

Defaults and conversions

> ⓘ **Note**
>
> Power Apps only supports **Float** today and it's the type of all numbers. **Decimal** support will be added soon.

Most Power Fx hosts use **Decimal** by default. Having this default means:

- Literal numbers in formulas. The number `1.234` is interpreted as a **Decimal** value. For example, the formula `1.234 * 2` interprets the `1.234` and `2` as **Decimal** and return a **Decimal** result.
- Value function. `Value( "1.234" )` returns a **Decimal** value. For example, in the formula `Value( "1.234" ) * 2`, the **Value** function interprets the contents of the text string `"1.234"` as a **Decimal**.

To work with **Float** values, the **Float** function is used. Extending our example, `Float( 1.234 )` converts the **Decimal** `1.234` to **Float**. **Float** can also be used as a replacement for **Value** to convert a string containing a floating point number such as `Float( "1.234" )` to a **Float** value, which is required if the number can't be represented as a **Decimal**.

In summary:

Expand table

Usage	Decimal	Float
Literal numbers in formulas	`1.234`	`Float( 1.234 )` `Float( "1.234" )`

Usage	Decimal	Float
Conversion from text string	`Value( "1.234" )` `Decimal( "1.234" )`	`Float( "1.234" )`
Conversion between numeric types	`Decimal( float )`	`Float( decimal )`
Conversion to text string	`Text( decimal )`	`Text( float )`

Mixing numeric types

Float and **Decimal** values can be freely mixed. When mixed, **Decimal** values are converted to **Float** values due to the larger range. As this conversion can result in a loss of precision, it's important to not mix the two needlessly. Since **Decimal** is the default literal data type and most numeric functions preserve the type, it's relatively easy to avoid moving to **Float** without desiring it.

For example, consider the following calculation using `pac power-fx repl` after installing the Power Platform CLI. Since both numbers are **Decimal**, the calculation is done in **Decimal**, and the result retains full precision:

Power Fx

```
>> 1.0000000000000000000000000001 * 2
2.0000000000000000000000000002
```

If instead, the second operand was changed to **Float** then the entire calculation would be done in **Float**, and the tiny fractional part would be lost:

Power Fx

```
>> 1.0000000000000000000000000001 * Float(2)
2
```

Date, Time, and DateTime

Time zones

Date/time values fall in these categories:

- **User local**: These values are stored in UTC (Coordinated Universal Time), but the app user's time zone affects how the app shows these values and how the app user specifies

them. As an example, the same moment appears differently to a user in Canada than it does to a user in Japan.
- **Time zone independent**: The app shows these values the same way and the app user specifies them the same way, regardless of time zone. The same moment appears the same way to a user in Canada as it does to a user in Japan. App authors who don't expect their apps to run in different time zones use these values because they're simpler overall.

This table shows some examples:

Expand table

Date/time type	Value stored in the database	Value displayed and entered 7 hours west of UTC	Value displayed and entered 4 hours east of UTC
User local	Sunday, May 19, 2019 4:00 AM	Saturday, May 18, 2019 9:00 PM	Sunday, May 19, 2019 8:00 AM
Time zone independent	Sunday, May 19, 2019 4:00 AM	Sunday, May 19, 2019 4:00 AM	Sunday, May 19, 2019 4:00 AM

For **User local** date/times, canvas apps use the time zone of the browser or device, but model-driven apps use the user's setting in Dataverse. These settings typically match, but results differ if these settings differ.

Use the DateAdd and TimeZoneInformation functions to convert local time to UTC and back again. See the examples at the end of the documentation for these functions.

Numeric equivalents

Canvas apps hold and calculate all date/time values, whether **User local** or **Time zone independent** in UTC. The app translates the values based on the app user's time zone when showing them and when the app user specifies them.

When a canvas app reads a **Time zone independent** value from a data source or writes such a value to a data source, the app automatically adjusts the value to compensate for the time zone of the app's user. The app then treats the value as a UTC value, consistent with all other date/time values in the app. Because of this compensation, the original **Time zone independent** value appears when the app adjusts the UTC value for the app user's time zone.

You can observe this behavior more closely by using the Value function to access the underlying numerical value for a date/time value. This function returns the date/time value as the number of milliseconds since January 1, 1970 00:00:00.000 UTC.

Because every date/time value is held in UTC, the formula **Value(Date(1970, 1, 1))** won't return zero in most parts of the world because the **Date** function returns a date in UTC. For example, the formula would return 28,800,000 in a time zone that's offset from UTC by eight hours. That number reflects the number of milliseconds in eight hours.

Returning to our example:

Expand table

Date/time type	Value stored in the database	Value displayed and entered 7 hours west of UTC	Value function returns
User local	Sunday, May 19, 2019 4:00 AM	Saturday, May 18, 2019 9:00 PM	1,558,238,400,000 (Sunday, May 19, 2019 4:00 AM UTC)
Time zone independent	Sunday, May 19, 2019 4:00 AM	Sunday, May 19, 2019 4:00 AM	1,558,263,600,000 (Sunday, May 19, 2019 11:00 AM UTC)

Converting Unix times

Unix times reflect the number of seconds since January 1, 1970 00:00:00 UTC. Because canvas apps use milliseconds instead of seconds, you can convert between the two by multiplying or dividing by 1,000.

For example, Unix time shows September 9, 2001, at 01:46:40 UTC as 1,000,000,000. To show that date/time value in a canvas app, multiply that number by 1,000 to convert it to milliseconds, and then use it in a Text function. The formula **Text(1000000000 * 1000, DateTimeFormat.UTC)** returns the string **2001-09-09T01:46:40.000Z**.

However, that function returns **Saturday, September 8, 2001 18:46:40** if you use the **DateTimeFormat.LongDateTime24** format in a time zone that's -7 hours offset from UTC (7 hours west of UTC). This result shows the **DateTime** value correctly based on the local time zone.

To convert to a Unix time, divide the result from **Value** by 1,000:
RoundDown(Value(UnixTime) / 1000, 0)

If you need the Unix time in a **Date** value for further calculations or display within Power Apps, use this formula:
DateAdd(Date(1970,1,1), UnixTime, Seconds)

SQL Server

SQL Server has **Datetime**, **Datetime2**, and other date/time data types that don't include a time-zone offset and don't indicate which time zone they're in. Canvas apps assume these values are stored in UTC and treat them as **User local**. If the values are meant to be time-zone independent, correct for the UTC translations by using the **TimeZoneOffset** function.

Canvas apps use the included time-zone information in **Datetimeoffset** fields when converting a value to the app's internal UTC representation. The apps always use UTC as the time zone (zero time zone offset) when they write data.

Canvas apps read and write values of the **Time** data type in SQL Server as text strings in the ISO 8601 duration format. For example, you must parse this string format and use the **Time** function to convert the text string **"PT2H1M39S"** to a **Time** value:

Power Fx

```
With(
    Match( "PT2H1M39S", "PT(?:(?<hours>\d+)H)?(?:(?<minutes>\d+)M)?(?:(?
<seconds>\d+)S)?" ),
    Time( Value( hours ), Value( minutes ), Value( seconds ) )
)
// Result: 2:01 AM (as shown in a label control, use the Text function to see the
seconds)
```

Mixing date and time information

Date, **Time**, and **DateTime** have different names, but they all hold the same information about dates and times.

A **Date** value can include time information with it, which is usually midnight. A **Time** value can carry date information, which is usually January 1, 1970. Dataverse also stores time information with a **Date Only** field but shows only the date information by default. Similarly, canvas apps sometimes distinguish between these data types to determine default formats and controls.

Adding and subtracting date and time values directly isn't recommended because time-zone and other conversions could cause confusing results. Either use the **Value** function to convert date/time values to milliseconds first and take into account the app user's time zone, or use the **DateAdd** and **DateDiff** functions to add or subtract from one of these values.

Choices and Yes/No

Choices and two-option data types give two or more choices for an app user to select. For example, an **Order Status** choice might offer the choices **New**, **Shipped**, **Invoiced**, and **Closed**.

The two-option data type gives only two choices.

Both of these data types show their labels as text. For example, a label control shows one of the order-status options if the control's **Text** property is set to a formula that references that choice. Option labels can be localized for app users in different locations.

When an app user selects an option and saves the change, the app sends the data to the database, which stores it in a way that's independent of language. An option in a choice is sent and stored as a number, and an option in a two-option data type is sent and stored as a boolean value.

The labels are for display only. You can't compare the labels directly because they're specific to a language. Instead, each choice has an enumeration that works with the underlying number or boolean value. For example, you can't use this formula:

```
If( ThisItem.OrderStatus = "Active", ...
```

But you can use this formula:

```
If( ThisItem.OrderStatus = OrderStatus.Active, ...
```

For global choices (which tables share), the name of the option-set enumeration matches the name of the global choice. For local choices (which are scoped to a table), the name can include the table name. This behavior avoids conflicts if multiple tables have choices with the same name. For example, the **Accounts** table might have an **OrderStatus** choice, and its name might be **OrderStatus (Accounts)**. That name has spaces and parentheses, so you need to surround it with single quotation marks if you reference it in a formula.

Two-option values also behave as boolean values. For example, a two-option value named **TaxStatus** might have the labels **Taxable** and **Non-Taxable**, which correspond to *true* and *false*. To show this, use this formula:

```
If( ThisItem.Taxable = TaxStatus.Taxable, ...
```

You can also use this formula:

```
If( ThisItem.Taxable, ...
```

DataSourceInfo function

Article • 04/11/2024

Applies to: Canvas apps Model-driven apps

Provides information about a data source.

Overview

Data sources can provide a wealth of information to optimize the user experience.

You can use column-level information to validate user input and provide immediate feedback to the user before using the **Patch** function. The **Validate** function uses this same information.

You can use information at the data-source level, for example, to disable or hide **Edit** and **New** buttons for users who don't have permissions to edit and create records.

Data sources vary in how much information they provide, including not providing any at all. Collections provide no information. If a piece of information isn't provided, a default is used, or *blank* is returned.

> **Note**
>
> Currently, the DataSourceInfo function is not supported in Microsoft Lists.

Description

Column information

You can use **DataSourceInfo** to obtain information about a particular column of a data source:

Expand table

Information Argument	Result Type	Description
DataSourceInfo.DisplayName	String	Display name for the column. If no display name is defined, returns the column name.

Information Argument	Result Type	Description
DataSourceInfo.MaxLength	Number	Maximum number of characters that the column can hold. Applies only to columns that contain strings. If a maximum isn't set, returns *blank*.
DataSourceInfo.MaxValue	Number	Maximum numeric value that a column can hold. Applies only to columns that contain numbers. If a maximum isn't set, returns *blank*.
DataSourceInfo.MinValue	Number	Minimum numeric value that a column can hold. Applies only to columns that contain numbers. If a minimum isn't set, returns *blank*.
DataSourceInfo.Required	Boolean	Is a value required for this column? If not set by the data source, returns **false**.

The third argument is the name of a column as a string. For example, column **Phone** in collection **People** would be passed as **"Phone"** including the double quotes.

Data-source information

You can also use **DataSourceInfo** to obtain information about a data source as a whole:

Expand table

Information Argument	Result Type	Description
DataSourceInfo.AllowedValues	Boolean	What types of permissions can users be granted for this data source? If not set by the data source, returns *blank*.
DataSourceInfo.CreatePermission	Boolean	Does the current user have permission to create records in this data source? If not set by the data source, returns **true**.
DataSourceInfo.DeletePermission	Boolean	Does the current user have permission to delete records in this data source? If not set by the data source, returns **true**.
DataSourceInfo.EditPermission	Boolean	Does the current user have permission to edit records in this data source? If not set by the data source, returns **true**.
DataSourceInfo.ReadPermission	Boolean	Does the current user have permission to read records in this data source? If not set by the data

Information Argument	Result Type	Description
		source, returns **true**.

> ⓘ Note
>
> **DataSourceInfo** returns *true* if it cannot determine whether the current user has the requested permission. Permissions will be checked again by the server when the actual operation is carried out and an error is displayed if it was not allowed. At this time, permissions checking with **DataSourceInfo** is only possible when using Microsoft Dataverse.

Syntax

DataSourceInfo(*DataSource*, *Information* [, *ColumnName*])

- *DataSource* – Required. The data source to use.
- *Information* – Required. The type of information that you want to retrieve.
- *ColumnName* – Optional. The column name for which to retrieve column-level information. For information at the data-source level, the *ColumnName* argument can't be used.

> ⓘ Note
>
> In Power Apps prior to version 3.24042, column names were specified with a text string using double quotes, and if connected to a data source they also needed to be logical names. For example, the logical name **"cr43e_name"** with double quotes was used instead of the display name **Name** without quotes. For SharePoint and Excel data sources that contain column names with spaces, each space was specified with **"_x0020_"**, for example **"Column Name"** as **"Column_x0020_Name"**. Afer this version, all apps were automatically updated to the new syntax described in this article.

Examples

The examples in this section use this data source, named **IceCream**:

Flavor	Quantity
"Chocolate"	100
"Vanilla"	200

The data source has also provided this information:

- The display name for **Quantity** is "Quantity on Hand".
- The maximum length of **Flavor** is 30 characters.
- The **Flavor** column must contain a value. The **Quantity** column isn't required.
- The minimum **Quantity** is 0.
- The maximum **Quantity** is 100.
- The current user can read and edit the records of the **IceCream** data source but can't create or delete records.

Expand table

Formula	Description	Result
DataSourceInfo(IceCream, DataSourceInfo.DisplayName, Quantity)	Returns the display name for the **Quantity** column of the **IceCream** data source.	"Quantity on Hand"
DataSourceInfo(IceCream, DataSourceInfo.MaxLength, Flavor)	Returns the maximum length of the string for the **Flavor** column of the **IceCream** data source.	30
DataSourceInfo(IceCream, DataSourceInfo.Required, Flavor)	Is the **Flavor** column of the **IceCream** data source required?	**true**
DataSourceInfo(IceCream, DataSourceInfo.Required, Quantity)	Is the **Quantity** column of the **IceCream** data source required?	**false**
DataSourceInfo(IceCream, DataSourceInfo.MaxValue, Quantity)	Returns the maximum numeric value for the **Quantity** column of the **IceCream** data source.	100
DataSourceInfo(IceCream, DataSourceInfo.MinValue, Quantity)	Returns the minimum numeric value for the **Quantity** column of the **IceCream** data source.	0
DataSourceInfo(IceCream, DataSourceInfo.ReadPermission)	Can the current user read records in the **IceCream** data source?	**true**
DataSourceInfo(IceCream, DataSourceInfo.EditPermission)	Can the current user edit records in the **IceCream** data source?	**true**

Formula	Description	Result
DataSourceInfo(IceCream, DataSourceInfo.CreatePermission)	Can the current user create records in the **IceCream** data source?	**false**
DataSourceInfo(IceCream, DataSourceInfo.DeletePermission)	Can the current user delete records in the **IceCream** data source?	**false**

Date, DateTime, and Time functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Converts date and time components to a date/time value.

Description

The **Date** function converts individual Year, Month, and Day values to a Date/Time value. The time portion is midnight.

- If Year is between 0 and 1899 (inclusive), the function adds that value to 1900 to calculate the year. **70** becomes **1970**.
- If Month is less than 1 or more than 12, the result subtracts or adds that many months from the beginning of the specified year.
- If Day is greater than the number of days in the specified month, the function adds that many days to the first day of the month and returns the corresponding date from a subsequent month. If Day is less than 1, the function subtracts that many days, plus 1, from the first day of the specified month.

The **Time** function converts individual Hour, Minute, Second, and optionally Millisecond values to a Date/Time value. The result has no date associated with it.

The **DateTime** function combines the **Date** and **Time** functions into a single function, taking both date and time arguments and returning a Date/Time value that has both date and time components.

See the **DateValue**, **TimeValue**, and **DateTimeValue** functions for information about how to convert a string to a value.

Also see working with dates and times for more information.

Syntax

Date(*Year*, *Month*, *Day*)

- *Year* - Required. Numbers greater than 1899 are interpreted as absolute (1980 is interpreted as 1980); numbers that range from 0 to 1899 are interpreted as relative to 1900. (For example, 80 is interpreted as 1980.)

- *Month* - Required. A number that ranges from 1 to 12.
- *Day* - Required. A number that ranges from 1 to 31.

Time(*Hour*, *Minute*, *Second* [, *Milliseconds*])

- *Hour* - Required. Number of hours, usually in the range 0 (12:00 AM) to 23 (11:00 PM).
- *Minute* - Required. Number of minutes, usually in the range 0 to 59.
- *Second* - Required. Number of seconds, usually in the range 0 to 59.
- *Milliseconds* - Optional. Number of milliseconds, usually in the range 0 to 999.

DateTime(*Year*, *Month*, *Day*, *Hour*, *Minute*, *Second* [, *Milliseconds*])

- *Year* - Required. Numbers greater than 1899 are interpreted as absolute (1980 is interpreted as 1980); numbers that range from 0 to 1899 are interpreted as relative to 1900. (For example, 80 is interpreted as 1980.)
- *Month* - Required. A number that ranges from 1 to 12.
- *Day* - Required. A number that ranges from 1 to 31.
- *Hour* - Required. Number of hours, usually in the range 0 (12:00 AM) to 23 (11:00 PM)
- *Minute* - Required. Number of minutes, usually in the range 0 to 59.
- *Second* - Required. Number of seconds, usually in the range 0 to 59.
- *Milliseconds* - Optional. Number of milliseconds, usually in the range 0 to 999.

Examples

Date

If a user typed

- **1979** in a text-input control named **HireYear**
- **3** in a text-input control named **HireMonth**
- **17** in a text-input control named **HireDay**

this formula would return `3/17/1979`:

Power Apps

```
Date( Value(HireYear.Text), Value(HireMonth.Text), Value(HireDay.Text) )
```

Time

If a user typed

- **14** in a text-input control named **BirthHour**
- **50** in a text-input control named **BirthMinute**
- **24** in a text-input control named **BirthSecond**

this formula would return `02:50:24 P`:

Power Apps

```
Text(
    Time(Value(BirthHour.Text), Value(BirthMinute.Text),
Value(BirthSecond.Text)),
    "hh:mm:ss A/P"
)
```

DateTime

If a user typed

- **2023** in a text-input control named **EclipseYear**
- **10** in a text-input control named **EclipseMonth**
- **28** in a text-input control named **EclipseDate**
- **13** in a text-input control named **EclipseHour**
- **14** in a text-input control named **EclipseMinute**
- **5** in a text-input control named **EclipseSecond**
- **231** in a text-input control named **EclipseMillisecond**

this formula would return `10/28/23 01:14:05.231 PM`:

Power Apps

```
Text(
    DateTime(Value(EclipseYear.Text), Value(EclipseMonth.Text),
Value(EclipseDate.Text),
        Value(EclipseHour.Text), Value(EclipseMinute.Text),
        Value(EclipseSecond.Text), Value(EclipseSecond.Millisecond)
    ),
    "yy/mm/dd hh:mm:ss.000 AM/PM"
)
```

DateAdd, DateDiff, and TimeZoneOffset functions

Article • 04/20/2025

Expand table

Functions	Applies to
DateAdd **DateDiff**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
TimeZoneOffset	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Expand table

Function	Applies to
DateAdd	
DateDiff	
TimeZoneOffset	

Adds to or finds the difference in date/time values and converts between local time and UTC.

Description

The **DateAdd** function adds a number of units to a date/time value. The result is a new date/time value. You can also subtract a number of units from a date/time value by specifying a negative value.

The **DateDiff** function returns the difference between two date/time values. The result is a whole number of units.

For both functions, units can be **TimeUnit.Milliseconds**, **TimeUnit.Seconds**, **TimeUnit.Minutes**, **TimeUnit.Hours**, **TimeUnit.Days**, **TimeUnit.Months**, **TimeUnit.Quarters**, or **TimeUnit.Years**. By default, both functions use **TimeUnit.Days** as units.

The **TimeZoneOffset** function returns the number of minutes between the user's local time and UTC (Coordinated Universal Time).

You can use **DateAdd** with the **TimeZoneOffset** to convert between the user's local time and UTC (Coordinated Universal Time). Adding **TimeZoneOffset** will convert a local time to UTC, and subtracting it (adding the negative) will convert from UTC to local time.

Also see Date, Time, and DateTime data types and working with dates and times for more information.

Syntax

DateAdd(*DateTime*, *Addition* [, *Units*])

- *DateTime* - Required. Date/time value to operate on.
- *Addition* - Required. Number, in *Units*, to add to the *DateTime*.
- *Units* - Optional. The type of *Units* to add: **TimeUnit.Milliseconds**, **TimeUnit.Seconds**, **TimeUnit.Minutes**, **TimeUnit.Hours**, **TimeUnit.Days**, **TimeUnit.Months**, **TimeUnit.Quarters**, or **TimeUnit.Years**. If not specified, **TimeUnit.Days** are used.

DateDiff(*StartDateTime*, *EndDateTime* [, *Units*])

- *StartDateTime* - Required. Starting date/time value.
- *EndDateTime* - Required. Ending date/time value.
- *Units* - Optional. The type of *Units* to subtract: **TimeUnit.Milliseconds**, **TimeUnit.Seconds**, **TimeUnit.Minutes**, **TimeUnit.Hours**, **TimeUnit.Days**, **TimeUnit.Months**, **TimeUnit.Quarters**, or **TimeUnit.Years**. If not specified, **TimeUnit.Days** are used.

TimeZoneOffset([*DateTime*])

- *DateTime* - Optional. Date/time value for which to return the offset. By default, the current date/time is used.

Examples

In all of these examples, assume that the current date and time is **July 15, 2013, 1:02 PM**.

Simple DateAdd

Expand table

Formula	Description	Result
Text(DateAdd(Now(), 3), "dd-mm-yyyy hh:mm")	Adds three days (default units) to the current date and time.	"18-07-2013 13:02"

Formula	Description	Result
Text(DateAdd(Now(), 4, TimeUnit.Hours), "dd-mm-yyyy hh:mm")	Add four hours to the current date and time.	"15-07-2013 17:02"
Text(DateAdd(Today(), 1, TimeUnit.Months), "dd-mm-yyyy hh:mm")	Adds one month to the current date, without time as **Today** doesn't return a time component.	"15-08-2013 00:00"
Text(DateAdd(Now(), -30, TimeUnit.Minutes), "dd-mm-yyyy hh:mm")	Subtracts 30 minutes from the current date and time.	"15-07-2013 12:32"

Simple DateDiff

Expand table

Formula	Description	Result
DateDiff(Now(), DateValue("1/1/2014"))	Returns the difference between the two units in the default units of **TimeUnit.Days**	170
DateDiff(Now(), DateValue("1/1/2014"), TimeUnit.Months)	Returns the difference between the two values in **TimeUnit.Months**	6
DateDiff(Now(), Today(), TimeUnit.Minutes)	Returns the difference between the current date/time and the current date only (no time) in minutes. Since the **Now** is later than **Today** the result will be negative.	-782

Difference of dates with fractional results

The function DateDiff only returns a whole number of the units being subtracted, and the precision is given in the unit specified. To calculate the difference with a higher precision, use a smaller unit, and convert the result appropriately, like in the examples below.

Expand table

Formula	Description	Result
DateDiff(TimeValue("09:45:00"), TimeValue("10:15:36"), TimeUnit.Hours)	The minutes/seconds are ignored, the difference is based on the time up to the hour.	1
DateDiff(TimeValue("09:45:00"), TimeValue("10:15:36"), TimeUnit.Minutes	The minutes are used in the difference, and the result is divided by 60 to have the difference in	0.5

Formula	Description	Result
)/60	hours.	
DateDiff(TimeValue("09:45:00"), TimeValue("10:15:36"), TimeUnit.Seconds)/3600	The minutes and seconds are used in the difference; the result is divided by 3600 to have the difference in hours.	0.51

Converting to UTC

To convert to UTC (Coordinated Universal Time), add the **TimeZoneOffset** for the given time.

For example, imagine the current date and time is **July 15, 2013, 1:02 PM** in Pacific Daylight Time (PDT, UTC-7). To determine the current time in UTC, use:

- **DateAdd(Now(), TimeZoneOffset(), TimeUnit.Minutes)**

TimeZoneOffset defaults to the current time, so you don't need to pass it an argument.

To see the result, use the **Text** function with the format *dd-mm-yyyy hh:mm*, which will return **15-07-2013 20:02**.

Converting from UTC

To convert from UTC, subtract the **TimeZoneOffset** (by adding the negative) for the given time.

For example, imagine the UTC date and time **July 15, 2013, 8:02 PM** is stored in a variable named **StartTime**. To adjust the time for the user's time zone, use:

- **DateAdd(StartTime, -TimeZoneOffset(StartTime), TimeUnit.Minutes)**

Note the negative sign before **TimeZoneOffset** to subtract the offset rather than add it.

To see the result, use the **Text** function with the format *dd-mm-yyyy hh:mm*, which will result in **15-07-2013 13:02** if you're in Pacific Daylight Time.

DateAdd, DateDiff, and TimeZoneOffset functions

Article • 04/20/2025

DateDiff(TimeValue("09:45:00"), TimeValue("10:15:36"), TimeUnit.Minutes	The minutes are used in the difference, and the result is divided by 60 to have the difference in	0.5

Formula	Description	Result
)/60	hours.	
DateDiff(TimeValue("09:45:00"), TimeValue("10:15:36"), TimeUnit.Seconds)/3600	The minutes and seconds are used in the difference; the result is divided by 3600 to have the difference in hours.	0.51

Converting to UTC

To convert to UTC (Coordinated Universal Time), add the **TimeZoneOffset** for the given time.

For example, imagine the current date and time is **July 15, 2013, 1:02 PM** in Pacific Daylight Time (PDT, UTC-7). To determine the current time in UTC, use:

- **DateAdd(Now(), TimeZoneOffset(), TimeUnit.Minutes)**

TimeZoneOffset defaults to the current time, so you don't need to pass it an argument.

To see the result, use the **Text** function with the format *dd-mm-yyyy hh:mm*, which will return **15-07-2013 20:02**.

Converting from UTC

To convert from UTC, subtract the **TimeZoneOffset** (by adding the negative) for the given time.

For example, imagine the UTC date and time **July 15, 2013, 8:02 PM** is stored in a variable named **StartTime**. To adjust the time for the user's time zone, use:

- **DateAdd(StartTime, -TimeZoneOffset(StartTime), TimeUnit.Minutes)**

Note the negative sign before **TimeZoneOffset** to subtract the offset rather than add it.

To see the result, use the **Text** function with the format *dd-mm-yyyy hh:mm*, which will result in **15-07-2013 13:02** if you're in Pacific Daylight Time.

DateValue, TimeValue, and DateTimeValue functions

06/19/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Converts date, time, or both in a *string* to a *date/time* value.

Description

- **DateValue** function converts a *date string* (like "10/01/2014") to a *date/time* value.
- **TimeValue** function converts a *time string* (like "12:15 PM") to a *date/time* value.
- **DateTimeValue** function converts a *date and time string* (like "January 10, 2013 12:13 AM") to a *date/time* value.

DateValue function ignores any time information in the date string, and **TimeValue** function ignores any date information in the time string.

> ⓘ **Note**
>
> The DateValue, TimeValue, and DateTimeValue functions by default use the language from the current user's settings. You can override it to ensure that strings are interpreted properly. For example, "10/1/1920" is interpreted as *October 1st* in "*en*" and as *January 10th* in "*fr*".

Dates must use one of these formats:

- MM/DD/YYYY or MM-DD-YYYY
- DD/MM/YYYY or DD-MM-YYYY
- YYYY/MM/DD or YYYY-MM-DD
- MM/DD/YY or MM-DD-YY
- DD/MM/YY or DD-MM-YY
- DD Mon YYYY
- Month DD, YYYY

To convert from numeric date, month and year components, read Date.
To convert from numeric hour, minute and second components, read Time.

For more information, see:

- Working with date and time
- Date/time and data types

Syntax

DateValue(*String* [, *Language*])
DateTimeValue(*String* [, *Language*])
TimeValue(*String* [, *Language*])

- *String* - Required. A text string that contains a date, time, or combination date and time value.
- *Language* - Optional. A language string, such as would be returned by the first two characters from the Language function. If not provided, the language of the current user's settings is used.

DateValue(*Dynamic*)
DateTimeValue(*Dynamic*)
TimeValue(*Dynamic*)

- *Dynamic* - Required. **Dynamic** value that represents a date or time. Acceptable values are dependent on the untyped provider. For **JSON**, the dynamic value is expected to be a JSON string that contains a date and time in ISO 8601 format. Dates or times in other formats will result in an error. Consider converting such values to **Text** first, then to a date or time. Keep in mind that time zones and locale-related formats are important considerations when communicating with external systems.

Examples

DateValue

If you type **10/11/2014** into a text-input control named **Startdate**, and then set the Text property of a label to these formulas:

- Convert a date from a string in the user's locale and show the result as a long date.

  Power Fx

  ```
  Text( DateValue( Startdate.Text ), DateTimeFormat.LongDate )
  ```

  Device set to **en** locale shows the label as **Saturday, October 11, 2014**.

> **Note**
>
> You can use several options with the **DateTimeFormat** enum. To display a list of options, type the parameter followed by a dot or period (.) in the formula bar or check Text function reference.

- Convert date from a string in the French locale and show the result as a long date. In this example, the months and day of the month are interpreted differently from English.

  ```
  Power Fx
  Text( DateValue( Startdate.Text, "fr" ), DateTimeFormat.LongDate )
  ```

  Device set to **en** locale shows the label as **Monday, November 10, 2014**.

If you enter **October 20, 2014** instead:

- Convert a date from a string in the user's locale and calculate the difference between two days, in days

  ```
  Power Fx
  DateDiff( DateValue( Startdate.Text ), Today() )
  ```

  Device set to **en** locale shows the label as **9**, indicating the number of days between October 11 and October 20. The DateDiff function can also show the difference in months, quarters, or years.

DateTimeValue

If you typed **10/11/2014 1:50:24.765 PM** into a text-input control named **Start**, and then set the Text property of a label to the following formula:

- Convert both a date and time string in the current locale.

  ```
  Power Fx
  Text( DateTimeValue( Start.Text ), DateTimeFormat.LongDateTime )
  ```

  Device set to **en** locale shows the label as **Saturday, October 11, 2014 1:50:24 PM**.

> **Note**

You can use several options with the **DateTimeFormat** enum. To display a list of options, type the parameter followed by a dot or period (.) in the formula bar or check Text function reference.

- Convert both a date and time string in the French locale. Month and day of the month are interpreted differently.

  Power Fx

  ```
  Text( DateTimeValue( Start.Text, "fr"), DateTimeFormat.LongDateTime )
  ```

  Device set to **en** locale shows the label as **Monday, November 10, 2014 1:50:24 PM**.

- Convert both a date and time string in the user's locale, and display the result with a fractional second.

  Power Fx

  ```
  Text( DateTimeValue( Start.Text ), "dddd, mmmm dd, yyyy hh:mm:ss.fff AM/PM" )
  ```

  Device set to **en** locale shows the label as **Saturday, October 11, 2014 01:50:24.765 PM**.

  As an alternative, you can specify **hh:mm:ss.f** or **hh:mm:ss.ff** to round the time to the nearest 10th or 100th of a second.

TimeValue

Name a text-input control **FinishedAt**, and set the Text property of a label to this formula:

Power Fx

```
If( TimeValue( FinishedAt.Text ) < TimeValue( "5:00:00.000 PM" ),
    "You made it!",
    "Too late!"
)
```

- If you type **4:59:59.999 PM** in the **FinishedAt** control, the label shows "*You made it!*"
- If you type **5:00:00.000 PM** in the **FinishedAt** control, the label shows "*Too late!*"

DateValue, TimeValue, and DateTimeValue functions

06/19/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Converts date, time, or both in a *string* to a *date/time* value.

Description

- **DateValue** function converts a *date string* (like "10/01/2014") to a *date/time* value.
- **TimeValue** function converts a *time string* (like "12:15 PM") to a *date/time* value.
- **DateTimeValue** function converts a *date and time string* (like "January 10, 2013 12:13 AM") to a *date/time* value.

DateValue function ignores any time information in the date string, and **TimeValue** function ignores any date information in the time string.

> ⓘ **Note**
>
> The DateValue, TimeValue, and DateTimeValue functions by default use the language from the current user's settings. You can override it to ensure that strings are interpreted properly. For example, "10/1/1920" is interpreted as *October 1st* in "*en*" and as *January 10th* in "*fr*".

Dates must use one of these formats:

- MM/DD/YYYY or MM-DD-YYYY
- DD/MM/YYYY or DD-MM-YYYY
- YYYY/MM/DD or YYYY-MM-DD
- MM/DD/YY or MM-DD-YY
- DD/MM/YY or DD-MM-YY
- DD Mon YYYY
- Month DD, YYYY

To convert from numeric date, month and year components, read Date.
To convert from numeric hour, minute and second components, read Time.

For more information, see:

- Working with date and time
- Date/time and data types

Syntax

DateValue(*String* [, *Language*])
DateTimeValue(*String* [, *Language*])
TimeValue(*String* [, *Language*])

- *String* - Required. A text string that contains a date, time, or combination date and time value.
- *Language* - Optional. A language string, such as would be returned by the first two characters from the Language function. If not provided, the language of the current user's settings is used.

DateValue(*Dynamic*)
DateTimeValue(*Dynamic*)
TimeValue(*Dynamic*)

- *Dynamic* - Required. **Dynamic** value that represents a date or time. Acceptable values are dependent on the untyped provider. For **JSON**, the dynamic value is expected to be a JSON string that contains a date and time in ISO 8601 format. Dates or times in other formats will result in an error. Consider converting such values to **Text** first, then to a date or time. Keep in mind that time zones and locale-related formats are important considerations when communicating with external systems.

Examples

DateValue

If you type **10/11/2014** into a text-input control named **Startdate**, and then set the Text property of a label to these formulas:

- Convert a date from a string in the user's locale and show the result as a long date.

  Power Fx

  ```
  Text( DateValue( Startdate.Text ), DateTimeFormat.LongDate )
  ```

  Device set to **en** locale shows the label as **Saturday, October 11, 2014**.

> **Note**
>
> You can use several options with the **DateTimeFormat** enum. To display a list of options, type the parameter followed by a dot or period (.) in the formula bar or check Text function reference.

- Convert date from a string in the French locale and show the result as a long date. In this example, the months and day of the month are interpreted differently from English.

  ```
  Power Fx
  Text( DateValue( Startdate.Text, "fr" ), DateTimeFormat.LongDate )
  ```

  Device set to **en** locale shows the label as **Monday, November 10, 2014**.

If you enter **October 20, 2014** instead:

- Convert a date from a string in the user's locale and calculate the difference between two days, in days

  ```
  Power Fx
  DateDiff( DateValue( Startdate.Text ), Today() )
  ```

  Device set to **en** locale shows the label as **9**, indicating the number of days between October 11 and October 20. The DateDiff function can also show the difference in months, quarters, or years.

DateTimeValue

If you typed **10/11/2014 1:50:24.765 PM** into a text-input control named **Start**, and then set the Text property of a label to the following formula:

- Convert both a date and time string in the current locale.

  ```
  Power Fx
  Text( DateTimeValue( Start.Text ), DateTimeFormat.LongDateTime )
  ```

  Device set to **en** locale shows the label as **Saturday, October 11, 2014 1:50:24 PM**.

> **Note**

You can use several options with the **DateTimeFormat** enum. To display a list of options, type the parameter followed by a dot or period (.) in the formula bar or check Text function reference.

- Convert both a date and time string in the French locale. Month and day of the month are interpreted differently.

  Power Fx

  ```
  Text( DateTimeValue( Start.Text, "fr"), DateTimeFormat.LongDateTime )
  ```

  Device set to **en** locale shows the label as **Monday, November 10, 2014 1:50:24 PM**.

- Convert both a date and time string in the user's locale, and display the result with a fractional second.

  Power Fx

  ```
  Text( DateTimeValue( Start.Text ), "dddd, mmmm dd, yyyy hh:mm:ss.fff AM/PM" )
  ```

  Device set to **en** locale shows the label as **Saturday, October 11, 2014 01:50:24.765 PM**.

  As an alternative, you can specify **hh:mm:ss.f** or **hh:mm:ss.ff** to round the time to the nearest 10th or 100th of a second.

TimeValue

Name a text-input control **FinishedAt**, and set the Text property of a label to this formula:

Power Fx

```
If( TimeValue( FinishedAt.Text ) < TimeValue( "5:00:00.000 PM" ),
    "You made it!",
    "Too late!"
)
```

- If you type **4:59:59.999 PM** in the **FinishedAt** control, the label shows "*You made it!*"
- If you type **5:00:00.000 PM** in the **FinishedAt** control, the label shows "*Too late!*"

Day, Month, Year, Hour, Minute, Second, and Weekday functions

Article • 06/10/2024

Applies to: Canvas apps Dataverse formula columns Desktop flows Model-driven apps Power Pages Power Platform CLI

Returns individual components of a Date/Time value.

Description

The **Day** function returns the day component of a Date/Time value, ranging from 1 to 31.

The **Month** function returns the month component of a Date/Time value, ranging from 1 to 12.

The **Year** function returns the year component of a Date/Time value, starting with 1900.

The **Hour** function returns the hour component of a Date/Time value, ranging from 0 (12:00 AM) to 23 (11:00 PM).

The **Minute** function returns the minute component of a Date/Time value, ranging from 0 to 59.

The **Second** function returns the second component of a Date/Time value, ranging from 0 to 59.

The **Weekday** function returns the weekday of a Date/Time value. By default, the result ranges from 1 (Sunday) to 7 (Saturday). You can specify a different range with a Microsoft Excel Weekday function code or a StartOfWeek enumeration value:

Expand table

Excel code	StartOfWeek enumeration	Description
1, 17	StartOfWeek.Sunday	Numbers 1 (Sunday) through 7 (Saturday). Default.
2, 11	StartOfWeek.Monday	Numbers 1 (Monday) through 7 (Sunday).
3	StartOfWeek.MondayZero	Numbers 0 (Monday) through 6 (Sunday).
12	StartOfWeek.Tuesday	Numbers 1 (Tuesday) through 7 (Monday).

Excel code	StartOfWeek enumeration	Description
13	**StartOfWeek.Wednesday**	Numbers 1 (Wednesday) through 7 (Tuesday).
14	**StartOfWeek.Thursday**	Numbers 1 (Thursday) through 7 (Wednesday).
15	**StartOfWeek.Friday**	Numbers 1 (Friday) through 7 (Thursday).
16	**StartOfWeek.Saturday**	Numbers 1 (Saturday) through 7 (Friday).

All functions return a number.

See working with dates and times for more information.

Syntax

Day(*DateTime*)
Month(*DateTime*)
Year(*DateTime*)
Hour(*DateTime*)
Minute(*DateTime*)
Second(*DateTime*)

- *DateTime* - Required. Date/Time value to operate on.

Weekday(*DateTime* [, *WeekdayFirst*])

- *DateTime* - Required. Date/Time value to operate on.
- *WeekdayFirst* - Optional. Excel code specifying which day starts the week. If not supplied, 1 (Sunday first) is used.

Examples

For the following example, the current time is **3:59:37 PM** on **Thursday, April 9, 2015**.

Expand table

Formula	Description	Result
Year(Now())	Returns the year component of the current time and date.	2015
Month(Now())	Returns the month component of the current time and date.	4

Formula	Description	Result
Day(Now())	Returns the day component of the current time and date.	9
Hour(Now())	Returns the hour component of the current time and date.	15
Minute(Now())	Returns the minute component of the current time and date.	59
Second(Now())	Returns the second component of the current time and date.	37
Weekday(Now())	Returns the weekday component of the current time and date, using the default start of the week as Sunday.	5
Weekday(Now(), 14)	Returns the weekday component of the current time and date, using an Excel code to specify the start of the week as Thursday.	1
Weekday(Now(), StartOfWeek.Wednesday)	Returns the weekday component of the current time and date, using a **StartOfWeek** enumeration to specify the start of the week as Wednesday.	2

Defaults function

10/10/2025

Applies to: ✅ Canvas apps ✅ Model-driven apps

Returns the default values for a data source.

Description

Use the **Defaults** function to prepopulate a data entry form, making it easier to fill.

This function returns a record that contains the default values for the data source. If a column within the data source doesn't have a default value, that property isn't present.

Data sources vary in how much default information they provide, including not providing any at all. When you work with a collection or another data source that doesn't support default values, the **Defaults** function returns an empty record.

You can combine the **Defaults** function with the **Patch** function to create a record.

Syntax

Defaults(*DataSource*)

- *DataSource* – Required. The data source for which you want default values.

Examples

Expand table

Formula	Description	Result
Defaults(Scores)	Returns the default values for the **Scores** data source.	**{ Score: 0 }**

Acos, Acot, Asin, Atan, Atan2, Cos, Cot, Degrees, Pi, Radians, Sin, and Tan functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Calculates trigonometric values.

Description

Primary functions

The **Cos** function returns the cosine of its argument, an angle specified in radians.

The **Cot** function returns the cotangent of its argument, an angle specified in radians.

The **Sin** function returns the sine of its argument, an angle specified in radians.

The **Tan** function returns the tangent of its argument, an angle specified in radians.

Inverse functions

The **Acos** function returns the arccosine, or inverse cosine, of its argument. The arccosine is the angle whose cosine is the argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Acot** function returns the principal value of the arccotangent, or inverse cotangent, of its argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Asin** function returns the arcsine, or inverse sine, of its argument. The arcsine is the angle whose sine is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan** function returns the arctangent, or inverse tangent, of its argument. The arctangent is the angle whose tangent is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan2** function returns the arctangent, or inverse tangent, of the specified *x* and *y* coordinates as arguments. The arctangent is the angle from the *x*-axis to a line that contains the origin (0, 0) and a point with coordinates (*x*, *y*). The angle is given in radians between -π and π, excluding -π. A positive result represents a counterclockwise angle from the *x*-axis; a negative result represents a clockwise angle. **Atan2(*a*, *b*)** equals **Atan(*b*/*a*)**, except that ***a*** can equal 0 (zero) with the **Atan2** function.

Helper functions

The **Degrees** function converts radians to degrees. π radians equals 180 degrees.

The **Pi** function returns the transcendental number π, which begins 3.141592...

The **Radians** function converts degrees to radians.

Notes

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results with a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined value, the result is *blank*. This can happen, for example, when using inverse functions with arguments that are out of range.

Syntax

Primary Functions

Cos(*Radians*)
Cot(*Radians*)
Sin(*Radians*)
Tan(*Radians*)

- *Radians* - Required. Angle to operate on.

Cos(*SingleColumnTable*)
Cot(*SingleColumnTable*)
Sin(*SingleColumnTable*)
Tan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of angles to operate on.

Inverse Functions

Acos(*Number*)
Acot(*Number*)
Asin(*Number*)
Atan(*Number*)

- *Number* - Required. Number to operate on.

Acos(*SingleColumnTable*)
Acot(*SingleColumnTable*)
Asin(*SingleColumnTable*)
Atan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Atan2(*X*, *Y*)

- *X* - Required. *X*-axis coordinate.
- *Y* - Required. *Y*-axis coordinate.

Helper Functions

Degrees(*Radians*)

- *Radians* - Required. Angle in radians to convert to degrees.

Pi()

Radians(*Degrees*)

- *Degrees* - Required. Angle in degrees to convert to radians.

Examples

Single number

Expand table

Formula	Description	Result
Cos(1.047197)	Returns the cosine of 1.047197 radians or 60 degrees.	0.5
Cot(Pi()/4)	Returns the cotangent of 0.785398... radians or 45 degrees.	1
Sin(Pi()/2)	Returns the sine of 1.570796... radians or 90 degrees.	1
Tan(Radians(60))	Returns the tangent of 1.047197... radians or 60 degrees.	1.732050...
Acos(0.5)	Returns the arccosine of 0.5, in radians.	1.047197...
Acot(1)	Returns the arccotangent of 1, in radians.	0.785398...
Asin(1)	Returns the arcsine of 1, in radians.	1.570796...
Atan(1.732050)	Returns the arctangent of 1.732050, in radians.	1.047197...
Atan2(5, 3)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (5,3), which is approximately 31 degrees.	0.540419...
Atan2(4, 4)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (4,4), which is exactly π/4 radians or 45 degrees.	0.785398...
Degrees(1.047197)	Returns the equivalent number of degrees for 1.047197 radians.	60
Pi()	Returns the transcendental number π.	3.141592...
Radians(15)	Returns the equivalent number of radians for 15 degrees.	0.261799...

Single-column table

The examples in this section use a data source that's named **ValueTable** and that contains the following data. The last record in the table is π/2 radians or 90 degrees.

Expand table

Value
0.5
-2
1.570796...

Expand table

Formula	Description	Result
Cos(ValueTable)	Returns the cosine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.877582..., -0.416146..., 0
Cot(ValueTable)	Returns the cotangent of each number in the table.	A single-column table with a `Value` column containing the following values: 1.830487..., 0.457657..., 0
Sin(ValueTable)	Returns the sine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.479425, -0.909297..., 1
Tan(ValueTable)	Returns the tangent of each number in the table.	A single-column table with a `Value` column containing the following values: 0.546302..., 2.185039..., 3060023.306952...
Acos(ValueTable)	Returns the arccosine of each number in the table.	A single-column table with a `Value` column containing the following values: 1.047197..., Blank(), Blank()
Acot(ValueTable)	Returns the arccotangent of each number in the table.	A single-column table with a `Value` column containing the following values: 1.107138..., 2.677945..., 0.566911...
Asin(ValueTable)	Returns the arcsine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.523598..., Blank(), Blank()
Atan(ValueTable)	Returns the arctangent of each number in the table.	A single-column table with a `Value` column containing the following values: 0.463647..., -1.107148..., 1.00388...
Degrees(ValueTable)	Returns the equivalent number of degrees for each number in the table, assumed to be angles in radians.	A single-column table with a `Value` column containing the following values: 28.647889..., -114.591559..., 90
Radians(ValueTable)	Returns the equivalent number of radians for each number in the table, assumed to be angles in degrees.	A single-column table with a `Value` column containing the following values: 0.008726..., -0.034906..., 0.027415...

Enable and Disable functions

10/10/2025

Applies to: Canvas apps

Turns a signal on or off.

Overview

Some signals can change often, requiring the app to recalculate as they do. Rapid changes over a long period of time can drain a device's battery. You can use these functions to manually turn a signal on or off.

When a signal isn't in use, it's automatically turned off.

Description

The **Enable** and **Disable** functions turn a signal on and off, respectively.

These functions currently only work for the **Location** signal.

These functions have no return value. You can use them only in behavior formulas.

Syntax

Enable(*Signal*)
Disable(*Signal*)

- *Signal* - Required. The signal to turn on or off.

Distinct function

Article • 04/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Summarizes records of a table, removing duplicates.

Description

The **Distinct** function evaluates a formula across each record of a table and returns a one-column table of the results with duplicate values removed. The name of the column is **Value**.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

When used with a data source, this function can't be delegated. Only the first portion of the data source will be retrieved and then the function applied. The result may not represent the complete story. A warning may appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

Syntax

Distinct(*Table*, *Formula*)

- *Table* - Required. Table to evaluate across.
- *Formula* - Required. Formula to evaluate for each record.

Example

1. Insert a **Button** control, and set its **OnSelect** property to this formula.

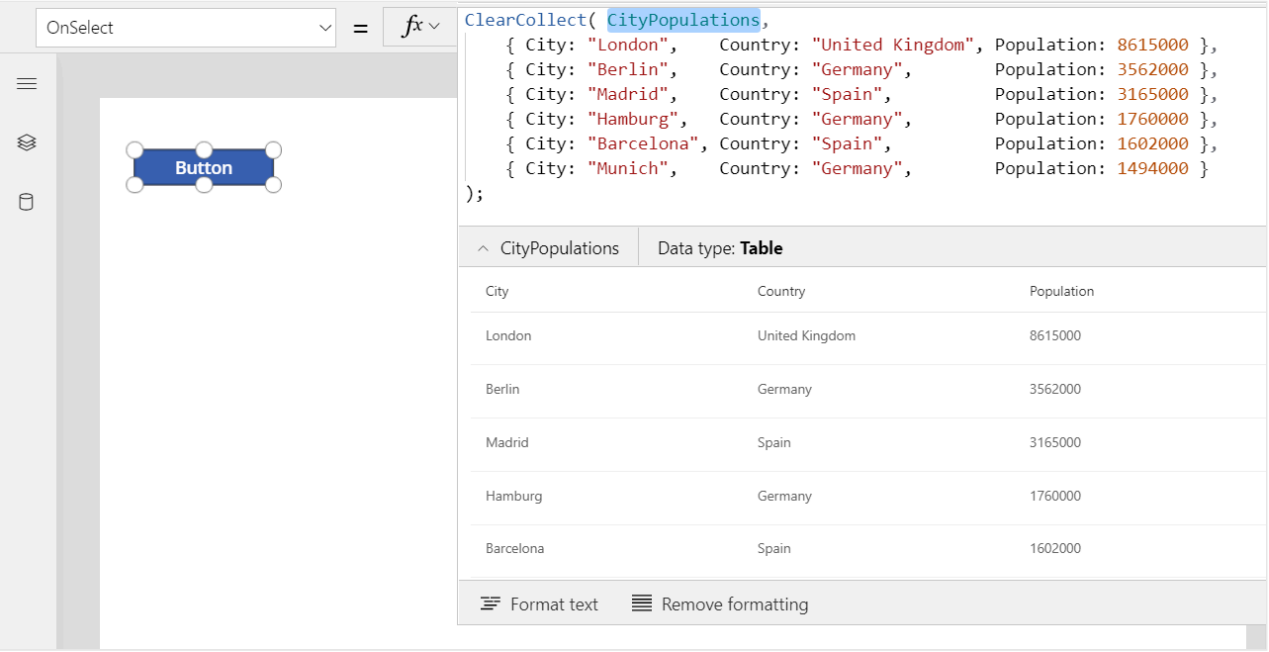
```
Power Fx
```

```
ClearCollect( CityPopulations,
    { City: "London",    Country: "United Kingdom", Population: 8615000 },
    { City: "Berlin",    Country: "Germany",        Population: 3562000 },
    { City: "Madrid",    Country: "Spain",          Population: 3165000 },
    { City: "Hamburg",   Country: "Germany",        Population: 1760000 },
```

```
    { City: "Barcelona", Country: "Spain",          Population: 1602000 },
    { City: "Munich",    Country: "Germany",        Population: 1494000 }
);
```

2. Select the button while holding down the Alt key.

   The formula is evaluated and the **CityPopulations** collection is created which you can show by selecting **CityPopulations** in the formula bar:

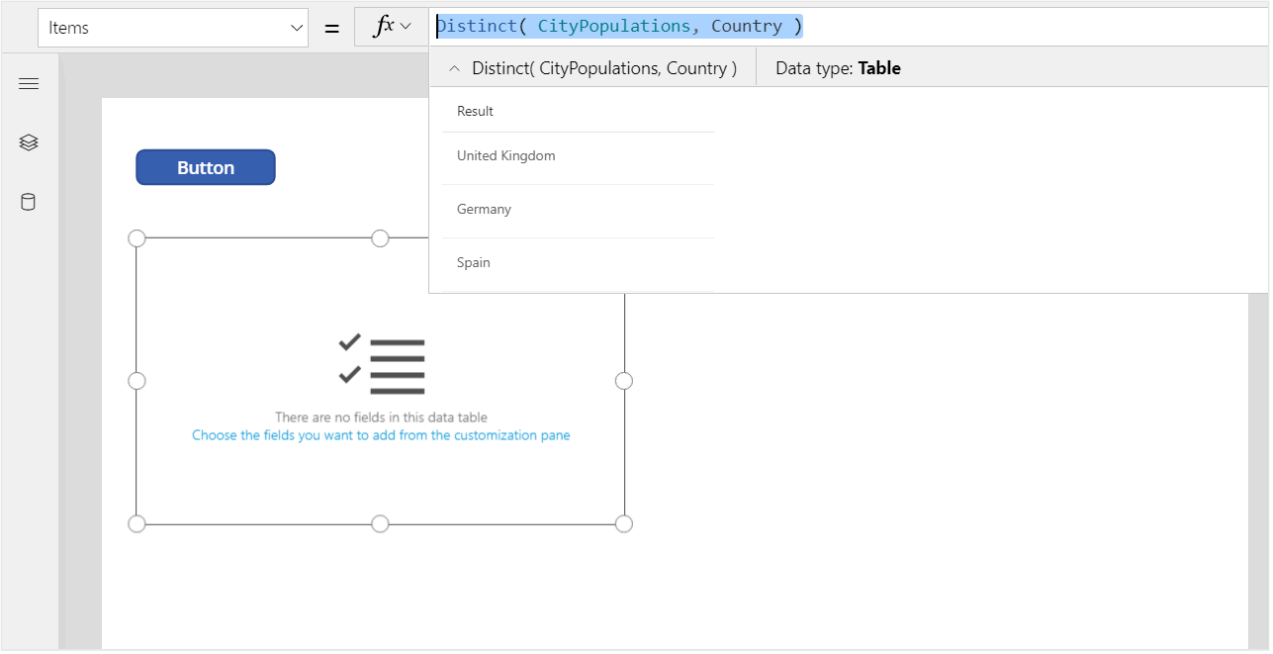


3. Insert a Data table control, and set its **Items** property to this formula:

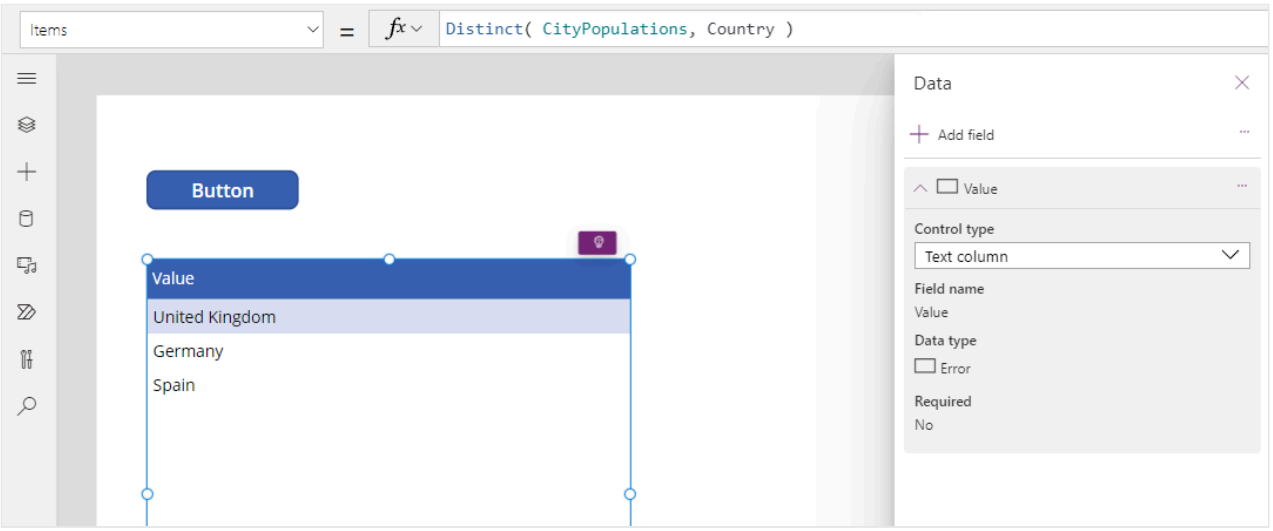
```
Power Fx

Distinct( CityPopulations, Country )
```

   You can view the result of this formula in the formula bar by selecting the entire formula:



4. Use the **Edit fields** link in the data table's properties pane to add the **Value** column:

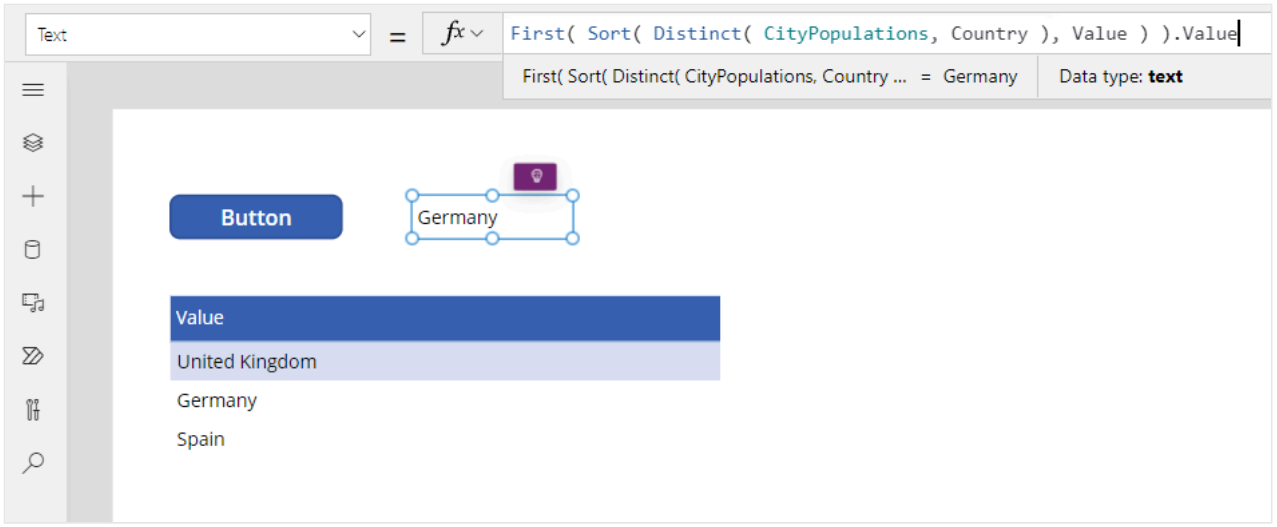


5. Insert a Label control, and set its **Text** property to the formula:

```
Power Fx

First( Sort( Distinct( CityPopulations, Country ), Value ) ).Value
```

This formula sorts the results from **Distinct** with the Sort function, takes the first record from the resulting table with the First function, and extracts the **Result** field to obtain just the country/region name.



Text
=
First(Sort(Distinct(CityPopulations, Country), Value)).Value
First(Sort(Distinct(CityPopulations, Country ... = Germany
Data type: text
Button
Germany
Value
United Kingdom
Germany
Spain

Download function

Applies to: ✅ Canvas apps ✅ Model-driven apps

Downloads a file from the web to the local device.

Description

The **Download** function downloads a file from the web to the local device.

In native players (Windows, Android, and iOS), the user is prompted for a location to save the file.

When used on the web, **Download** is dependent on the browser's settings and pop-up blocker configuration to determine what happens with the file. For images, videos, PDFs, and other file types that the browser natively supports, a new browser tab is opened to display the file. Many browsers support saving the contents to the local file system.

Only on Windows, **Download** returns the location where the file was stored locally as a text string.

Download can only be used in behavior formulas.

Syntax

Download(*Address*)

- *Address* – Required. The URL address of a web resource to download.

> ⓘ **Note**
>
> Power Apps cannot authenticate download requests to the address provided in the Download() function.
>
> For example, when using this function to download a file stored on a SharePoint site that requires authentication, the request might work when using a web browser since the browser session might authenticate against the SharePoint site using cached credentials. However, in Power Apps mobile app, the request won't work since authenticating the download request is not handled by the mobile device.

Examples

Simple Download

The following formula downloads the user's guide for the Surface Book, a PDF file:

Power Fx

```
Download( "https://go.microsoft.com/fwlink/?linkid=827480" )
```

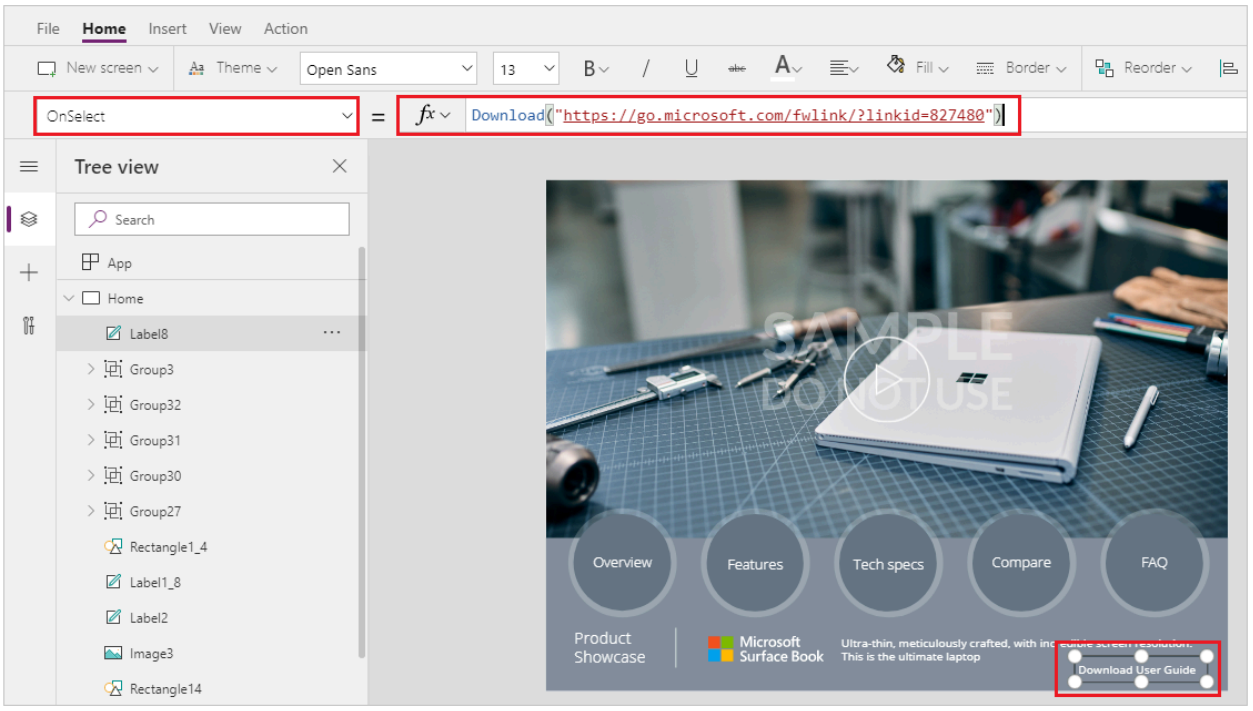
When run in a mobile device, the user is prompted for a location to save the file.

When run in most web browsers, a new tab is opened to display the PDF file as most browsers natively support this file type.

Step by Step

The **Product Showcase** tablet layout template was used for the following example. To create an app with this template, follow the steps from create an app article and select the **Product Showcase** template. You can also use your own app.

1. Go to Power Apps.
2. Select **Apps** from left navigation pane.
3. Select your app and then select **Edit**.
4. Select **Insert** from the menu and then select **Label**.
5. Move the label to the bottom right of the screen.
6. From the properties pane on the right-side, select **Color** as *white* and set **Border thickness** at *1*.
7. Select the **Text** property from right-side and enter text as *Download User Guide*.
8. From property list on top left, select **OnSelect**.
9. Enter formula as `Download("https://go.microsoft.com/fwlink/?linkid=827480")`. You can also use any other URL of your choice.



10. Save and publish the app.
11. Play the app.
12. Select the **Download User Guide** button to download the guide.

> **Note**
>
> - Your browser settings determine whether to download the file or open the file directly in a new tab. For more details, go to Download function description.
> - If the Download formula is used to retrieve a file and the file isn't downloaded successfully, it's recommended to check whether the download is blocked by a browser pop-up blocker or if the browser is waiting for the user's response to a dialog box asking for permission to download the file.

AddColumns, DropColumns, RenameColumns, and ShowColumns functions

06/21/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions

Shapes a table or record by adding, dropping, renaming, and selecting its columns.

The ForAll function can also be used to shape a table, by returning a table of new records created from existing columns.

Overview

These functions shape a table or record by adjusting its columns:

- Reduce a table or record that contains multiple columns down to a single column for use with single-column functions, such as **Lower** or **Sqrt**.
- Add a calculated column to a table or record (for example, a **Total Price** column that shows the results of multiplying **Quantity** by **Unit Price**).
- Rename a column to something more meaningful, for display to users or for use in formulas.

A table is a value in Power Apps, just like a string or a number. You can specify a table as an argument in a formula, and functions can return a table as a result.

> **Note**
>
> The functions that this topic describes don't modify the original table. Instead, they take that table as an argument and return a new table with a transform applied. For more information, see working with tables.

You can't modify the columns of a data source by using these functions. You must modify the data at its source. You can add columns to a collection with the **Collect** function. For more information, see working with data sources.

Description

The **AddColumns** function adds a column to a table or record, and a formula defines the values in that column. Existing columns remain unmodified.

The formula is evaluated for the provided record, or for each record of the provided table.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

The **DropColumns** function excludes columns from a table or record. All other columns remain unmodified. **DropColumns** excludes columns, and **ShowColumns** includes columns.

Use the **RenameColumns** function to rename one or more columns of a table or record by providing at least one argument pair that specifies the name of a column that the table or record contains (the old name, which you want to replace) and the name of a column that the table or record doesn't contain (the new name, which you want to use). The old name must already exist in the table or record, and the new name must not exist. Each column name may appear only once in the argument list as either an old column name or a new column name. To rename a column to an existing column name, first drop the existing column with **DropColumns**, or rename the existing column out of the way by nesting one **RenameColumns** function within another.

The **ShowColumns** function includes columns of a table or record and drops all other columns. You can use **ShowColumns** to create a single-column table or record from a multi-column table or record. **ShowColumns** includes columns, and **DropColumns** excludes columns.

For all these functions, the result is a new table or record with the transform applied. The original table or record isn't modified. You can't modify an existing table or record with a formula. SharePoint, Microsoft Dataverse, SQL Server, and other data sources provide tools for modifying the columns of lists and tables, which are often referred to as the schema. The functions in this topic only transform an input table or record, without modifying the original, into an output table or record for further use.

The arguments to these functions support delegation. For example, a **Filter** function used as an argument to pull in related records searches through all listings, even if the '**[dbo].[AllListings]**' data source contains a million rows:

Power Fx

```
AddColumns( RealEstateAgents,
   Listings,
```

```
    Filter(  '[dbo].[AllListings]', ListingAgentName = AgentName )
)
```

However, the output of these functions is subject to the non-delegation record limit. In this example, only 500 records are returned even if the **RealEstateAgents** data source has 501 or more records.

If you use **AddColumns** in this manner, **Filter** must make separate calls to the data source for each of those first records in **RealEstateAgents**, which causes lots of network chatter. If **[dbo](.[AllListings]** is small enough and doesn't change often. You can call the **Collect** function in OnStart to cache the data source in your app when it starts. As an alternative, you could restructure your app so that you pull in the related records only when the user asks for them.

> **Note**
>
> In Power Apps prior to version 3.24042, column names were specified with a text string using double quotes, and if connected to a data source they also needed to be logical names. For example, the logical name **"cr43e_name"** with double quotes was used instead of the display name **Name** without quotes. For SharePoint and Excel data sources that contain column names with spaces, each space was specified with **"_x0020_"**, for example **"Column Name"** as **"Column_x0020_Name"**. After this version, all apps were automatically updated to the new syntax described in this article.

Syntax

AddColumns(*TableOrRecord*, *ColumnName1*, *Formula1* [, *ColumnName2*, *Formula2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.
- *ColumnName(s)* - Required. Names of the columns to add.
- *Formula(s)* - Required. Formulas to evaluate for each record. The result is added as the value of the corresponding new column. You can reference other columns of the table or record in this formula.

DropColumns(*TableOrRecord*, *ColumnName1* [, *ColumnName2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.
- *ColumnName(s)* - Required. Names of the columns to drop.

RenameColumns(*TableOrRecord*, *OldColumnName1*, *NewColumnName1* [, *OldColumnName2*, *NewColumnName2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.

- *OldColumnName(s)* - Required. Names of the columns to rename from the original table or record. This element appears first in the argument pair (or first in each argument pair if the formula includes more than one pair).
- *NewColumnName(s)* - Required. Replacement names. This element appears last in the argument pair (or last in each argument pair if the formula includes more than one pair).

ShowColumns(*TableOrRecord*, *ColumnName1* [, *ColumnName2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.
- *ColumnName(s)* - Required. Names of the columns to include.

Examples

The examples in this section use the **IceCreamSales** data source, which contains the data in this table:

Flavor	UnitPrice	QuantitySold
"Strawberry"	1.99	20
"Chocolate"	2.99	45
"Vanilla"	1.50	35

None of these examples modify the **IceCreamSales** data source. Each function transforms the value of the data source as a table and returns that value as the result.

Expand table

Formula	Description	Result
AddColumns(IceCreamSales, Revenue, UnitPrice * QuantitySold)	Adds a **Revenue** column to the result. For each record, **UnitPrice * QuantitySold** is evaluated, and the result is placed in the new column.	
DropColumns(IceCreamSales, UnitPrice)	Excludes the **UnitPrice** column from the result. Use this function to exclude columns, and use **ShowColumns** to include them.	ShowColumns(IceCreamSales, Flavor)	Includes only the **Flavor** column in the result. Use this function include columns, and use **DropColumns** to exclude them.	
RenameColumns(IceCreamSales, UnitPrice, Price)	Renames the **UnitPrice** column in the result.	

Formula	Description	Result
RenameColumns(IceCreamSales, UnitPrice, Price, QuantitySold, Number)	Renames the **UnitPrice** and **QuantitySold** columns in the result.	<table><tr><th>Flavor</th><th>Price</th><th>Number</th></tr><tr><td>"Strawberry"</td><td>1.99</td><td>20</td></tr><tr><td>"Chocolate"</td><td>2.99</td><td>45</td></tr><tr><td>"Vanilla"</td><td>1.50</td><td>35</td></tr></table>
DropColumns(RenameColumns(AddColumns(IceCreamSales, Revenue, UnitPrice * QuantitySold), UnitPrice, Price), Quantity)	Performs the following table transforms in order, starting from the inside of the formula: 1. Adds a **Revenue** column based on the per record calculation of **UnitPrice * Quantity**. 2. Renames **UnitPrice** to **Price**. 3. Excludes the **Quantity** column. Order is important, for example we can't calculate with **UnitPrice** after it's renamed.	<table><tr><th>Flavor</th><th>Price</th><th>Revenue</th></tr><tr><td>"Strawberry"</td><td>1.99</td><td>39.80</td></tr><tr><td>"Chocolate"</td><td>2.99</td><td>134.55</td></tr><tr><td>"Vanilla"</td><td>1.49</td><td>52.15</td></tr></table>

Step by step

Let's try some of the examples from earlier in this article.

1. Create a collection by adding a **Button** control and setting its **OnSelect** property to this formula:

   Power Fx

   ```
   ClearCollect( IceCreamSales,
      Table(
          { Flavor: "Strawberry", UnitPrice: 1.99, QuantitySold: 20 },
          { Flavor: "Chocolate", UnitPrice: 2.99, QuantitySold: 45 },
          { Flavor: "Vanilla", UnitPrice: 1.50, QuantitySold: 35 }
      )
   )
   ```

2. Run the formula by selecting the button while holding down the Alt key.

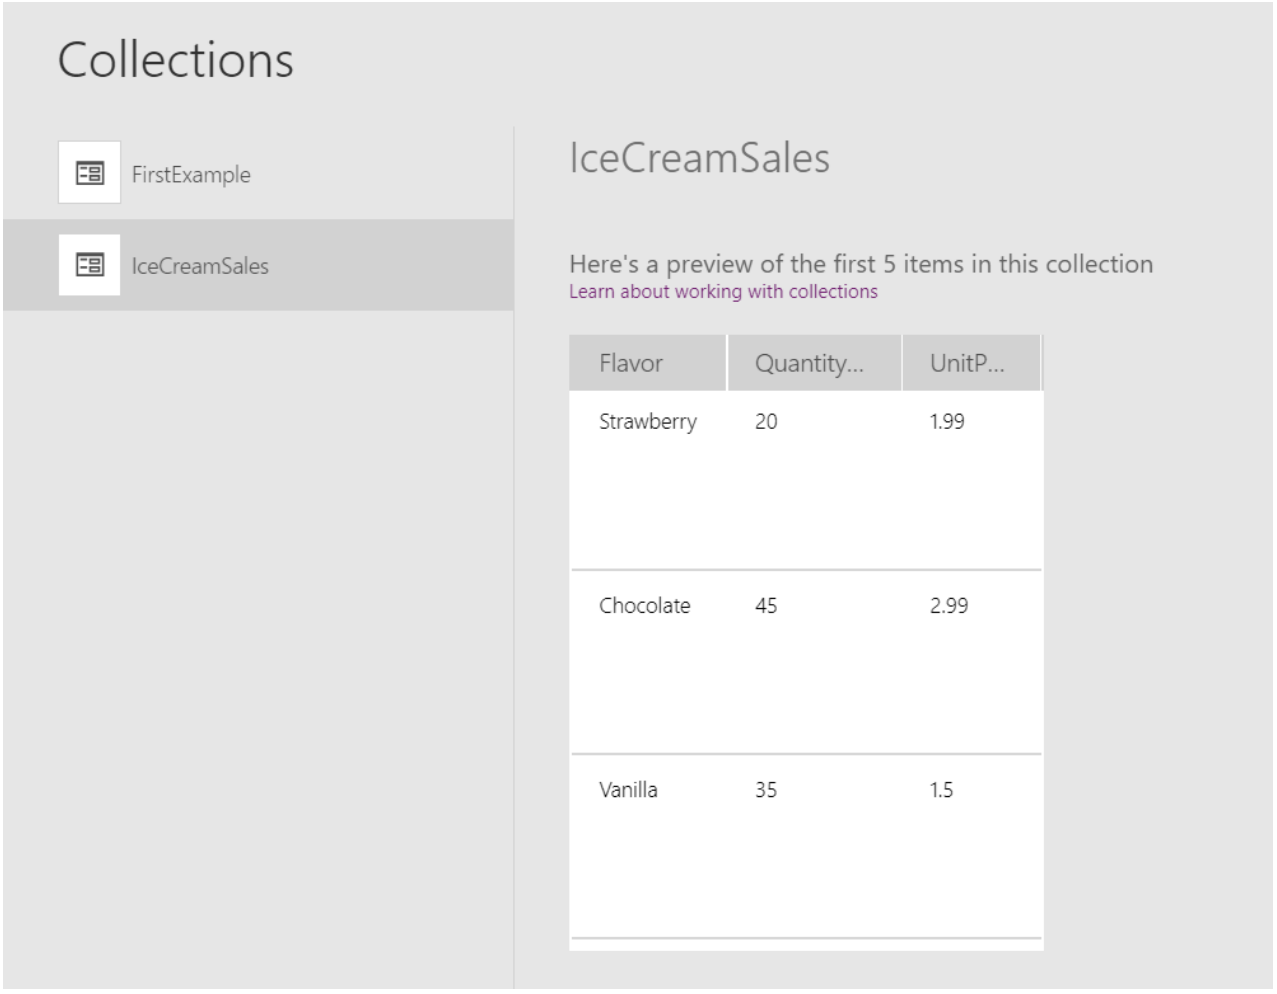
3. Add a second **Button** control, set its **OnSelect** property to this formula, and then run it:

   Power Fx

   ```
   ClearCollect( FirstExample,
      AddColumns( IceCreamSales, Revenue, UnitPrice * QuantitySold )
   )
   ```

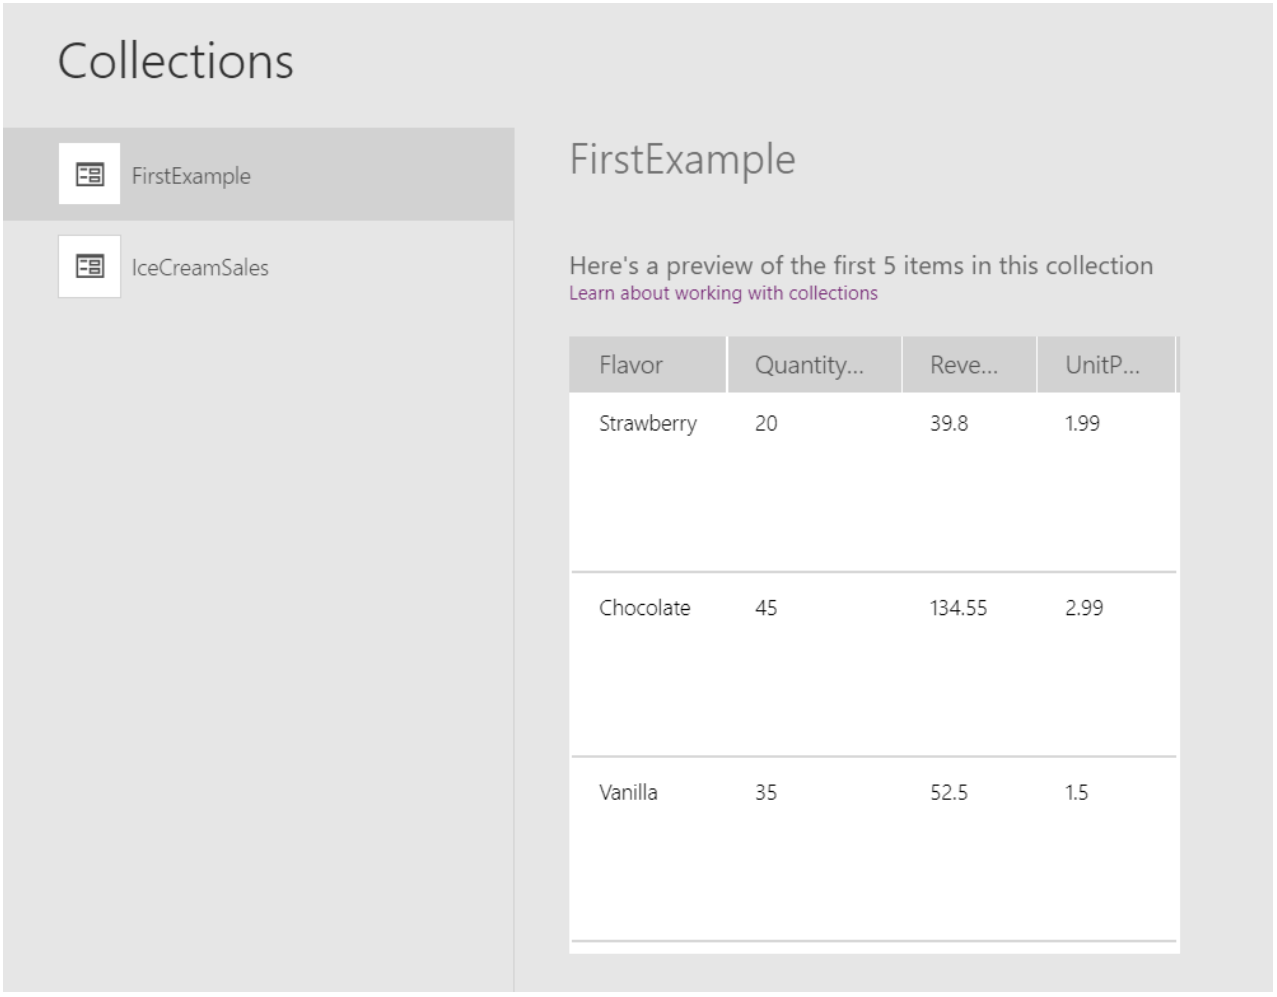
4. On the **File** menu, select **Collections**, and then select **IceCreamSales** to show that collection.

As this graphic shows, the second formula didn't modify this collection. The **AddColumns** function used **IceCreamSales** as a read-only argument; the function didn't modify the table to which that argument refers.



5. Select **FirstExample**.

   As this graphic shows, the second formula returned a new table with the added column. The **ClearCollect** function captured the new table in the **FirstExample** collection, adding something to the original table as it flowed through the function without modifying the source:



Map columns in a component

See Map columns.

EditForm, NewForm, SubmitForm, ResetForm, and ViewForm functions

Article • 03/22/2024

Applies to: Canvas apps

View, edit, or create an item, save the contents, and reset the controls in an **Edit form** control.

Overview

These functions change the state of the **Edit form** control. The form control can be in one of these modes:

Expand table

Mode	Description
FormMode.Edit	The form is populated with an existing record and the user can modify the values of the fields. Once complete, the user can save the changes to the record.
FormMode.New	The form is populated with default values and the user can modify the values of the fields. Once complete, the user can add the record to the data source.
FormMode.View	The form is populated with an existing record but the user cannot modify the values of the fields.

Description

These functions are often invoked from the **OnSelect** formula of a **Button** or **Image** control so that the user can save edits, abandon edits, or create a record. You can use controls and these functions together to create a complete solution.

These functions return no values.

You can use these functions only in behavior formulas.

SubmitForm

Use the **SubmitForm** function in the **OnSelect** property of a Button control to save any changes in a Form control to the data source.

Before submitting any changes, this function checks for validation issues with any field that's marked as required or that has one or more constraints on its value. This behavior matches that of the **Validate** function.

SubmitForm also checks the **Valid** property of the Form, which is an aggregation of all the **Valid** properties of the **Card** controls that the Form control contains. If a problem occurs, the data isn't submitted, and the **Error** and **ErrorKind** properties of the Form control are set accordingly.

If validation passes, **SubmitForm** submits the change to the data source.

- If successful, the Form's **OnSuccess** behavior runs, and the **Error** and **ErrorKind** properties are cleared. If the form was in **FormMode.New** mode, it is returned to **FormMode.Edit** mode.
- If unsuccessful, the Form's **OnFailure** behavior runs, and the **Error** and **ErrorKind** properties are set accordingly. The mode of the form is unchanged.

EditForm

The **EditForm** function changes the Form control's mode to **FormMode.Edit**. In this mode, the contents of the Form control's **Item** property are used to populate the form. If the **SubmitForm** function runs when the form is in this mode, a record is changed, not created. **FormMode.Edit** is the default for the Form control.

> ⓘ **Note**
>
> When the form is in edit mode and Item is null, data card properties are not evaluated and will return default values.

NewForm

The **NewForm** function changes the Form control's mode to **FormMode.New**. In this mode, the contents of the Form control's **Item** property are ignored, and the default values of the Form's **DataSource** property populate the form. If the **SubmitForm** function runs when the form is in this mode, a record is created, not changed.

ResetForm

The **ResetForm** function resets the contents of a form to their initial values, before the user made any changes. If the form is in **FormMode.New** mode, the form is reset to **FormMode.Edit** mode. The **OnReset** behavior of the form control also runs. You can also reset individual controls with the **Reset** function but only from within the form.

ViewForm

The **ViewForm** function changes the Form control's mode to **FormMode.View**. In this mode, the contents of the Form control's **Item** property are used to populate the form. The **SubmitForm** and **ResetForm** functions have no effect when in this mode.

DisplayMode Property

The current mode can be read through the **Mode** property. The mode also determines the value of the **DisplayMode** property, which can be used by data cards and controls within the form control. Often, the data card's **DisplayMode** property will be set to **Parent.DisplayMode** (referencing the form) as will the control's **DisplayMode** property (referencing the data card):

Expand table

Mode	DisplayMode	Description
FormMode.Edit	**DisplayMode.Edit**	Data cards and controls are editable, ready to accept changes to a record.
FormMode.New	**DisplayMode.Edit**	Data cards and controls are editable, ready to accept a new record.
FormMode.View	**DisplayMode.View**	Data cards and controls are not editable and optimized for viewing.

Syntax

SubmitForm(*FormName*)

- *FormName* - Required. Form control to submit to the data source.

EditForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.Edit** mode.

NewForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.New** mode.

ResetForm(*FormName*)

- *FormName* - Required. Form control to reset to initial values. Also switches the form from **FormMode.New** mode to **FormMode.Edit** mode.

ViewForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.View** mode.

Examples

See Understand data forms for complete examples.

1. Add a Button control, set its **Text** property to show **Save**, and set its **OnSelect** property to this formula:

   SubmitForm(EditForm)

2. Set the **OnFailure** property of a Form control to blank and its **OnSuccess** property to this formula:

   Back()

3. Name a **Label** control **ErrorText**, and set its **Text** property to this formula:

   EditForm.Error

   When the user selects the **Save** button, any changes in the Form control are submitted to the underlying data source.

   - If the submission succeeds, any changes are saved or, if the Form control is in **New** mode, a record is created. **ErrorText** is *blank* and the previous screen reappears.
   - If the submission fails, **ErrorText** shows a user-friendly error message, and the current screen remains visible so that the user can correct the problem and try again.

4. Add a Button control, set its **Text** property to show **Cancel**, and set its **OnSelect** property to this formula:

   ResetForm(EditForm); Back()

   When the user selects the **Cancel** button, the values in the Form control are reset to what they were before the user started to edit it, the previous screen reappears,

and the Form control is returned to **Edit** mode if it was in **New** mode.

5. Add a Button control, set its Text property to show **New**, and set its OnSelect property to this formula:

   NewForm(EditForm); Navigate(EditScreen, None)

   When the user selects the **New** button, the Form control switches to **New** mode, the default values for the Form control's data source populate that control, and the screen that contains the Form control appears. When the **SubmitForm** function runs, a record is created instead of updated.

Enable and Disable functions

10/10/2025

Applies to: Canvas apps

Turns a signal on or off.

Overview

Some signals can change often, requiring the app to recalculate as they do. Rapid changes over a long period of time can drain a device's battery. You can use these functions to manually turn a signal on or off.

When a signal isn't in use, it's automatically turned off.

Description

The **Enable** and **Disable** functions turn a signal on and off, respectively.

These functions currently only work for the **Location** signal.

These functions have no return value. You can use them only in behavior formulas.

Syntax

Enable(*Signal*)
Disable(*Signal*)

- *Signal* - Required. The signal to turn on or off.

EncodeHTML, EncodeUrl, and PlainText functions

Article • 04/20/2025

Expand table

Functions	Applies to
EncodeHTML	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions
EncodeUrl **PlainText**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Encodes and decodes strings.

Description

The **EncodeUrl** function encodes a URL string, replacing certain non-alphanumeric characters with % and a hexadecimal number.

The **EncodeHTML** function encodes a string, replacing certain characters that need to be escaped to appear properly in an HTML context. For example, the characters <, >, and & are replaced by <, >, and &, respectively.

The **PlainText** function removes HTML and XML tags, converting certain tags such as these to an appropriate symbol:

- ** **
- **"**

The return value from these functions is the encoded or decoded string. This function doesn't remove all HTML and XML tags.

Syntax

EncodeUrl(*String*)

- *String* - Required. URL to be encoded.

EncodeHTML(*String*)

- *String* - Required. HTML to be encoded.

PlainText(*String*)

- *String* - Required. String from which HTML and XML tags are stripped.

Examples

If you show an RSS feed in a text gallery and then set the **Text** property of a label in that gallery to **ThisItem.description**, the label might show raw HTML or XML code as in this example:

HTML

```
<p>
  We have done an unusually &quot;deep&quot; globalization and
  localization.
</p>
```

If you set the **Text** property of the label to **PlainText(ThisItem.description)**, the text appears as in this example:

```
    We have done an unusually "deep" globalization and localization.
```

With the formula **EncodeHTML(ThisItem.description)**, the HTML tags are encoded so that they show up as text when interpreted as HTML, which can be useful to see the HTML structure:

```
&lt;p&gt;
  We have done an unusually&amp;nbsp;&amp;quot;deep&amp;quot; globalization and
  localization.
&lt;/p&gt;
```

If instead of a label you have an HTML text control in the gallery, and you set the **HtmlText** property of that control to **ThisItem.description** you also see the decoded text, because the HTML text control is interpreting the tags as HTML.

EndsWith and StartsWith functions

Article • 04/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Tests whether a text string begins or ends another text string.

Description

The **EndsWith** function tests whether one text string ends with another.

The **StartsWith** function tests whether one text string begins with another.

For both functions, the tests are case insensitive if the back-end datasource supports it by default. For example, collections, Dataverse, SharePoint, and SQL Server support case insensitivity by default. Oracle does not. The return value of both is a Boolean **true** or **false**.

Use **EndsWith** and **StartsWith** with the **Filter** function to search the data within your app. You can also use the **in** operator or the **Search** function to look anywhere within text strings, not just at the beginning or end. Your choice of functions will depend on the needs of your app and which function can be delegated for your particular data source. If one of these functions can't be delegated, a delegation warning will appear at authoring time to warn you of this limitation.

Syntax

EndsWith(*Text*, *EndText*)

- *Text* – Required. The text to test.
- *EndText* – Required. The text to search for at the end of *Text*. If *EndText* is an empty string, **EndsWith** returns *true*.

StartsWith(*Text*, *StartText*)

- *Text* – Required. The text to test.
- *StartText* – Required. The text to search for at the beginning of *Text*. If *StartText* is an empty string, **StartsWith** returns *true*.

Examples

Expand table

Formula	Description	Result
EndsWith("Hello World", "world")	Tests whether **"Hello World"** ends with **"world"**. The test is case insensitive.	**true**
EndsWith("Good bye", "good")	Tests whether **"Good bye"** ends with **"good"**. The *EndText* argument (**"good"**) appears in the text but not at the end.	**false**
EndsWith("Always say hello", "hello")	Tests whether **"Always say hello"** ends with **"hello"**.	**true**
EndsWith("Bye bye", "")	Tests whether **"Bye bye"** ends with an empty text string (**Len** returns 0). Easing its use in **Filter** expressions, **EndsWith** is defined to return **true** in this case.	**true**

Expand table

Formula	Description	Result
StartsWith("Hello World", "hello")	Tests whether **"Hello World"** begins with **"hello"**. The test is case insensitive.	**true**
StartsWith("Good bye", "hello")	Tests whether **"Good bye"** begins with **"hello"**.	**false**
StartsWith("Always say hello", "hello")	Tests whether **"Always say hello"** begins with **"hello"**. Although **"hello"** appears in the text, it doesn't appear at the beginning.	**false**
StartsWith("Bye bye", "")	Tests whether **"Bye bye"** starts with an empty text string (**Len** returns 0). Easing its use in **Filter** expressions, **StartsWith** is defined to return **true** in this case.	**true**

Search user experience

In many apps, you can type one or more characters into a search box to filter a list of records in a large data set. As you type, the list shows only those records that match the search criteria.

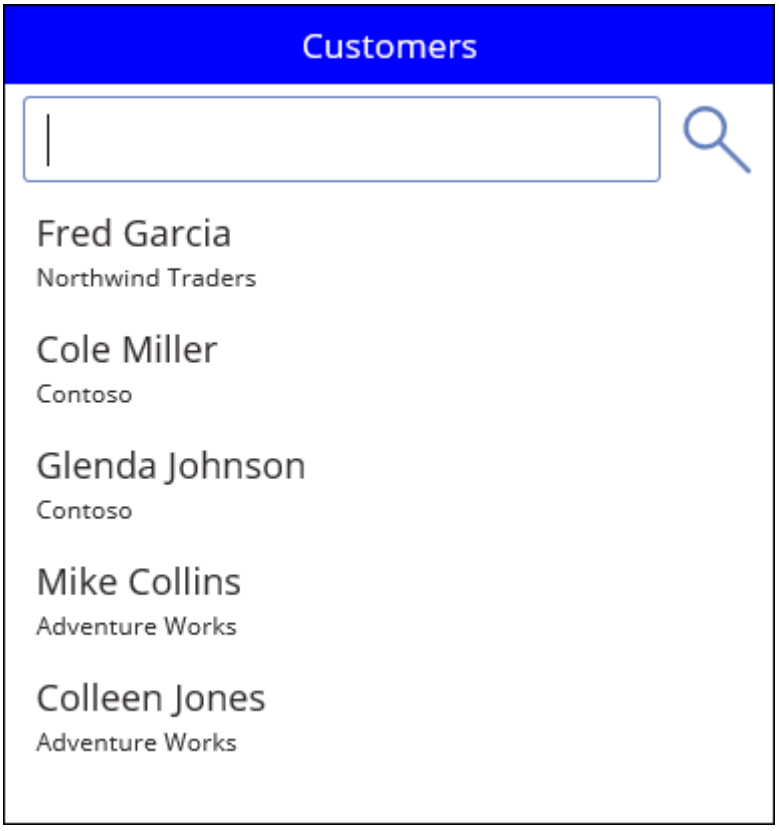
The examples in the rest of this topic show the results of searching a **Customers** list that contains this data:

Name	Company
"Fred Garcia"	"Northwind Traders"
"Cole Miller"	"Contoso"
"Glenda Johnson"	"Contoso"
"Mike Collins"	"Adventure Works"
"Colleen Jones"	"Adventure Works"

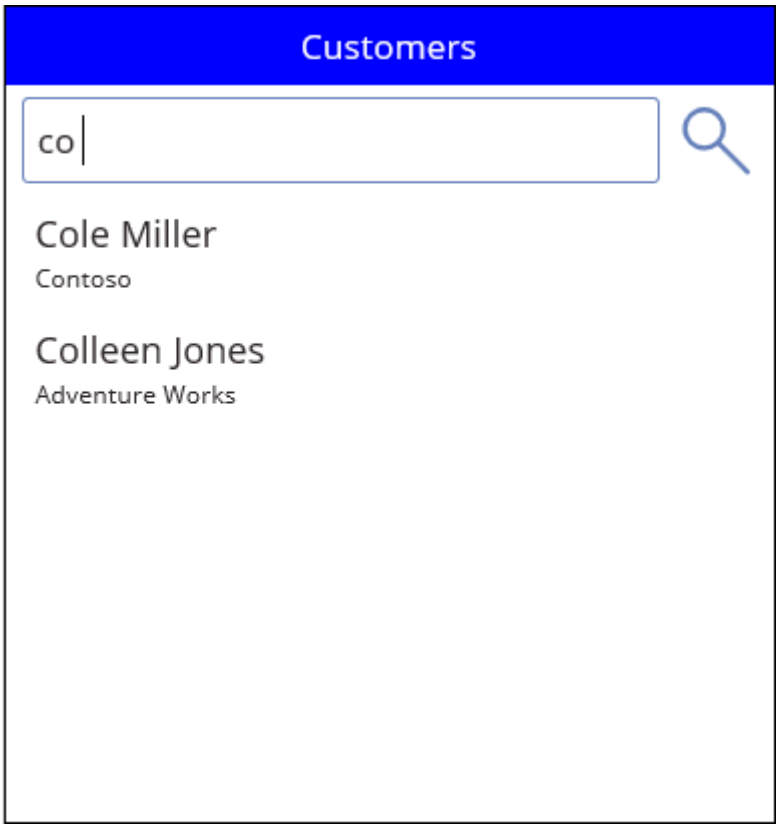
To create this data source as a collection, create a **Button** control and set its **OnSelect** property to this formula:

ClearCollect(Customers, Table({ Name: "Fred Garcia", Company: "Northwind Traders" }, { Name: "Cole Miller", Company: "Contoso" }, { Name: "Glenda Johnson", Company: "Contoso" }, { Name: "Mike Collins", Company: "Adventure Works" }, { Name: "Colleen Jones", Company: "Adventure Works" }))

As in this example, you can show a list of records in a **Gallery control** at the bottom of a screen. Near the top of the screen, you can add a **Text input** control, named **SearchInput**, so that users can specify which records interest them.



As the user types characters in **SearchInput**, the results in the gallery are automatically filtered. In this case, the gallery is configured to show records for which the name of the customer (not the name of the company) starts with the sequence of characters in **SearchInput**.If the user types **co** in the search box, the gallery shows these results:



To filter based on the **Name** column, set the **Items** property of the gallery control to one of these formulas:

Expand table

Formula	Description	Result
Filter(Customers, StartsWith(Name, SearchInput.Text))	Filters the **Customers** data source for records in which the search string appears at the start of the **Name** column. The test is case insensitive. If the user types **co** in the search box, the gallery shows **Colleen Jones** and **Cole Miller**. The gallery doesn't show **Mike Collins** because the **Name** column for that record doesn't start with the search string.	
Filter(Customers, SearchInput.Text in Name)	Filters the **Customers** data source for records in which the search string appears anywhere in the **Name** column. The test is case insensitive. If the user types **co** in the search box, the gallery shows **Colleen Jones**, **Cole Miller,** and **Mike Collins** because the search string appears somewhere in the **Name** column of all of those records.	
Search(Customers, SearchInput.Text, "Name")	Similar to using the **in** operator, the **Search** function searches for a match anywhere within the **Name** column of each record. Note that you must enclose the column name in double quotation marks.	

You can expand your search to include the **Company** column as well as the **Name** column:

Expand table

Formula	Description	Result
Filter(Customers, StartsWith(Name, SearchInput.Text) || StartsWith(Company, SearchInput.Text))	Filters the **Customers** data source for records in which either the **Name** column or the **Company** column starts with the search string (for example, **co**). The || operator is *true* if either **StartsWith** function is *true*.	
Filter(Customers, SearchInput.Text in Name || SearchInput.Text in Company)	Filters the **Customers** data source for records in which either the **Name** column or the **Company** column contains the search string (for example, **co**) anywhere within it.	
Search(Customers, SearchInput.Text, "Name", "Company")	Similar to using the **in** operator, the **Search** function searches the **Customers** data source for records in which either the **Name** column or the **Company** column contains the search string (for example, **co**) anywhere within it. The **Search** function is easier to read and write than **Filter** if you want to specify multiple columns and multiple **in** operators. Note that you must enclose the names of the columns in double quotation marks.	

Error, IfError, IsError, IsBlankOrError functions

Article • 10/16/2024

Applies to: ✅ Canvas apps ✅ Dataverse formula columns ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Detects errors and provides an alternative value or takes action. Create a custom error or pass through an error.

> **Note**
>
> If an app has disabled the *Formula-level error management* feature under **Settings** > **Updates** > **Retired**, those functions will not work correctly.

IfError

The **IfError** function tests values until it finds an error. If the function discovers an error, the function evaluates and returns a corresponding replacement value and stops further evaluation. A default value can also be supplied for when no errors are found. The structure of **IfError** resembles that of the **If** function: **IfError** tests for errors, while **If** tests for **true**.

Use **IfError** to replace an error with a valid value so that downstream calculations can continue. For example, use this function if user input might result in a division by zero:

Power Apps

```
IfError( 1/x, 0 )
```

This formula returns `0` if the value of `x` is zero, as `1/x` produces an error. If `x` isn't zero, then `1/x` is returned.

Stopping further processing

When chaining formulas together in behavior formulas, such as:

Power Apps

```
Patch( DS1, ... );
Patch( DS2, ... )
```

The second Patch function to `DS2` will be attempted even if the **Patch** to `DS1` fails. The scope of an error is limited to each formula that is chained.

Use **IfError** to do an action and only continue processing if the action was successful. Applying **IfError** to this example:

Power Apps

```
IfError(
    Patch( DS1, ... ), Notify( "problem in the first action" ),
    Patch( DS2, ... ), Notify( "problem in the second action" )
)
```

If the **Patch** of `DS1` has a problem, the first **Notify** is executed. No further processing occurs including the second **Patch** of `DS2`. If the first **Patch** succeeds, the second **Patch** will execute.

If supplied, the optional *DefaultResult* argument is returned if no errors are discovered. Without this argument, the last *Value* argument is returned.

Building on the last example, the return value from **IfError** can be checked to determine if there were any problems:

Power Apps

```
IfError(
    Patch( DS1, ... ), Notify( "problem in the first action" );  false,
    Patch( DS2, ... ), Notify( "problem in the second action" ); false,
    true
)
```

Type compatibility

IfError returns the value of one of its arguments. The types of all values that might be returned by **IfError** must be compatible.

In the last example, **Patch** returns a record that isn't compatible with the Booleans used for the *Replacement* formulas or the *DefaultResult*. Which is fine, since there's no situation in which the return value from these **Patch** calls would be returned by **IfError**.

> ⓘ **Note**
>
> While the behavior in process for a change, the types of all arguments to **IfError** must be compatible currently.

In the simple example described earlier:

```
Power Apps
IfError( 1/x, 0 )
```

The types of `1/x` and `0` were compatible as both were numbers. If they're not, the second argument is coerced to match the type of the first argument.

Excel displays **#DIV/0!** when a division by zero occurs.

Consider **IfError** with the following instead:

```
Power Apps
IfError( 1/x, "#DIV/0!" )
```

The above formula won't work. The text string `"#DIV/0!"` is coerced to the type of the first argument to **IfError**, which is a number. The result of **IfError** is yet another error since the text string can't be coerced. As a fix, convert the first argument to a text string so that **IfError** always returns a text string:

```
Power Apps
IfError( Text( 1/x ), "#DIV/0!" )
```

As seen above, **IfError** can return an error if the *Replacement* or *DefaultResult* is an error.

FirstError / AllErrors

Within in the replacement formulas, information about the errors found is available through the **FirstError** record and **AllErrors** table. **AllErrors** is a table of error information records with **FirstError** being a shortcut to the first record of this table. **FirstError** always returns the same value as **First(AllErrors)**.

Error records include:

Expand table

Field	Type	Description
Kind	ErrorKind enum (number)	Category of the error.
Message	Text string	Message about the error, suitable to be displayed to the end user.
Source	Text string	Location in where the error originated, used for reporting. For example, for a formula bound to a control property, this value is in the form *ControlName.PropertyName*.
Observed	Text string	Location in where the error is surfaced to the user, used for reporting. For example, for a formula bound to a control property, this value is in the form *ControlName.PropertyName*.
Details	Record	Details about the error. Currently, details are provided only for network errors. This record includes **HttpStatusCode** which contains the HTTP status code and **HttpResponse** which contains the body of the response from the connector or service.

For example, consider the following formula as a **Button** control's **OnSelect** property:

Power Apps

```
Set( a, 1/0 )
```

And this formula on the **OnSelect** property of a second **Button** control:

Power Apps

```
IfError( a, Notify( "Internal error: originated on " & FirstError.Source &
", surfaced on " & FirstError.Observed ) )
```

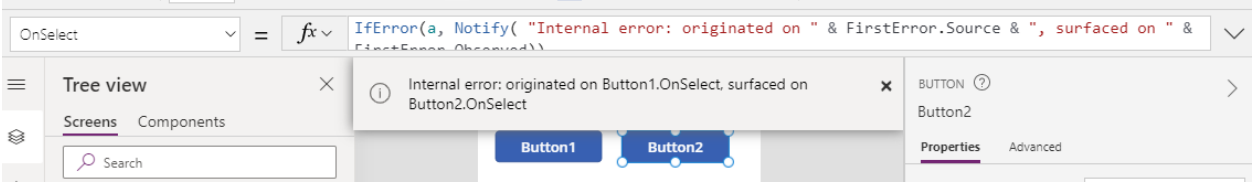
The example formula above would display the following banner when the two buttons are activated in sequence:



Typically, there will be only one error that **FirstError** can sufficiently work with. However, there are scenarios where multiple errors may be returned. For example, when using a formula chaining operator or the **Concurrent** function. Even in these situations,

reporting **FirstError** might be enough to reveal a problem instead overloading a user with multiple errors. If you still have a requirement to work with each error individually, you can use the **AllErrors** table.

IsError

The **IsError** function tests for an error value.

The return value is a Boolean *true* or *false*.

Using **IsError** prevents any further processing of the error.

IsBlankOrError

The **IsBlankOrError** function tests for either a blank value or an error value and is the equivalent of `Or( IsBlank( X ), IsError( X ) )`.

When enabling error handling for existing apps, consider replacing **IsBlank** with **IsBlankOrError** to preserve existing app behavior. Before the addition of error handling, a *blank* value was used to represent both null values from databases and error values. Error handling separates these two interpretations of *blank* which could change the behavior of existing apps that continue to use **IsBlank**.

The return value is a boolean *true* or *false*.

Using **IsBlankOrError** prevents any further processing of the error.

Use the **Error** function to create and report a custom error. For example, you might have logic to determine whether any given value is valid for your context or not—something not checked for a problem automatically. You can create and return your own error, complete with **Kind** and **Message**, using the same record described above for the **IfError** function.

In the context of **IfError**, use the **Error** function to rethrow or pass through an error. For example, your logic in **IfError** may decide that in some cases an error can be safely ignored, but in other cases the error is important to send through. Within **IfError** or **App.OnError**, use **Error(FirstError)** to pass through an error.

The **Error** function can also be passed a table of errors, as would be found in the **AllErrors** table. Use **Error(AllErrors)** to rethrow all the errors and not just the first.

A *blank* record or empty table passed to **Error** results in no error.

Syntax

Error(**ErrorRecord**)
Error(**ErrorTable**)

- *ErrorRecord* – Required. Error information record, including **Kind**, **Message**, and other fields. **Kind** is required. **FirstError** can be passed directly.
- *ErrorTable* – Required. Table of error information records. **AllErrors** can be passed directly.

IfError(*Value1*, *Replacement1* [, *Value2*, *Replacement2*, ... [, *DefaultResult*]])

- *Value(s)* – Required. Formula(s) to test for an error value.
- *Replacement(s)* – Required. The formulas to evaluate and values to return if matching *Value* arguments returned an error.
- *DefaultResult* – Optional. The formulas to evaluate if the formula doesn't find any errors.

IsError(*Value*)
IsBlankOrError(*Value*)

- *Value* – Required. Formula to test.

Examples

Simple IfError

Expand table

Formula	Description	Result
IfError(1, 2)	The first argument isn't an error. The function has no other errors to check and no default return value. The function returns the last *value* argument evaluated.	1
IfError(1/0, 2)	The first argument returns an error value (because of division by zero). The function evaluates the second argument and returns it as the result.	2
IfError(10, 20, 30)	The first argument isn't an error. The function has no other errors to check but does have a default return value. The function returns the *DefaultResult* argument.	30
IfError(10, 11, 20, 21, 300)	The first argument **10** isn't an error, so the function doesn't evaluate that argument's corresponding replacement **11**. The third argument	300

Formula	Description	Result
	20 isn't an error either, so the function doesn't evaluate that argument's corresponding replacement **21**. The fifth argument **300** has no corresponding replacement and is the default result. The function returns that result because the formula contains no errors.	
IfError(1/0, Notify("There was an internal problem"))	The first argument returns an error value (due to division by zero). The function evaluates the second argument and displays a message to the user. The return value of **IfError** is the return value of **Notify**, coerced to the same type as the first argument to **IfError** (a number).	1

Simple IsError

Expand table

Formula	Description	Result
IsError(1)	The argument isn't an error.	*false*
IsError(Blank())	The argument is a blank, but not an error.	*false*
IsError(1/0)	The argument is an error.	*true*
If(IsError(1/0), Notify("There was an internal problem"))	The argument to **IsError** returns an error value (because of division by zero). This function returns *true*, which causes the **If** to display a message to the user with the **Notify** function. The return value of **If** is the return value of **Notify**, coerced to the same type as the first argument to **If** (a boolean).	*true*

Simple IsBlankOrError

Expand table

Formula	Description	Result
IsBlankOrError(1)	The argument isn't an error or a blank.	*false*
IsBlankOrError(Blank())	The argument is a blank.	*true*
IsBlankOrError(1/0)	The argument is an error.	*true*

Simple Error

In this example, dates are validated relative to one another, resulting in an error if there is a problem.

Power Apps

```
If( StartDate > EndDate,
    Error( { Kind: ErrorKind.Validation, Message: "Start Date must be before
End Date" } ) )
```

In this example, some errors are allowed to pass through while others are suppressed and replaced with a value. In the first case, **b** is in an error state because the **Value** function has an invalid argument. Because this is unexpected by the formula writer, it is passed through so the user sees it. In the second case, with the same formula, **b** has the value 0, resulting in a division by zero. In this case, the formula writer may know that this is acceptable for this logic, suppress the error (no banner is shown), and return -1 instead.

Power Apps

```
With( {a: 1, b: Value("a")},
      IfError( a/b, If( FirstError.Kind <> ErrorKind.Div0, Error( FirstError
), -1 ) ) )
// returns an error with Kind = ErrorKind.InvalidArgument

With( {a: 1, b: 0} )
      IfError( a/b, If( FirstError.Kind <> ErrorKind.Div0, Error( FirstError
), -1 ) ) )
// returns -1
```

The **AllErrors** table can be filtered like any other table. Used with the **Error** function, expected errors can be removed and the remaining errors retained and reported. For example, if we knew that division by zero wasn't going to be a problem in a particular context, those errors could be filtered out, leaving all other errors intact with the following formula:

Power Apps

```
Error( Filter( AllErrors, Kind <> ErrorKind.Div0 ) )
```

Step by step

1. Add a Text input control, and name it **TextInput1** if it doesn't have that name by default.

2. Add a Label control, and name it **Label1** if it doesn't have that name by default.

3. Set the formula for **Label1**'s **Text** property to:

Power Apps

```
IfError( Value( TextInput1.Text ), -1 )
```

4. In **TextInput1**, enter **1234**.

   Label1 shows the value **1234** as this is a valid input to the Value function.

5. In **TextInput1**, enter **ToInfinity**.

   Label1 shows the value **-1** as this isn't a valid input to the Value function. Without wrapping the Value function with IfError, the label would show no value as the error value is treated as a *blank*.

Errors function

10/10/2025

Applies to: ✅ Canvas apps ✅ Model-driven apps

Provides error information for previous changes to a data source.

Overview

Errors can happen when a record of a data source is changed. Many causes are possible, including network outages, inadequate permissions, and edit conflicts.

The functions that modify data in data sources, such as **Patch**, **Collect**, **Remove**, **RemoveIf**, **Update**, **UpdateIf**, and **SubmitForm** report errors in two ways:

- Each of these functions returns an error value as the result of the operation. Errors can be detected with **IsError** and replaced or suppressed with **IfError** and **App.OnError** as usual. See Error Handling for more information.
- After the operation, the **Errors** function will also return the errors for previous operations. It can be useful for displaying the error message on a form screen without needing to capture the error in a state variable.

You can avoid some errors before they happen by using the **Validate** and **DataSourceInfo** functions. See working with data sources for more suggestions on how to work with and avoid errors.

Description

The **Errors** function returns a table of errors that contains the following columns:

- **Record**. The record in the data source that had the error. If the error occurred during the creation of a record, this column is *blank*.
- **Column**. The column that caused the error, if the error can be attributed to a single column. If not, it's *blank*.
- **Message**. A description of the error. This error string can be displayed for the end user. This message may be generated by the data source and could be long and contain raw column names that may not have any meaning to the user.
- **Error**. An error code that can be used in formulas to help resolve the error:

Expand table

ErrorKind	Description
ErrorKind.Conflict	Another change was made to the same record, resulting in a change conflict. Use the **Refresh** function to reload the record and try the change again.
ErrorKind.ConstraintViolation	One or more constraints have been violated.
ErrorKind.CreatePermission	An attempt was made to create a record, and the current user doesn't have permission to create records.
ErrorKind.DeletePermission	An attempt was made to delete a record, and the current user doesn't have permission to delete records.
ErrorKind.EditPermission	An attempt was made to edit a record, and the current user doesn't have permission to edit records.
ErrorKind.GeneratedValue	An attempt was made to change a column that the data source generates automatically.
ErrorKind.MissingRequired	The value for a required column is missing from the record.
ErrorKind.None	There's no error.
ErrorKind.NotFound	An attempt was made to edit or delete a record, but the record couldn't be found. Another user may have changed the record.
ErrorKind.ReadOnlyValue	An attempt was made to change a column that's read only.
ErrorKind.Sync	An error was reported by the data source. Check the Message column for more information.
ErrorKind.Unknown	There was an error, but of an unknown kind.
ErrorKind.Validation	There was a general validation issue detected, that didn't fit one of the other kinds.

Errors can be returned for the entire data source, or for only a selected row by providing the *Record* argument to the function.

Patch or another data function may return a *blank* value if, for example, a record couldn't be created. You can pass *blank* to **Errors**, and it returns appropriate error information in these cases. Subsequent use of data functions on the same data source clears this error information.

If there are no errors, the table that **Errors** returns will be empty and can be tested with the **IsEmpty** function.

Syntax

Errors(*DataSource* [, *Record*])

- *DataSource* – Required. The data source for which you want to return errors.
- *Record* – Optional. A specific record for which you want to return errors. If you don't specify this argument, the function returns errors for the entire data source.

Examples

Step by Step

For this example, we'll be working with the **IceCream** data source, a data source for which Power Apps will attempt to detect conflicts:

Flavor	Quantity
"Chocolate"	100
"Vanilla"	200

> ⓘ **Note**
>
> Power Apps does not attempt to detect conflicts for changes to Dataverse tables.

Through the app, a user loads the Chocolate record into a data-entry form and then changes the value of **Quantity** to 90. The record to be worked with is placed in the context variable **EditRecord**:

- **UpdateContext({ EditRecord: LookUp(IceCream, Flavor = "Chocolate") })**

To make this change in the data source, the **Patch** function is used:

- **Patch(IceCream, EditRecord, Gallery.Updates)**

Where **Gallery.Updates** evaluates to **{ Quantity: 90 }**, since only the **Quantity** property has been modified.

Unfortunately, just before the **Patch** function was invoked, somebody else modifies the **Quantity** for Chocolate to 80. Because this is a supported data source for conflict detection, Power Apps will detect this and not allow the conflicting change to occur. You can check for this situation with the formula:

- **IsEmpty(Errors(IceCream, EditRecord))**

Which returns **false**, because the **Errors** function returned the following table:

Expand table

Record	Column	Message	Error
{ Flavor: "Chocolate", Quantity: 100 }	*blank*	"Another user has modified the record that you're trying to modify. Reload the record and try again."	ErrorKind.Conflict

You can place a label on the form to show this error to the user.

- To show the error, set the label's **Text** property to this formula:
  Label.Text = First(Errors(IceCream, EditRecord)).Message

You can also add a **Reload** button on the form, so that the user can efficiently resolve the conflict.

- To show the button only when a conflict has occurred, set the button's **Visible** property to this formula:
  !IsEmpty(Lookup(Errors(IceCream, EditRecord), Error = ErrorKind.Conflict))
- To revert the change, which the user selects the button, set its **OnSelect** property to this formula:
  ReloadButton.OnSelect = Revert(IceCream, EditRecord)

Operators and Identifiers in Power Apps

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Some of these operators are dependent on the language of the author. For more information about language support in canvas apps, see Global apps.

Expand table

Symbol	Type	Example	Description
'...'	Identifier	**'Account Name'**	Identifiers that contain special characters, including spaces, are enclosed in single quotes
"..."	Text string	**"Hello, World"**	Text strings are enclosed in double quotes
$"..."	String interpolation	**$"Dear {FirstName},"**	Formulas embedded within a text string
.	Property Selector	**Slider1.Value** **Color.Red** **Acceleration.X**	Extracts a property from a table, control, signal, or enumeration. For backward compatibility, **!** may also be used.
. [language dependent]	Decimal separator	**1.23**	Separator between whole and fractional parts of a number. The character depends on the language.
( )	Parentheses	**Filter(T, A < 10)** **(1 + 2) * 3**	Enforces precedence order, and groups subexpressions in a larger expression
+	Arithmetic operators	**1 + 2**	Addition
-		**2 - 1**	Subtraction and sign
*		**2 * 3**	Multiplication
/		**2 / 3**	Division (also see the **Mod** function)
^		**2 ^ 3**	Exponentiation, equivalent to the **Power** function

Symbol	Type	Example	Description
%		**20%**	Percentage (equivalent to "* 1/100")
=	Comparison operators	**Price = 100**	Equal to
>		**Price > 100**	Greater than
>=		**Price >= 100**	Greater than or equal to
<		**Price < 100**	Less than
<=		**Price <= 100**	Less than or equal to
<>		**Price <> 100**	Not equal to
&	String concatenation operator	**"hello" & " " & "world"**	Makes multiple strings appear continuous
&& or **And**	Logical operators	**Price < 100 && Slider1.Value = 20** or **Price < 100 And Slider1.Value = 20**	Logical conjunction, equivalent to the **And** function
|| or **Or**		**Price < 100 || Slider1.Value = 20** or **Price < 100 Or Slider1.Value = 20**	Logical disjunction, equivalent to the **Or** function
! or **Not**		**!(Price < 100)** or **Not (Price < 100)**	Logical negation, equivalent to the **Not** function
exactin	Membership operators	**Gallery1.Selected exactin SavedItems**	Belonging to a collection or a table
exactin		**"Windows" exactin "To display windows in the Windows operating system..."**	Substring test (case-sensitive)
in		**Gallery1.Selected in SavedItems**	Belonging to a collection or a table
in		**"The" in "The keyboard and the monitor..."**	Substring test (case-insensitive)
@	Disambiguation operator	**MyTable[@fieldname]**	Field disambiguation
@		**[@MyVariable]**	Global disambiguation

Symbol	Type	Example	Description
, [language dependent]	List separator	**If(X < 10, "Low", "Good")** **{ X: 12, Y: 32 }** **[1, 2, 3]**	Separates: • arguments in function calls • fields in a record • records in a table This character depends on the language.
; [language dependent]	Formula chaining	**Collect(T, A); Navigate(S1, "")**	Separate invocations of functions in behavior properties. The chaining operator depends on the language.
As	As operator	**AllCustomers As Customer**	Overrides **ThisItem** and **ThisRecord** in galleries and record scope functions. **As** is useful for providing a better, specific name and is especially important in nested scenarios.
Self	Self operator	**Self.Fill**	Access to properties of the current control
Parent	Parent operator	**Parent.Fill**	Access to properties of a control container
ThisItem	ThisItem operator	**ThisItem.FirstName**	Access to fields of a Gallery or form control
ThisRecord	ThisRecord operator	**ThisRecord.FirstName**	Access to the complete record and individual fields of the record within **ForAll**, **Sum**, **With**, and other record scope functions. Can be overridden with the **As** operator.

> ⓘ Note
>
> The @ operator can also be used to validate the type of the record object against a data source. For example, `Collect(coll,Account@{'Account Number: 1111')`

in and exactin operators

Use the **in** and **exactin** operators to find a string in a data source, such as a collection or an imported table. The **in** operator identifies matches regardless of case, and the **exactin** operator identifies matches only if they're capitalized the same way. Here's an example:

1. Create or import a collection named **Inventory**, and show it in a gallery, as the first procedure in Show images and text in a gallery describes.

2. Set the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" in ProductName)

   The gallery shows all products except Callisto because the name of that product is the only one that doesn't contain the letter you specified.

3. Change the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" exactin ProductName)

   The gallery shows only Europa because only its name contains the letter that you specified in the case that you specified.

ThisItem, ThisRecord, and As operators

A few controls and functions apply formulas to individual records of a table. To refer to the individual record in a formula, use one of the following:

Expand table

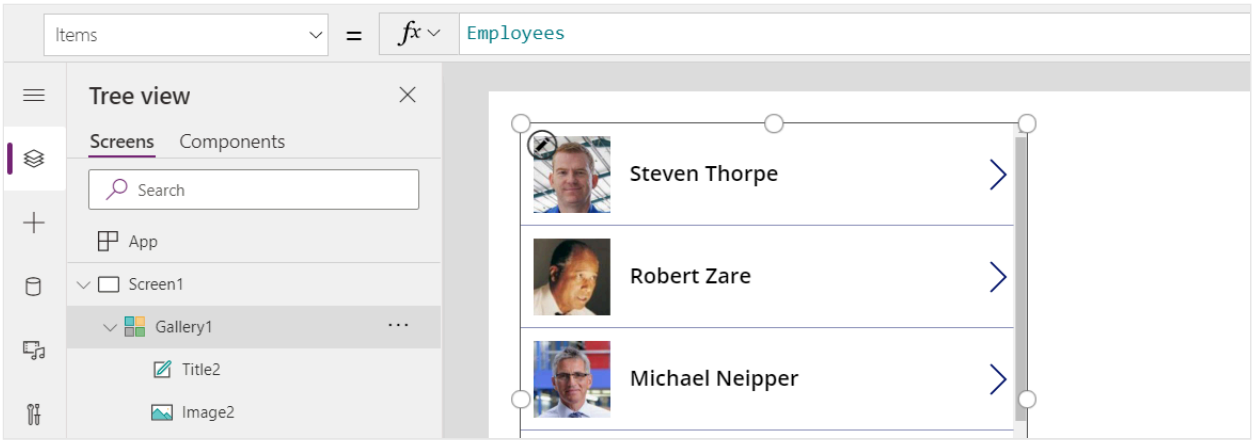
Operator	Applies to	Description
ThisItem	**Gallery** control **Edit form** control **Display form** control	The default name for the current record in a **Gallery** or form control.
ThisRecord	**ForAll**, **Filter**, **With**, **Sum** and other record scope functions	The default name for the current record in **ForAll** and other record scope functions.
As *name*	**Gallery** control **ForAll**, **Filter**, **With**, **Sum** and other record scope functions	Defines a *name* for the current record, replacing default **ThisItem** or **ThisRecord**. Use **As** to make formulas easier to understand and resolve ambiguity when nesting.

ThisItem operator

For example, in the following **Gallery** control, the **Items** property is set to the **Employees** data source (such as the **Employees** table included with the Northwind Traders sample):

Power Apps

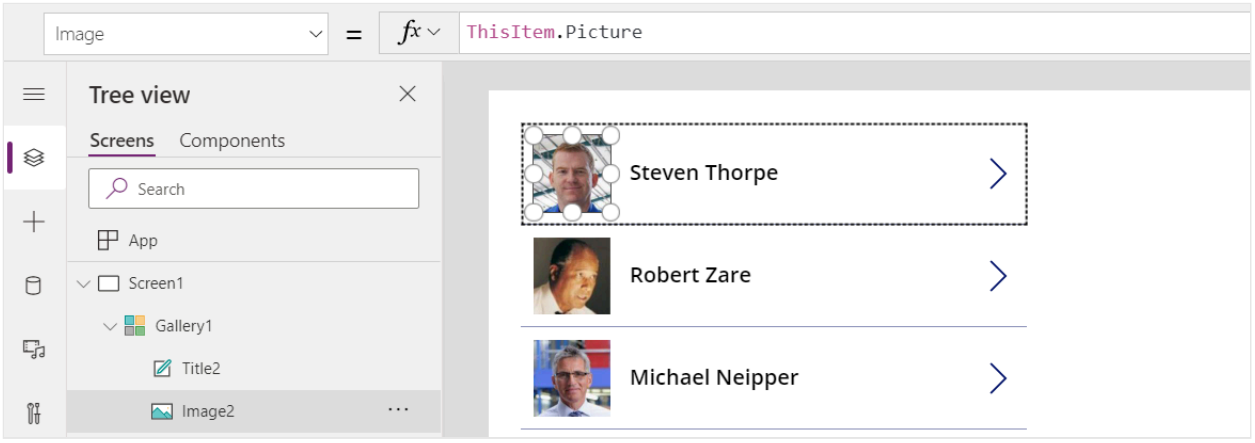
```
Employees
```



The first item in the gallery is a template that is replicated for each employee. In the template, the formula for the picture uses **ThisItem** to refer to the current item:

Power Apps

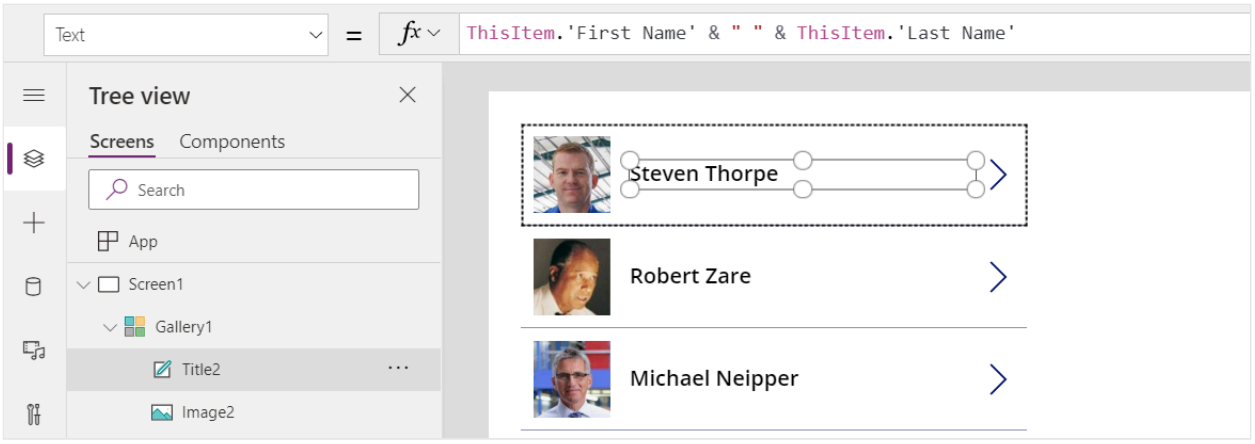
```
ThisItem.Picture
```



Likewise, the formula for the name also uses **ThisItem**:

Power Apps

```
ThisItem.'First Name' & " " & ThisItem.'Last Name'
```

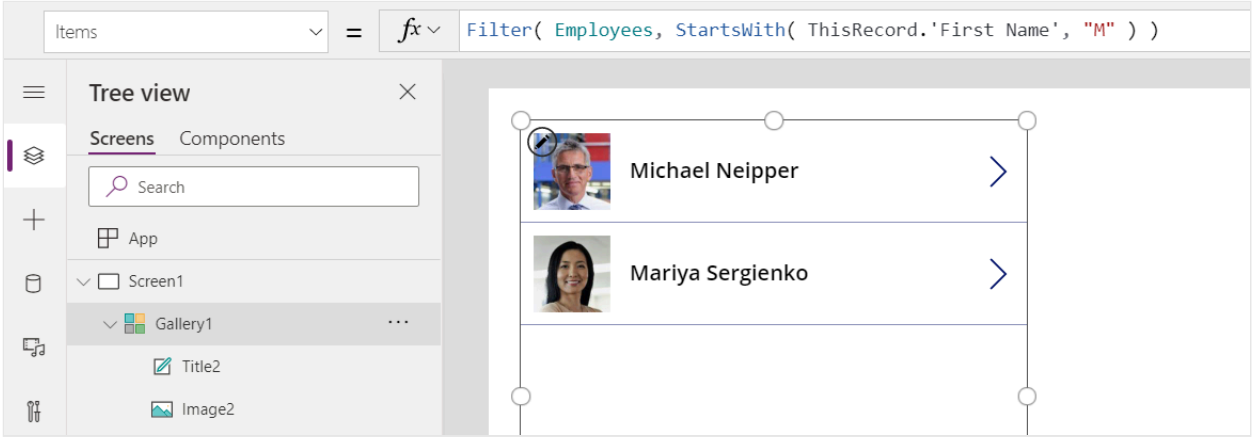


ThisRecord operator

ThisRecord is used in functions that have a record scope. For example, we can use the **Filter** function with our gallery's **Items** property to only show first names that being with *M*:

Power Apps

```
Filter( Employees, StartsWith( ThisRecord.Employee.'First Name', "M" ) )
```



ThisRecord is optional and implied by using the fields directly, for example, in this case, we could have written:

Power Apps

```
Filter( Employees, StartsWith( 'First Name', "M" ) )
```

Although optional, using **ThisRecord** can make formulas easier to understand and may be required in ambiguous situations where a field name may also be a relationship name. **ThisRecord** is optional while **ThisItem** is always required.

Use **ThisRecord** to reference the whole record with **Patch**, **Collect**, and other record scope functions. For example, the following formula sets the status for all inactive employees to active:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees,
              Patch( Employees, ThisRecord, { Status: 'Status
(Employees)'.Active } ) ) )
```

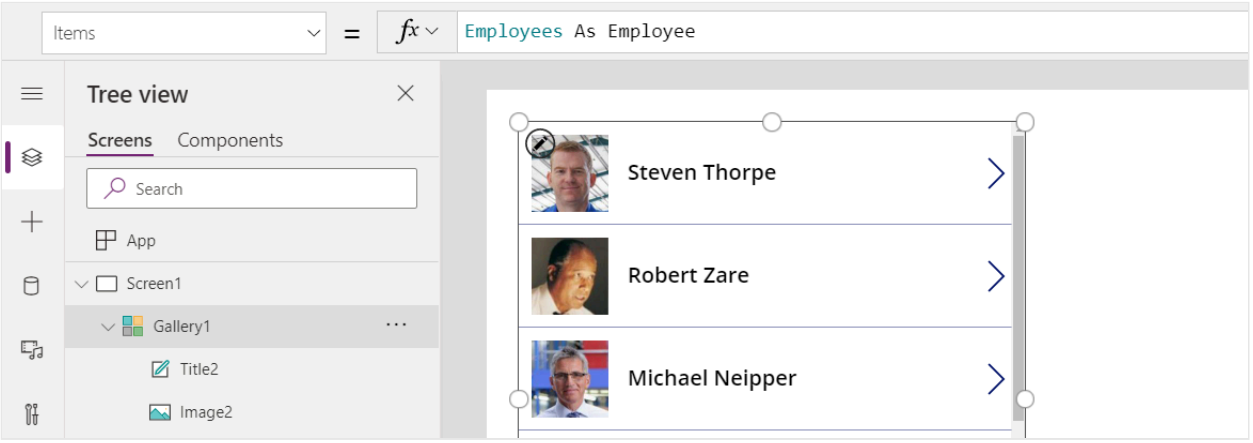
As operator

Use the **As** operator to name a record in a gallery or record scope function, overriding the default **ThisItem** or **ThisRecord**. Naming the record can make your formulas easier to understand and may be required in nested situations to access records in other scopes.

For example, you can modify the **Items** property of our gallery to use **As** to identify that we are working with an Employee:

Power Apps

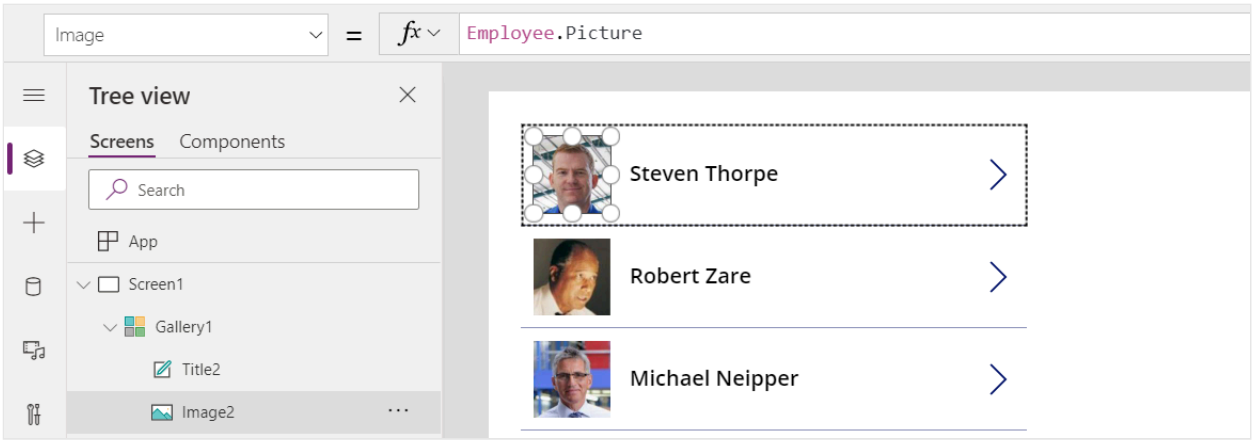
```
Employees As Employee
```



The formulas for the picture and name are adjusted to use this name for the current record:

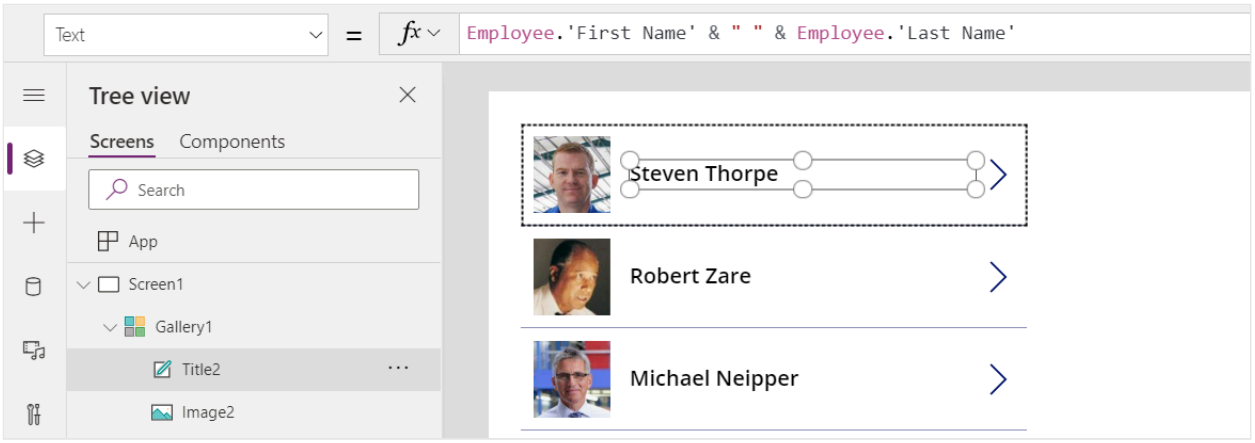
Power Apps

```
Employee.Picture
```



Power Apps

```
Employee.'First Name' & " " & Employee.'Last Name'
```



As can also be used with record scope functions to replace the default name **ThisRecord**. We can apply this to our previous example to clarify the record we're working with:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees As Employee,
              Patch( Employees, Employee, { Status: 'Status
(Employees)'.Active } ) ) )
```

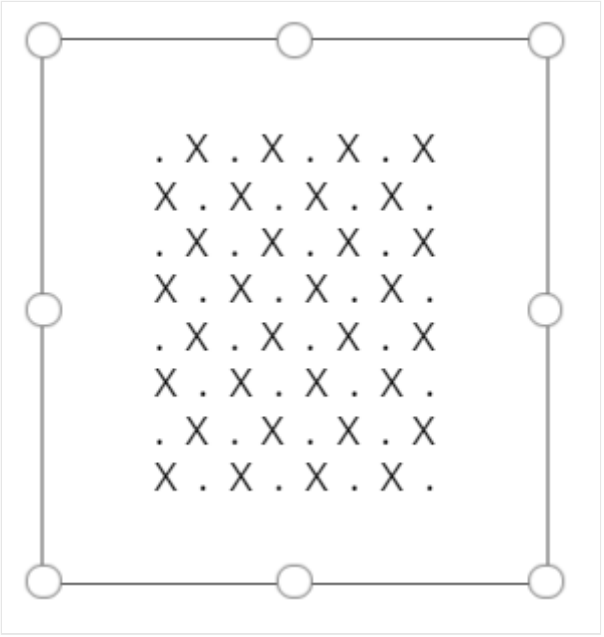
When nesting galleries and record scope functions, **ThisItem** and **ThisRecord** always refers to the inner most scope, leaving records in outer scopes unavailable. Use **As** to make all record scopes available by giving each a unique name.

For example, this formula produces a chessboard pattern as a text string by nesting two **ForAll** functions:

Power Apps

```
Concat(
    ForAll( Sequence(8) As Rank,
        Concat(
            ForAll( Sequence(8) As File,
                    If( Mod(Rank.Value + File.Value, 2) = 1, " X ", " . " )
            ),
            Value
        ) & Char(10)
    ),
    Value
)
```

Setting a **Label** control's **Text** property to this formula displays:



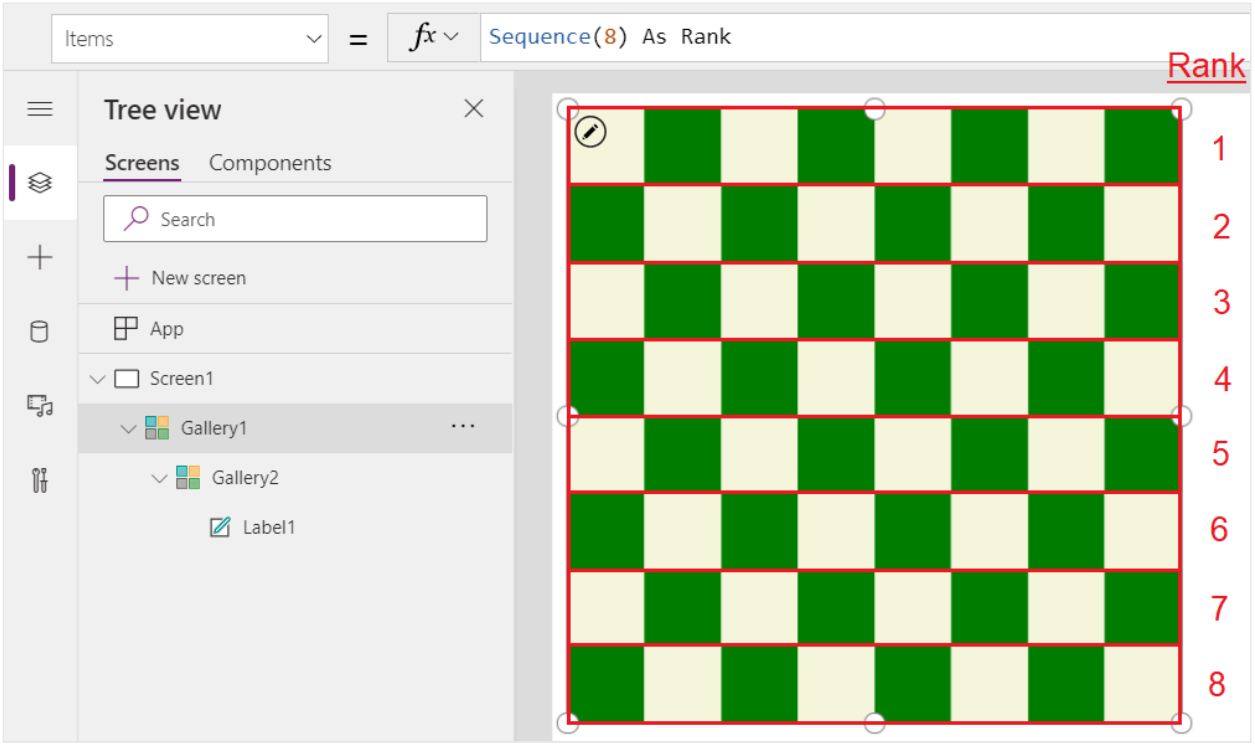
Let's unpack what is happening here:

- We start by iterating an unnamed table of 8 numbered records from the Sequence function. This loop is for each row of the board, which is commonly referred to as **Rank** and so we give it this name.
- For each row, we iterate another unnamed table of 8 columns, and we give the common name **File**.
- If **Rank.Value** + **File.Value** is an odd number, the square gets an **X**, otherwise a dot. This part of the formula is referencing both **ForAll** loops, made possible by using the **As** operator.
- Concat is used twice, first to assemble the columns and then the rows, with a Char(10) thrown in to create a new line.

A similar example is possible with nested **Gallery** controls instead of **ForAll** functions. Let's start with the vertical gallery for the **Rank**. This gallery control will have an **Items** formula of:

Power Apps

```
Sequence(8) as Rank
```



Within this gallery, we'll place a horizontal gallery for the **File**, that will be replicated for each **Rank**, with an **Items** property of:

Power Apps

```
Sequence(8) as File
```

And finally, within this gallery, we'll add a **Label** control that will be replicated for each **File** and each **Rank**. We'll size it to fill the entire space and use the **Fill** property to provide the color with this formula:

Power Apps

```
If( Mod( Rank.Value + File.Value, 2 ) = 1, Green, Beige )
```

Self and Parent operators

There are three ways to refer to a control and its properties within a formula:

Expand table

Method	Description
By control name	Any control can be referenced by name from anywhere within the app. For example, **Label1.Fill** refers to the fill property of the control who's name is **Label1**.
Self operator	It's often convenient to reference another property of the same control when writing a formula. Instead of using an absolute reference by name, it's easier and more portable to use a relative reference to one*self*. The **Self** operator provides that easy access to the current control. For example, **Self.Fill** refers to the fill color of the current control.

Method	Description
Parent operator	Some controls host other controls, such as the **Screen** and **Gallery** controls. The hosting control of the controls within it's called the *parent*. Like the **Self** operator, the **Parent** operator provides an easy relative reference to the container control. For example, **Parent.Fill** refers to the fill property of the control that is the container for the current control.

Self and **Parent** are operators and not properties on the controls themselves. Referring to **Parent.Parent**, **Self.Parent** or **Parent.Self** is not supported.

Identifier names

The names of variables, data sources, columns, and other objects can contain any Unicode.

Use single quotes around a name that contains a space or other special character. Use two single quotes together to represent one single quote in the name. Names that don't contain special characters don't require single quotes.

Here are some example column names you might encounter in a table, and how they're represented in a formula:

Expand table

Column name in a database	Column reference in a formula
SimpleName	`SimpleName`
NameWith123Numbers	`NameWith123Numbers`
Name with spaces	`'Name with spaces'`
Name with "double" quotes	`'Name with "double" quotes'`
Name with 'single' quotes	`'Name with ''single'' quotes'`
Name with an @ at sign	`'Name with an @ at sign'`

Double quotes are used to designate text strings.

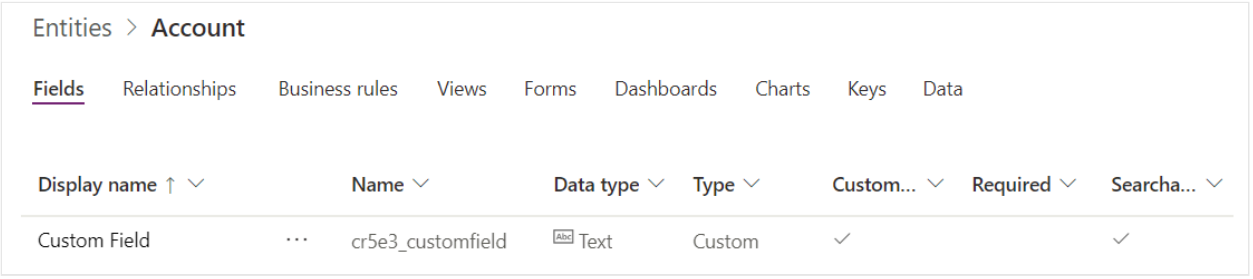
Display names and logical names

Some data sources such as SharePoint and Microsoft Dataverse have two different names to refer to the same table or column of data:

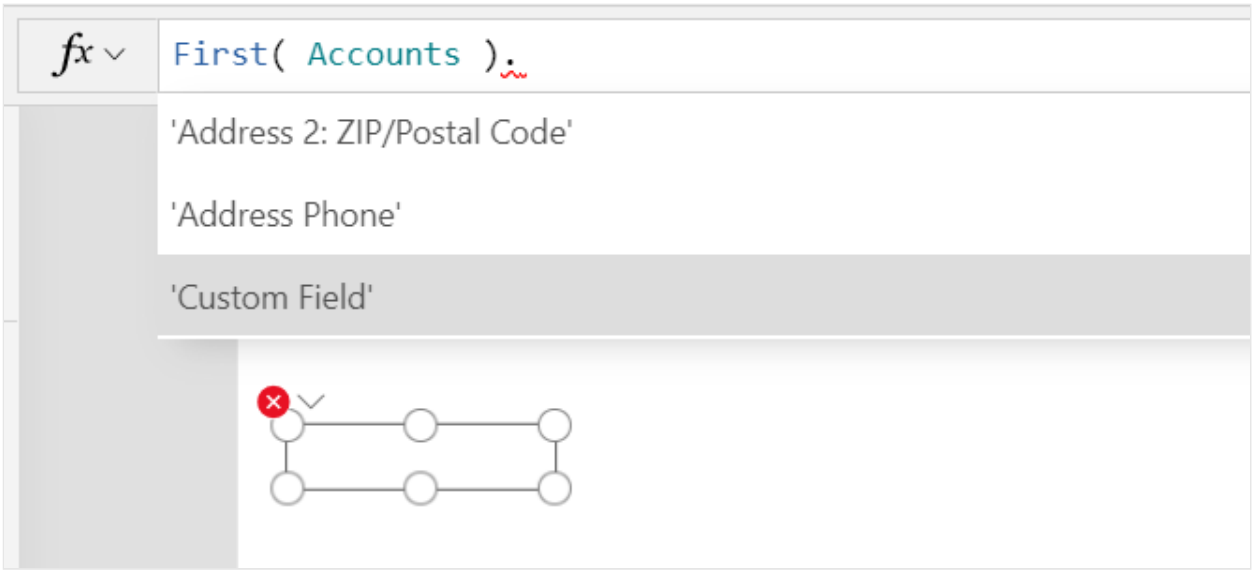
- **Logical name** - A name that is guaranteed to be unique, doesn't change after being created, usually doesn't allow spaces or other special characters, and isn't localized into different languages. As a result, the name can be cryptic. These names are used by professional developers. For example, **cra3a_customfield**. This name may also be referred to as **schema name** or just **name**.
- **Display name** - A name that is user-friendly and intended to be seen by end users. This name may not be unique, may change over time, may contain spaces and any Unicode character, and may be localized into different languages. Corresponding to the example above, the display name may be **Custom Field** with space in between the words.

Since display names are easier to understand, Canvas apps will suggest them as choices and not suggest logical names. Although logical names aren't suggested, they can still be used if typed indirectly.

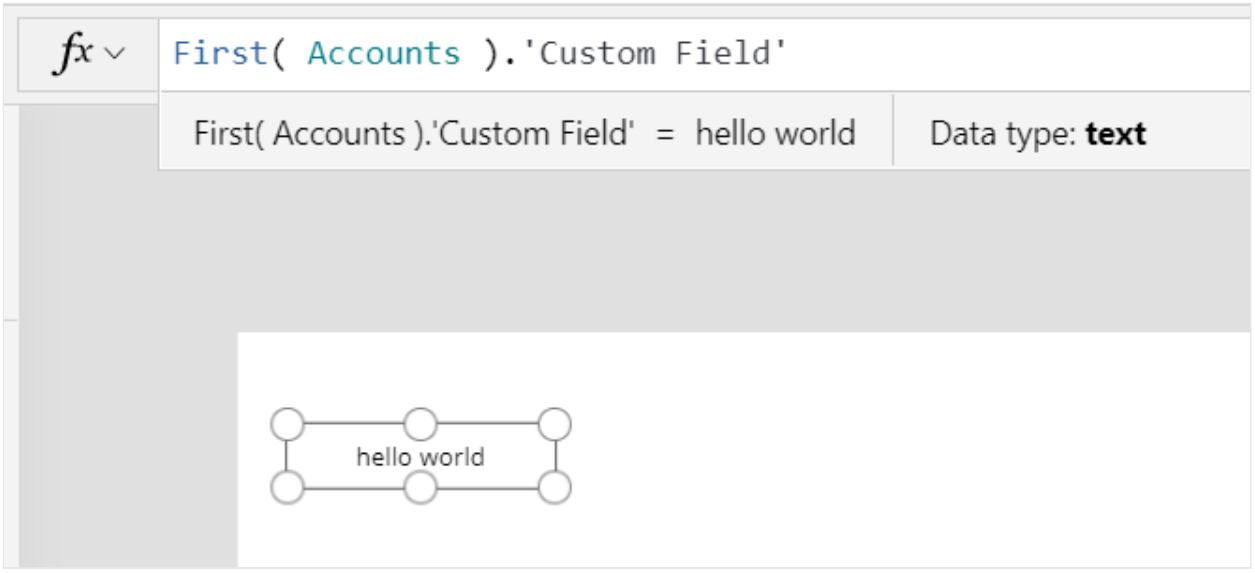
For example, imagine you've added a **Custom Field** to a table in Dataverse. A logical name will be assigned for you by the system, which you can modify only when creating the field. The result would look similar to:



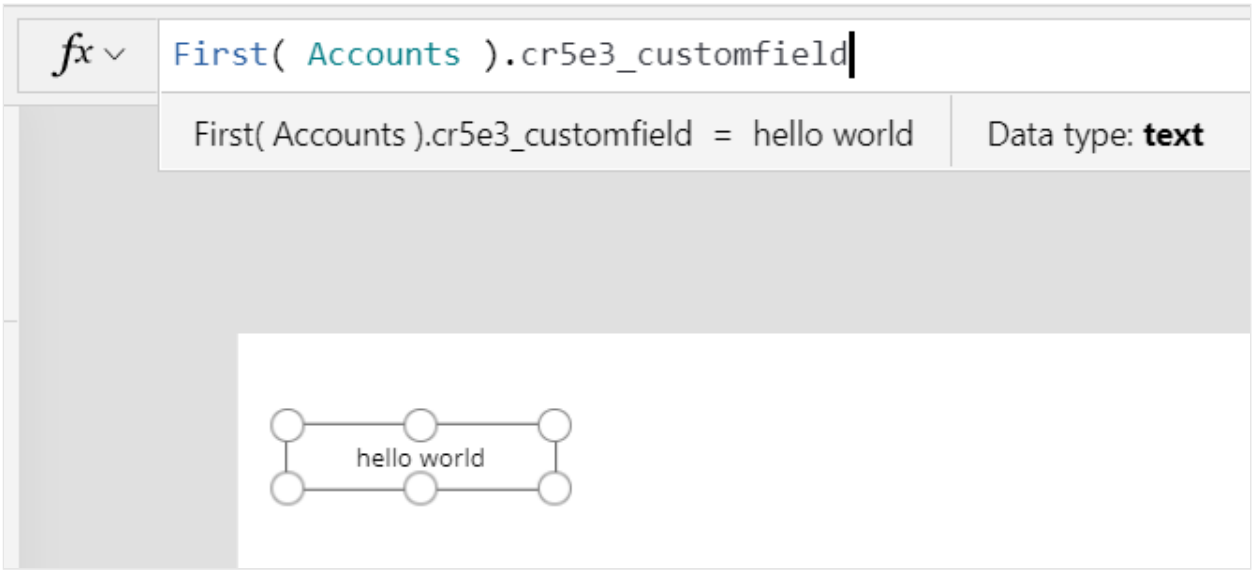
When authoring a reference to a field of Accounts, the suggestion will be made to use '**Custom Field**' since this is the display name. Single quotes must be used because this name has a space in it:



After selecting the suggestion, 'Custom Field' is shown in the formula bar and the data is retrieved:



Although it isn't suggested, we could also use the logical name for this field. This will result in the same data being retrieved. Single quotes are not required since this name doesn't contain spaces or special characters:

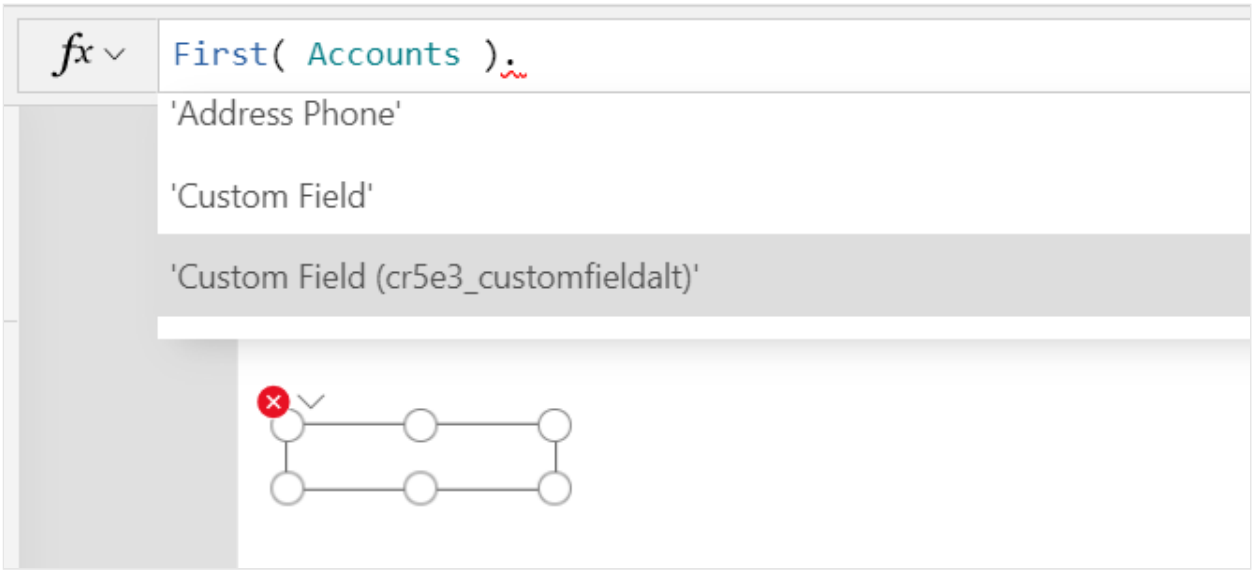


Behind the scenes, a mapping is maintained between the display names seen in formulas and the underlying logical names. Since logical names must be used to interact with the data source, this mapping is used to convert from the current display name to the logical name automatically and that is what is seen in the network traffic. This mapping is also used to convert back to logical names to switch into new display names, for example, if a display name changes or a maker in a different language edits the app.

> **Note**
>
> Logical names are not translated when moving an app between environments. For Dataverse system table and field names, this should not be a problem as logical names are consistent across environments. But any custom fields, such as **cra3a_customfield** in this example above, may have a different environment prefix (**cra3a** in this case). Display names are preferred as they can be matched against display names in the new environment.

Name disambiguation

Since display names aren't unique, the same display name may appear more than once in the same table. When this happens, the logical name will be added to the end of the display name in parentheses for one of more of the conflicting names. Building on the example above, if there was a second field with the same display name of **Custom Field** with a logical name of **cra3a_customfieldalt** then the suggestions would show:



Name disambiguation strings are added in other situations where name conflicts occur, such as the names of table, choices, and other Dataverse items.

Disambiguation operator

Some functions create record scopes for accessing the fields of table while processing each record, such as **Filter**, **AddColumns**, and **Sum**. Field names added with the record scope override the same names from elsewhere in the app. When this happens, you can still access values from outside the record scope with the @ disambiguation operator:

- To access values from nested record scopes, use the @ operator with the name of the table being operated upon using this pattern:
  Table[@*FieldName*]
- To access global values, such as data sources, collections, and context variables, use the pattern [@*ObjectName*] (without a table designation).

For more information and examples, see record scopes.

Exit function

10/10/2025

Applies to: ✅ Canvas apps ✅ Power Platform CLI

Exits the currently running app and optionally signs out the current user.

Description

The **Exit** function exits the currently running app. The user is returned to the list of apps. The user can then select another app to open.

Exit stops any further formula evaluation. Any function calls chained with a semicolon operator after the **Exit** aren't carried out.

Use the optional *Signout* argument to sign the current user out of Power Apps. *Signout* is useful when devices are shared to ensure user security.

While authoring the app, calling **Exit** doesn't exit or sign out the user. However, it stops the evaluation of the rest of the formula.

Exit can only be used in behavior formulas.

Syntax

Exit([*Signout*])

- *Signout* – Optional. A Boolean value that if *true* signs the current user out of Power Apps. The default is *false* and the user remains signed in.

Examples

Expand table

Formula	Description
Exit()	Exits the current app and leaves the user signed in. The user is returned to the list of apps.
Exit(true)	Exits the current app and the user is signed out. The user needs to sign back in with their credentials before running an app.

Abs, Exp, Ln, Power, Log, and Sqrt functions

Article • 04/20/2025

Expand table

Functions	Applies to
Abs **Exp** **Ln** **Power** **Sqrt**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Log	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Calculates absolute values, logarithms, square roots, and the results of raising *e* or any number to specified powers.

Description

The **Abs** function returns the non-negative value of its argument. If a number is negative, **Abs** returns the positive equivalent.

The **Exp** function returns *e* raised to the power of its argument. The transcendental number *e* begins 2.7182818...

The **Ln** function returns the natural logarithm (base *e*) of its argument.

The **Power** function returns a number raised to a power. It's equivalent to using the ^ operator.

The **Log** function returns the logarithm of its first argument in the base specified by its second argument (or 10 if not specified).

The **Sqrt** function returns the number that, when multiplied by itself, equals its argument.

If you pass a single number, the return value is a single result based on the function called. If you pass a single-column table that contains numbers, the return value is a single-column table of results in a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined valued, the result is *blank*. Which can happen with square roots and logarithms of negative numbers.

Syntax

Abs(*Number*)
Exp(*Number*)
Ln(*Number*)
Sqrt(*Number*)

- *Number* - Required. Number to operate on.

Power(*Base*, *Exponent*)

- *Base* - Required. Base number to raise.
- *Exponent* - Required. The exponent to which the base number is raised.

Log(*Number*, *Base*)

- *Number* - Required. Number to calculate the logarithm.
- *Base* - Optional. The base of the logarithm to calculate. By default, 10 (when not specified).

Abs(*SingleColumnTable*)
Exp(*SingleColumnTable*)
Ln(*SingleColumnTable*)
Sqrt(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Examples

Single number

Expand table

Formula	Description	Result
Abs(-55)	Returns the number without the negative sign.	55
Exp(2)	Returns *e* raised to the power of 2, or *e* * *e*.	7.389056...
Ln(100)	Returns the natural logarithm (base *e*) of the number 100.	4.605170...
Log(100)	Returns the logarithm in base 10 of the number 100.	2
Log(64, 2)	Returns the logarithm in base 2 of the number 64.	6

Formula	Description	Result
Power(5, 3)	Returns 5 raised to the power of 3, or 5 * 5 * 5.	125
Sqrt(9)	Returns the number that, when multiplied by itself, results in 9.	3

Single-column table

The examples in this section use a data source that's named **ValueTable** and that contains this data:

Expand table

Value
9
-4
2

Expand table

Formula	Description	Result
Abs(ValueTable)	Returns the absolute value of each number in the table.	A single-column table with a `Value` column containing the following values: 9, 4, 2
Exp(ValueTable)	Returns *e* raised to the power of each number in the table.	A single-column table with a `Value` column containing the following values: 8103.083927..., 0.018315..., 7.389056...
Ln(ValueTable)	Returns the natural logarithm of each number in the table.	A single-column table with a `Value` column containing the following values: 2.197224..., Blank(), 0.693147...
Sqrt(ValueTable)	Returns the square root of each number in the table	A single-column table with a `Value` column containing the following values: 3, Blank(), 1.414213...

Step-by-step example

1. Add a **Text input** control, and name it **Source**.
2. Add a **Label** control, and set its **Text** property to this formula:
   Sqrt(Value(Source.Text))

3. Type a number into **Source**, and confirm that the **Label** control shows the square root of the number that you typed.

Filter, Search, and LookUp functions

Applies to: ✅ Canvas apps ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Finds one or more records in a table.

Watch this video to learn how to use **Filter**, **Search**, and **LookUp** functions:

https://learn-video.azurefd.net/vod/player?id=55b2c144-b5ac-4d66-b398-fea03eb21f17&locale=en-us&embedUrl=%2Fpower-platform%2Fpower-fx%2Freference%2Ffunction-filter-lookup

> **Note**
>
> PAC CLI pac power-fx commands do not support the **Search** function.

Description

The **Filter** function finds records in a table that satisfy a formula. Use **Filter** to find a set of records that match one or more criteria and discard those records that don't.

The **LookUp** function finds the first record in a table that satisfies a formula. Use **LookUp** to find a single record that matches one or more criteria.

For both, the formula is evaluated for each record of the table. Records that result in *true* are included in the result. Besides the normal formula operators, you can use the **in** and **exactin** operators for substring matches.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

The **Search** function finds records in a table that contain a string in one of their columns. The string might occur anywhere within the column; for example, searching for "rob" or "bert" would find a match in a column that contains "Robert". Searching is case-insensitive. Unlike **Filter** and **LookUp**, the **Search** function uses a single string to match instead of a formula.

Filter and **Search** return a table that contains the same columns as the original table and the records that match the criteria. **LookUp** returns only the first record found, after applying a

formula to reduce the record to a single value. If no records are found, **Filter** and **Search** return an empty table, and **LookUp** returns *blank*.

Tables are a value in Power Apps, just like a string or number. They can be passed to and returned from functions. **Filter**, **Search**, and **LookUp** don't modify a table. Instead, they take a table as an argument and return a table, a record, or a single value from it. See working with tables for more details.

Delegation

When possible, Power Apps will delegate filter and sort operations to the data source and page through the results on demand. For example, when you start an app that shows a **Gallery** control filled with data, only the first set of records will be initially brought to the device. As the user scrolls, additional data is brought down from the data source. The result is a faster start time for the app and access to very large data sets.

However, delegation may not always be possible. Data sources vary on what functions and operators they support with delegation. If complete delegation of a formula isn't possible, the authoring environment will flag the portion that can't be delegated with a warning. When possible, consider changing the formula to avoid functions and operators that can't be delegated. The delegation list details which data sources and operations can be delegated.

If delegation is not possible, Power Apps will pull down only a small set of records to work on locally. Filter and sort functions will operate on a reduced set of records. What is available in the **Gallery** may not be the complete story, which could be confusing to users.

See the delegation overview for more information.

Syntax

Filter(Table*, *Formula1* [, *Formula2*, ...])

- *Table* - Required. Table to search.
- *Formula(s)* - Required. The formula by which each record of the table is evaluated. The function returns all records that result in **true**. You can reference columns within the table. If you supply more than one formula, the results of all formulas are combined with the **And** function.

Search(Table*, *SearchString*, *Column1* [, *Column2*, ...])

- *Table* - Required. Table to search.

- *SearchString* - Required. The string to search for. If *blank* or an empty string, all records are returned.
- *Column(s)* - Required. The names of columns within *Table* to search. If *SearchString* is found within the data of any of these columns as a partial match, the full record will be returned.

> **Note**
>
> In Power Apps prior to version 3.24042, column names for the **Search** function were specified with a text string using double quotes, and if connected to a data source they also needed to be logical names. For example, the logical name **"cr43e_name"** with double quotes was used instead of the display name **Name** without quotes. For SharePoint and Excel data sources that contain column names with spaces, each space was specified with **"_x0020_"**, for example **"Column Name"** as **"Column_x0020_Name"**. After this version, all apps were automatically updated to the new syntax described in this article.

LookUp(Table*, *Formula* [, *ReductionFormula*])

- *Table* - Required. Table to search. In the UI, the syntax is shown as *source* above the function box.
- *Formula* - Required. The formula by which each record of the table is evaluated. The function returns the first record that results in **true**. You can reference columns within the table. In the UI, the syntax is shown as *condition* above the function box.
- *ReductionFormula* - Optional. This formula is evaluated over the record that was found, and then reduces the record to a single value. You can reference columns within the table. If you don't use this parameter, the function returns the full record from the table. In the UI, the syntax is shown as *result* above the function box.

Examples

The following examples use the **IceCream** data source:

Flavor	Quantity	OnOrder
"Chocolate"	100	75
"Vanilla"	200	50
"Strawberry"	300	0
"Mint Chocolate"	60	100

Expand table

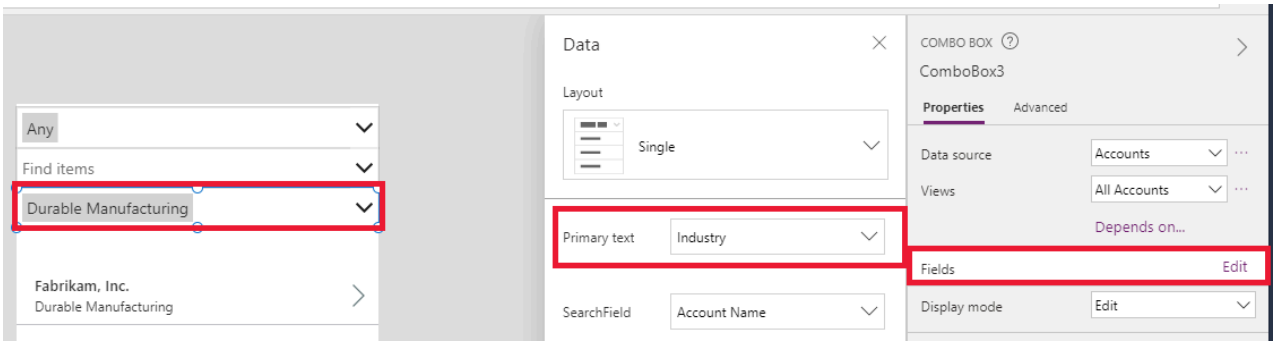
Formula	Description	Result
Filter(IceCream, OnOrder > 0)	Returns records where **OnOrder** is greater than zero.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Chocolate"</td><td>100</td><td>75</td></tr><tr><td>"Vanilla"</td><td>200</td><td>50</td></tr><tr><td>"Mint Chocolate"</td><td>60</td><td>100</td></tr></table>
Filter(IceCream, Quantity + OnOrder > 225)	Returns records where the sum of **Quantity** and **OnOrder** columns is greater than 225.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Vanilla"</td><td>200</td><td>50</td></tr><tr><td>"Strawberry"</td><td>300</td><td>0</td></tr></table>
Filter(IceCream, "chocolate" in Lower(Flavor))	Returns records where the word "chocolate" appears in the **Flavor** name, independent of uppercase or lowercase letters.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Chocolate"</td><td>100</td><td>75</td></tr><tr><td>"Mint Chocolate"</td><td>60</td><td>100</td></tr></table>
Filter(IceCream, Quantity < 10 && OnOrder < 20)	Returns records where the **Quantity** is less than 10 and **OnOrder** is less than 20. No records match these criteria, so an empty table is returned.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr></table>
Search(IceCream, "choc", Flavor)	Returns records where the string "choc" appears in the **Flavor** name, independent of uppercase or lowercase letters.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Chocolate"</td><td>100</td><td>75</td></tr><tr><td>"Mint Chocolate"</td><td>60</td><td>100</td></tr></table>
Search(IceCream, "", Flavor)	Because the search term is empty, all records are returned.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Chocolate"</td><td>100</td><td>75</td></tr><tr><td>"Vanilla"</td><td>200</td><td>50</td></tr><tr><td>"Strawberry"</td><td>300</td><td>0</td></tr><tr><td>"Mint Chocolate"</td><td>60</td><td>100</td></tr></table>
LookUp(IceCream, Flavor = "Chocolate", Quantity)	Searches for a record with **Flavor** equal to "Chocolate", of which there's one. For the first record that's found, returns the **Quantity** of that record.	100
LookUp(IceCream, Quantity > 150, Quantity + OnOrder)	Searches for a record with **Quantity** greater than 150, of which there are multiple. For the first record that's found, which is "Vanilla" **Flavor**, returns the sum of **Quantity** and **OnOrder** columns.	250
LookUp(IceCream, Flavor = "Pistachio", OnOrder)	Searches for a record with **Flavor** equal to "Pistachio", of which there are none. Because none is found, **Lookup** returns *blank*.	*blank*
LookUp(IceCream, Flavor = "Vanilla")	Searches for a record with **Flavor** equal to "Vanilla", of which there's one. Since no reduction formula was supplied, the entire record is returned.	{ Flavor: "Vanilla", Quantity: 200, OnOrder: 75 }

Filtering with choice columns

The following example uses the **Account** table in Microsoft Dataverse as data source. This example shows how to **Filter** list of accounts based on selected Combo box control values:

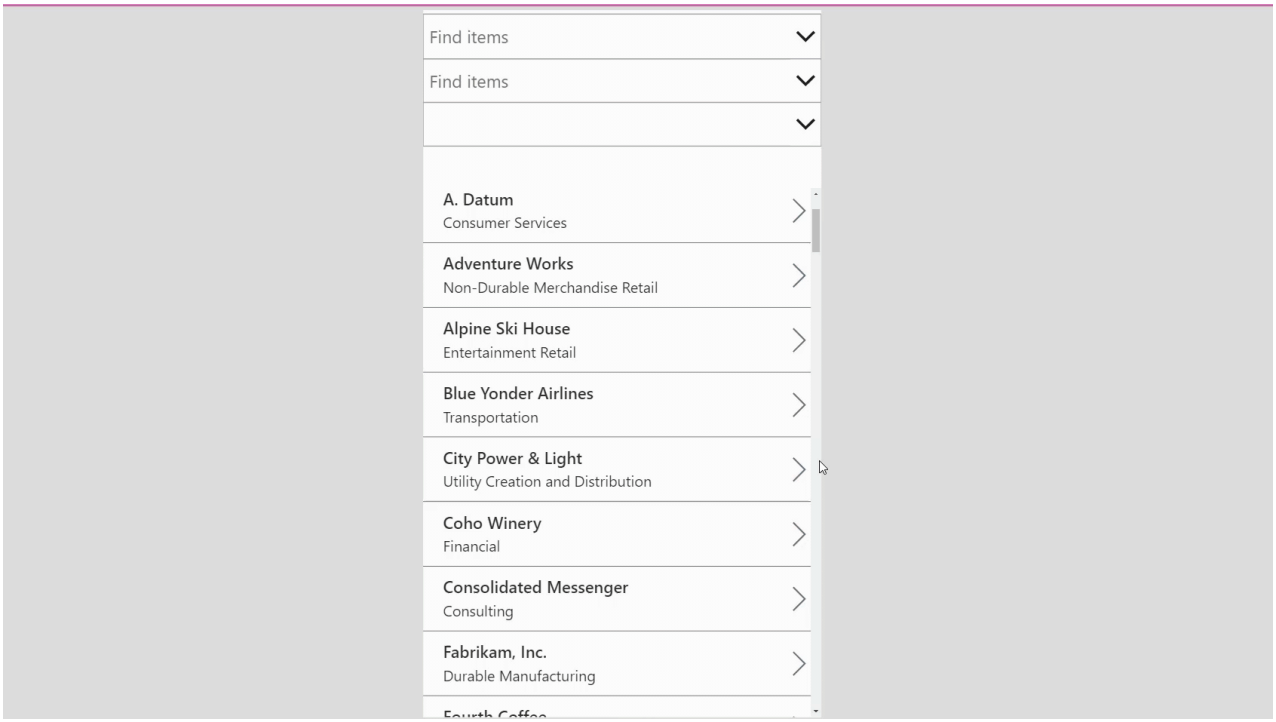
Step by step

1. Open a blank app.
2. Add a new screen by selecting the **New Screen** option.
3. On the **Insert** tab, select **Gallery** and then select **Vertical**.
4. On the **Properties** tab of the right-hand pane, open **Data Source** and then select **Accounts**.
5. (Optional) In the **Layout** list, select different options.
6. On the **Insert** tab, select **Input** and then select **Combo box**. Repeat the step to add two more combo box controls.
7. For each combo box control, on the **Properties** tab of the right-hand pane, open **Data Source** and then select **Accounts**. Select **Edit** next to **Fields** option and then select the **Primary text** and **SearchField** values. The **Primary text** should be the choices column you want to add to the combo box. Repeat the step for other two combo box controls.



8. Now select **Gallery** control and set the **Items** property to the following formula:

```
Filter(Accounts,
 'Industry' = ComboBox3.Selected.Industry Or
IsBlank(ComboBox3.Selected.Industry),
 'Relationship Type' = ComboBox2.Selected.'Relationship Type' Or
   IsBlank(ComboBox2.Selected.'Relationship Type'),
 'Preferred Method of Contact' = ComboBox1.Selected.'Preferred Method of
Contact' Or
   IsBlank(ComboBox1.Selected.'Preferred Method of Contact'))
```



Search user experience

The following examples use the **IceCream** data source:

In many apps, you can type one or more characters into a search box to filter a list of records in a large data set. As you type, the list shows only those records that match the search criteria.

The examples in the rest of this article show the results of searching a list, named **Customers**, that contain this data:

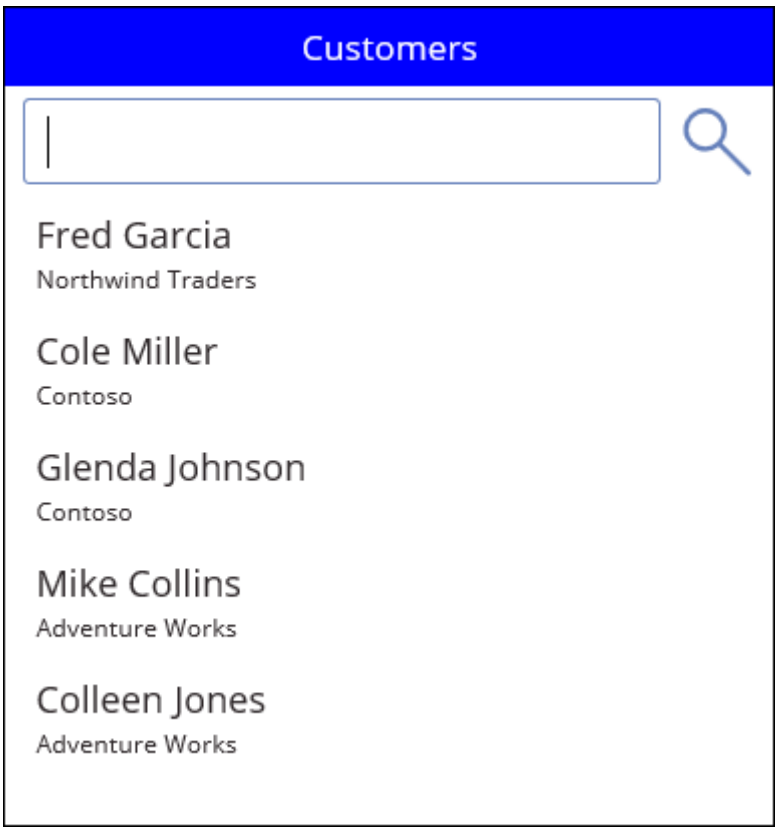
Name	Company
"Fred Garcia"	"Northwind Traders"
"Cole Miller"	"Contoso"
"Glenda Johnson"	"Contoso"
"Mike Collins"	"Adventure Works"
"Colleen Jones"	"Adventure Works"

To create this data source as a collection, create a **Button** control and set its **OnSelect** property to this formula:

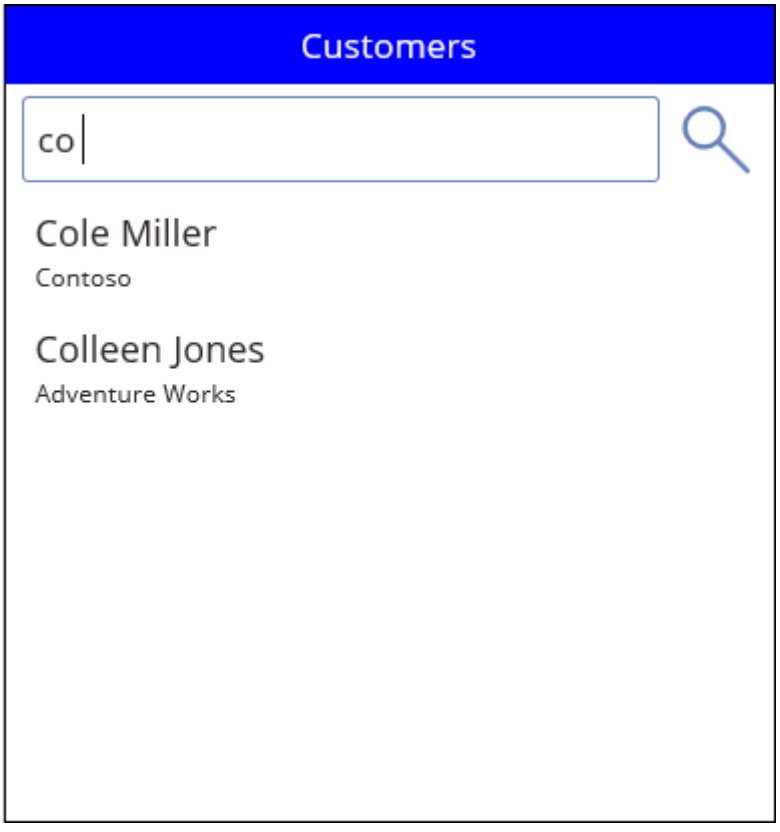
ClearCollect(Customers, Table({ Name: "Fred Garcia", Company: "Northwind Traders" }, { Name: "Cole Miller", Company: "Contoso" }, { Name: "Glenda Johnson", Company: "Contoso" }, { Name: "Mike Collins", Company: "Adventure Works" }, { Name: "Colleen Jones", Company: "Adventure Works" }))

As in this example, you can show a list of records in a **Gallery control** at the bottom of a screen. Near the top of the screen, you can add a **Text input** control, named **SearchInput**, so

that users can specify which records interest them.



As the user types characters in **SearchInput**, the results in the gallery are automatically filtered. In this case, the gallery is configured to show records for which the name of the customer (not the name of the company) starts with the sequence of characters in **SearchInput**. If the user types **co** in the search box, the gallery shows these results:



To filter based on the **Name** column, set the **Items** property of the gallery control to one of these formulas:

Expand table

Formula	Description	Result
Filter(Customers, StartsWith(Name, SearchInput.Text))	Filters the **Customers** data source for records in which the search string appears at the start of the **Name** column. The test is case insensitive. If the user types **co** in the search box, the gallery shows **Colleen Jones** and **Cole Miller**. The gallery doesn't show **Mike Collins** because the **Name** column for that record doesn't start with the search string.	
Filter(Customers, SearchInput.Text in Name)	Filters the **Customers** data source for records in which the search string appears anywhere in the **Name** column. The test is case insensitive. If the user types **co** in the search box, the gallery shows **Colleen Jones, Cole Miller,** and **Mike Collins** because the search string appears somewhere in the **Name** column of all of those records.	Search(Customers, SearchInput.Text, Name)	Similar to using the **in** operator, the **Search** function searches for a match anywhere within the **Name** column of each record. You must enclose the column name in double quotation marks.	

You can expand your search to include the **Company** column and the **Name** column:

Expand table

Formula	Description	Result
`Filter(Customers, StartsWith(Name, SearchInput.Text) || StartsWith(Company, SearchInput.Text) )`	Filters the **Customers** data source for records in which either the **Name** column or the **Company** column starts with the search string (for example, **co**). The || operator is *true* if either **StartsWith** function is *true*.	
`Filter(Customers, SearchInput.Text in Name || SearchInput. Text in Company)`	Filters the **Customers** data source for records in which either the **Name** column or the **Company** column contains the search string (for example, **co**) anywhere within it.	
`Search(Customers, SearchInput.Text, Name, Company)`	Similar to using the **in** operator, the **Search** function searches the **Customers** data source for records in which either the **Name** column or the **Company** column contains the search string (for example, **co**) anywhere within it. The **Search** function is easier to read and write	

Formula	Description	Result
	than **Filter** if you want to specify multiple columns and multiple **in** operators.	

Last updated on 02/06/2025

Find function

Article • 04/20/2025

Applies to: Canvas apps Cards Copilot Studio Desktop flows Model-driven apps Power Platform CLI Dataverse functions Power Pages

Finds a string of text, if it exists, within another string.

Description

The **Find** function looks for a string within another string and is case sensitive. To ignore case, first use the Lower function on the arguments.

Find returns the starting position of the string that was found. Position 1 is the first character of the string. **Find** returns *blank* if the string in which you're searching doesn't contain the string for which you're searching.

Syntax

Find(*FindString*, *WithinString* [, *StartingPosition*])

- *FindString* - Required. The string to find.
- *WithinString* - Required. The string to search within.
- *StartingPosition* - Optional. The starting position to start searching. Position 1 is the first character.

Examples

Expand table

Formula	Description	Result
Find("World", "Hello World")	Returns the starting position of **"World"**.	7
Find("World", "Hello World, Hello World", 10)	Returns the starting position of the first occurrence of **"World"** after the 10th character.	20
Find("Mars", "Hello World")	Returns blank since the FindString is not in the WithinString	Blank()

First, FirstN, Index, Last, and LastN functions

04/20/2025

Applies to: ✅ Canvas apps ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Returns the first, last, or a specific record, or a set of first or last records, from a table.

Description

The **First** function returns the first record of a table.

The **FirstN** function returns the first set of records of a table; the second argument specifies the number of records to return.

The **Last** function returns the last record of a table.

The **LastN** function returns the last set of records of a table; the second argument specifies the number of records to return.

The **Index** function returns a record of a table based on its ordered position in the table. Record numbering begins with 1 so `First( table )` returning the same record as `Index( table, 1 )`. **Index** returns an error if the requested record index is less than 1, greater than the number of records in the table, or the table is empty.

First, **Index**, and **Last** return a single record. **FirstN** and **LastN** return a table, even if you specify only a single record.

Delegation

When used with a data source, these functions can't be delegated. Only the first portion of the data source will be retrieved and then the function applied. The result may not represent the complete story. A warning may appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

For example, when used with a data source containing a large table with 1 million records, **Last** will be subject to the non-delegation limit and will not return the last record of the entire data source. Likewise, using **Index** to request a record in the middle of 1 million records will result in an error because the index is out of range based on the non-delegation limit.

Syntax

First(*Table*)
Last(*Table*)

- *Table* - Required. Table to operate on.

FirstN(*Table* [, *NumberOfRecords*])
LastN(*Table* [, *NumberOfRecords*])

- *Table* - Required. Table to operate on.
- *NumberOfRecords* - Optional. Number of records to return. If you don't specify this argument, the function returns one record.

Index(*Table*, *RecordIndex*)

- *Table* - Required. Table to operate on.
- *RecordIndex* - Required. The index of the record to return. Record numbering begins with 1.

Examples

For the following examples, we'll use the **IceCream** data source, which contains the data in this table:

Flavor	Quantity
"Chocolate"	100
"Vanilla"	200
"Strawberry"	300
"Mint Chocolate"	60
"Pistachio"	200

This table can be placed in a collection with this formula (put in the OnStart formula for a Button control and press the button):

Power Fx

```
Collect( IceCream, Table( { Flavor: "Chocolate", Quantity: 100 },
                          { Flavor: "Vanilla", Quantity: 200 },
                          { Flavor: "Strawberry", Quantity: 300 },
                          { Flavor: "Mint Chocolate", Quantity: 60 },
                          { Flavor: "Pistachio", Quantity: 200 } ) )
```

Expand table

Formula	Description	Result
First(IceCream)	Returns the first record of **IceCream**.	{ Flavor: "Chocolate", Quantity: 100 }
Last(IceCream)	Returns the last record of **IceCream**.	{ Flavor: "Pistachio", Quantity: 200 }
Index(IceCream, 3)	Returns the third record of **IceCream**.	{ Flavor: "Strawberry", Quantity: 300 }
FirstN(IceCream, 2)	Returns a table containing the first two records of **IceCream**.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Chocolate"</td><td>100</td></tr><tr><td>"Vanilla"</td><td>200</td></tr></table>
LastN(IceCream, 2)	Returns a table containing the last two records of **IceCream**.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Mint Chocolate"</td><td>60</td></tr><tr><td>"Pistachio"</td><td>200</td></tr></table>
Index(IceCream, 4).Quantity	Returns the fourth record of the table, and extracts the Quantity column.	60
Index(IceCream, 10)	Returns an error since the record requested is beyond the bounds of the table.	*Error*

First, FirstN, Index, Last, and LastN functions

04/20/2025

Applies to: ✅ Canvas apps ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Returns the first, last, or a specific record, or a set of first or last records, from a table.

Description

The **First** function returns the first record of a table.

The **FirstN** function returns the first set of records of a table; the second argument specifies the number of records to return.

The **Last** function returns the last record of a table.

The **LastN** function returns the last set of records of a table; the second argument specifies the number of records to return.

The **Index** function returns a record of a table based on its ordered position in the table. Record numbering begins with 1 so `First( table )` returning the same record as `Index( table, 1 )`. **Index** returns an error if the requested record index is less than 1, greater than the number of records in the table, or the table is empty.

First, **Index**, and **Last** return a single record. **FirstN** and **LastN** return a table, even if you specify only a single record.

Delegation

When used with a data source, these functions can't be delegated. Only the first portion of the data source will be retrieved and then the function applied. The result may not represent the complete story. A warning may appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

For example, when used with a data source containing a large table with 1 million records, **Last** will be subject to the non-delegation limit and will not return the last record of the entire data source. Likewise, using **Index** to request a record in the middle of 1 million records will result in an error because the index is out of range based on the non-delegation limit.

Syntax

First(*Table*)
Last(*Table*)

- *Table* - Required. Table to operate on.

FirstN(*Table* [, *NumberOfRecords*])
LastN(*Table* [, *NumberOfRecords*])

- *Table* - Required. Table to operate on.
- *NumberOfRecords* - Optional. Number of records to return. If you don't specify this argument, the function returns one record.

Index(*Table*, *RecordIndex*)

- *Table* - Required. Table to operate on.
- *RecordIndex* - Required. The index of the record to return. Record numbering begins with 1.

Examples

For the following examples, we'll use the **IceCream** data source, which contains the data in this table:

                          { Flavor: "Vanilla", Quantity: 200 },
                          { Flavor: "Strawberry", Quantity: 300 },
                          { Flavor: "Mint Chocolate", Quantity: 60 },
                          { Flavor: "Pistachio", Quantity: 200 } ) )
```

Expand table

Formula	Description	Result
First(IceCream)	Returns the first record of **IceCream**.	{ Flavor: "Chocolate", Quantity: 100 }
Last(IceCream)	Returns the last record of **IceCream**.	{ Flavor: "Pistachio", Quantity: 200 }
Index(IceCream, 3)	Returns the third record of **IceCream**.	{ Flavor: "Strawberry", Quantity: 300 }
FirstN(IceCream, 2)	Returns a table containing the first two records of **IceCream**.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Chocolate"</td><td>100</td></tr><tr><td>"Vanilla"</td><td>200</td></tr></table>
LastN(IceCream, 2)	Returns a table containing the last two records of **IceCream**.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Mint Chocolate"</td><td>60</td></tr><tr><td>"Pistachio"</td><td>200</td></tr></table>
Index(IceCream, 4).Quantity	Returns the fourth record of the table, and extracts the Quantity column.	60
Index(IceCream, 10)	Returns an error since the record requested is beyond the bounds of the table.	*Error*

ForAll function

10/10/2025

Applies to: ✅ Canvas apps ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Calculates values and performs actions for all the records in a table.

Description

The **ForAll** function evaluates a formula for all the records in a table. The formula can calculate a value and/or perform actions, such as modifying data or working with a connection. Use the **With** function to evaluate the formula for a single record.

Use the **Sequence** function with the **ForAll** function to iterate based on a count.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

Return value

The result of each formula evaluation is returned in a table, in the same order as the input table.

If the result of the formula is a single value, the resulting table is a single-column table. If the result of the formula is a record, the resulting table contains records with the same columns as the result record.

If the result of the formula is a *blank* value, then there's no record in the result table for that input record. In this case, there are fewer records in the result table than the source table.

Taking action

The formula can include functions that take action, such as modifying the records of a data source with the **Patch** and **Collect** functions. The formula can also call methods on connections. Multiple actions can be performed per record by using the **;** operator. You can't modify the table that is the subject of the **ForAll** function.

When writing your formula, keep in mind that records can be processed in any order and, when possible, in parallel. The first record of the table may be processed after the last record.

Take care to avoid ordering dependencies. For this reason, you can't use the **UpdateContext**, **Clear**, and **ClearCollect** functions within a **ForAll** function because they could easily be used to hold variables that would be susceptible to this effect. You can use **Collect**, but the order in which records are added is undefined.

Several functions that modify data sources, including **Collect**, **Remove**, and **Update**, return the changed data source as their return value. These return values can be large and consume significant resources if returned for every record of the **ForAll** table. You may also find that these return values aren't what you expect because **ForAll** can operate in parallel and may separate the side effects of these functions from obtaining their result. If the return value from **ForAll** isn't used, which is often the case with data modification functions, then the return value won't be created and there are no resource or order concerns. But if you're using the result of a **ForAll** and one of the functions that returns a data source, think carefully about how you structure the result and try it out first on small data sets.

Alternatives

Many functions in Power Apps can process more than one value at a time by using a single-column table. For example, the **Len** function can process a table of text values, returning a table of lengths, in the same manner, that **ForAll** could. This can eliminate the need to use **ForAll** in many cases, can be more efficient, and is easier to read.

Another consideration is that **ForAll** isn't delegable while other functions may be, such as **Filter**.

Delegation

When used with a data source, this function can't be delegated. Only the first portion of the data source will be retrieved and then the function applied. The result may not represent the complete story. A warning may appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

Syntax

ForAll(*Table*, *Formula*)

- *Table* - Required. Table to be acted upon.
- *Formula* - Required. The formula to evaluate for all records of the *Table*.

Examples

Calculations

The following examples use the **Squares** data source:

Value
1
4
9

To create this data source as a collection, set the **OnSelect** property of a **Button** control to this formula, open Preview mode, and then select the button:

```
ClearCollect( Squares, [ "1", "4", "9" ] )
```

Expand table

Formula	Description	Result
ForAll(Squares, Sqrt(Value)) **Sqrt(Squares)**	For all the records of the input table, calculates the square root of the **Value** column. The **Sqrt** function can also be used with a single-column table, making it possible to perform this example without using **ForAll**.	**Value** 1 2 3
ForAll(Squares, Power(Value, 3))	For all the records of the input table, raises the **Value** column to the third power. The **Power** function doesn't support single-column tables. Therefore, **ForAll** must be used in this case.	**Value** 1 64 729

Using a connection

The following examples use the **Expressions** data source:

Value
"Hello"
"Good morning"
"Thank you"
"Goodbye"

To create this data source as a collection, set the **OnSelect** property of a **Button** control to this formula, open Preview mode, and then select the button:

```
ClearCollect( Expressions, [ "Hello", "Good morning", "Thank you", "Goodbye" ] )
```

This example also uses a Microsoft Translator connection. To add this connection to your app, see the article about how to manage connections.

Expand table

Formula	Description	Result
ForAll(Expressions, MicrosoftTranslator.Translate(Value, "es"))	For all the records in the Expressions table, translate the contents of the **Value** column into Spanish (abbreviated "es").	Value "Hola" "Buenos días" "Gracias" "Adiós"
ForAll(Expressions, MicrosoftTranslator.Translate(Value, "fr"))	For all the records in the Expressions table, translate the contents of the **Value** column into French (abbreviated "fr").	Value "Salut" "Bonjour" "Merci" "Au revoir"

Copying a table

Sometimes you need to filter, shape, sort, and manipulate data. Power Apps provides many functions for doing this, such as **Filter**, **AddColumns**, and **Sort**. Power Apps treats each table as a value, allowing it to flow through formulas and be consumed easily.

And sometimes you want to make a copy of this result for later use, or you want to move information from one data source to another. Power Apps provides the **Collect** function to copy data.

But before you make that copy, think carefully if it's needed. Many situations can be addressed by filtering and shaping the underlying data source on-demand with a formula. Some of the downsides to making a copy include:

- Two copies of the same information mean that one of them can fall out of sync.
- Making a copy can consume much of the computer memory, network bandwidth, and/or time.
- For most data sources, copying can't be delegated, limiting how much data can be moved.

The following examples use the **Products** data source:

Product	Quantity Requested	Quantity Available
"Widget"	6	3
"Gadget"	10	20
"Gizmo"	4	11
"Apparatus"	7	6

To create this data source as a collection, set the **OnSelect** property of a **Button** control to this formula, open Preview mode, and then select the button:

Power Fx

```
ClearCollect( Products,
    Table(
        { Product: "Widget",    'Quantity Requested': 6,  'Quantity Available': 3
},
        { Product: "Gadget",    'Quantity Requested': 10, 'Quantity Available': 20
},
        { Product: "Gizmo",     'Quantity Requested': 4,  'Quantity Available': 11
},
        { Product: "Apparatus", 'Quantity Requested': 7,  'Quantity Available': 6
}
    )
)
```

Our goal is to work with a derivative table that includes only the items where more has been requested than is available, and for which we need to place an order:

Product	Quantity To Order
"Widget"	3
"Apparatus"	1

We can perform this task in a couple of different ways, all of which produce the same result, with various pros and cons.

Table shaping on demand

Don't make that copy! We can use the following formula anywhere we need:

Power Fx

```
// Table shaping on demand, no need for a copy of the result
ShowColumns(
    AddColumns(
        Filter( Products, 'Quantity Requested' > 'Quantity Available' ),
        "Quantity To Order", 'Quantity Requested' - 'Quantity Available'
    ),
```

```
    "Product",
    "Quantity To Order"
)
```

A record scope is created by the **Filter** and **AddColumns** functions to perform the comparison and subtraction operations, respectively, with the '**Quantity Requested**' and '**Quantity Available**' fields of each record.

In this example, the **Filter** function can be delegated. This is important, as it can find all the products that meet the criteria, even if that is only a few records out of a table of millions. At this time, **ShowColumns** and **AddColumns** cannot be delegated, so the actual number of products that need to be ordered is limited. If you know the size of this result is always be relatively small, this approach is fine.

And because we didn't make a copy, there's no extra copy of the information to manage or fall out of date.

ForAll on demand

Another approach is to use the **ForAll** function to replace the table-shaping functions:

Power Fx

```
ForAll( Products,
    If( 'Quantity Requested' > 'Quantity Available',
        {
            Product: Product,
            'Quantity To Order': 'Quantity Requested' - 'Quantity Available'
        }
    )
)
```

This formula may be simpler for some people to read and write.

No part of the **ForAll** is delegable. Only the first portion of the **Products** table is evaluated, which could be a problem if this table is large. Because **Filter** could be delegated in the previous example, it could work better with large data sets.

Collect the result

In some situations, a copy of data may be required. You may need to move information from one data source to another. In this example, orders are placed through a **NewOrder** table on a vendor's system. For high-speed user interactions, you may want to cache a local copy of a table so that there's no server latency.

We use the same table shaping as the previous two examples, but we capture the result into a collection:

Power Fx

```
ClearCollect( NewOrder,
    ShowColumns(
        AddColumns(
            Filter( Products, 'Quantity Requested' > 'Quantity Available' ),
            "Quantity To Order", 'Quantity Requested' - 'Quantity Available'
        ),
        "Product",
        "Quantity To Order"
    )
)
```

Power Fx

```
ClearCollect( NewOrder,
    ForAll( Products,
        If( 'Quantity Requested' > 'Quantity Available',
            {
                Product: Product,
                'Quantity To Order': 'Quantity Requested' - 'Quantity Available'
            }
        )
    )
)
```

ClearCollect and **Collect** can't be delegated. As a result, the amount of data that can be moved in this manner is limited.

Collect within ForAll

Finally, we can perform the **Collect** directly within the **ForAll**:

Power Fx

```
Clear( NewOrder );
ForAll( Products,
    If( 'Quantity Requested' > 'Quantity Available',
        Collect( NewOrder,
            {
                Product: Product,
                'Quantity To Order': 'Quantity Requested' - 'Quantity Available'
            }
        )
```

```
    )
)
```

Again, the **ForAll** function can't be delegated at this time. If our **Products** table is large, **ForAll** looks at the first set of records only and we may miss some products that need to be ordered. But for tables that we know are remain small, this approach is fine.

Note that we aren't capturing the result of the **ForAll**. The **Collect** function calls made from within it returns the **NewOrder** data source for all the records, which could add up to numerous data if we were capturing it.

Map table in a component

See Map tables.

GroupBy and Ungroup functions

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Groups and ungroups records of a table.

Description

The **GroupBy** function returns a table with records grouped together based on the values in one or more columns. Records in the same group are placed into a single record, with a column added that holds a nested table of the remaining columns.

The **Ungroup** function reverses the **GroupBy** process. This function returns a table, breaking into separate records any records that were grouped together.

You can group records by using **GroupBy**, modify the table that it returns, and then ungroup records in the modified table by using **Ungroup**. For example, you can remove a group of records by following this approach:

- Use the **GroupBy** function.
- Use the **Filter** function to remove the entire group of records.
- Use the **Ungroup** function.

You can also aggregate results based on a grouping:

- Use the **GroupBy** function.
- Use the **AddColumns** function with **Sum**, **Average**, and other aggregate functions to add a new column, which is an aggregate of the group tables.
- Use the **DropColumns** function to drop the group table.

Ungroup tries to preserve the original order of the records that were fed to **GroupBy**. This isn't always possible (for example, if the original table contains *blank* records).

A table is a value in Power Apps, just like a string or a number. You can specify a table as an argument for a function, and a function can return a table. **GroupBy** and **Ungroup** don't modify a table; instead they take a table as an argument and return a different table. See working with tables for more details.

> **Note**

In Power Apps prior to version 3.24042, column names were specified with a text string using double quotes, and if connected to a data source they also needed to be logical names. For example, the logical name **"cr43e_name"** with double quotes was used instead of the display name **Name** without quotes. For SharePoint and Excel data sources that contain column names with spaces, each space was specified with **"_x0020_"**, for example **"Column Name"** as **"Column_x0020_Name"**. After this version, all apps were automatically updated to the new syntax described in this article.

Syntax

GroupBy(*Table*, *ColumnName1* [, *ColumnName2*, ...], *GroupColumnName*)

- *Table* - Required. Table to be grouped.
- *ColumnName(s)* - Required. The column names in *Table* by which to group records. These columns become columns in the resulting table.
- *GroupColumnName* - Required. The column name for the storage of record data not in the *ColumnName(s)*.

Ungroup(*Table*, *GroupColumnName*)

- *Table* - Required. Table to be ungrouped.
- *GroupColumnName* - Required. The column that contains the record data setup with the **GroupBy** function.

Examples

Create a collection

1. Add a button, and set its **Text** property so that the button shows **Original**.
2. Set the **OnSelect** property of the **Original** button to this formula:

Power Apps

```
ClearCollect( CityPopulations,
    { City: "London",    Country: "United Kingdom", Population: 8615000},
    { City: "Berlin",    Country: "Germany",        Population: 3562000},
    { City: "Madrid",    Country: "Spain",          Population: 3165000},
    { City: "Rome",      Country: "Italy",          Population: 2874000},
    { City: "Paris",     Country: "France",         Population: 2273000},
    { City: "Hamburg",   Country: "Germany",        Population: 1760000},
    { City: "Barcelona", Country: "Spain",          Population: 1602000},
    { City: "Munich",    Country: "Germany",        Population: 1494000},
```

```
    { City: "Milan",     Country: "Italy",          Population: 1344000}
)
```

3. While holding down the Alt key, select the **Original** button.

   You just created a collection, named **CityPopulations**, that contains this data:

City	Country	Population
"London"	"United Kingdom"	8,615,000
"Berlin"	"Germany"	3,562,000
"Madrid"	"Spain"	3,165,000
"Rome"	"Italy"	2,874,000
"Paris"	"France"	2,273,000
"Hamburg"	"Germany"	1,760,000
"Barcelona"	"Spain"	1,602,000
"Munich"	"Germany"	1,494,000
"Milan"	"Italy"	1,344,000

4. To display this collection, select **Collections** on the **File** menu and then select the **CityPopulations** collection. The first five records in the collection appear:

Group records

1. Add another button, and set its **Text** property to "**Group**".

2. Set the **OnSelect** property of this button to this formula:

ClearCollect(CitiesByCountry, GroupBy(CityPopulations, Country, Cities))

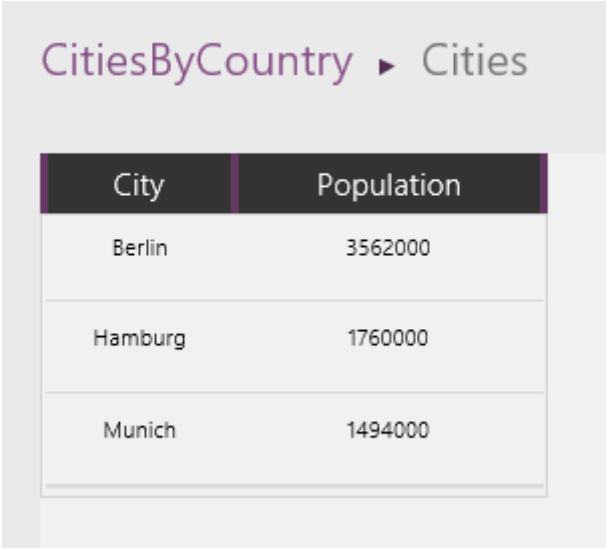
3. While holding down the Alt key, select the **Group** button.

   You just created a collection, named **CitiesByCountry**, in which the records of the previous collection are grouped by the **Country** column.

Cities	Country
City / **Population** "London" / 8,615,000	"United Kingdom"
City / **Population** "Berlin" / 3,562,000 "Hamburg" / 1,760,000 "Munich" / 1,494,000	"Germany"
City / **Population** "Madrid" / 3,165,000 "Barcelona" / 1,602,000	"Spain"
City / **Population** "Rome" / 2,874,000 "Milan" / 1,344,000	"Italy"
City / **Population** "Paris" / 2,273,000	"France"

4. To display the first five records in this collection, select **Collections** on the **File** menu.

5. To display the populations of cities in a country/region, select the table icon in the **Cities** column for that country/region (for example, Germany):



Filter and ungroup records

1. Add another button, and set its **Text** property so that the button shows **"Filter"**.

2. Set the **OnSelect** property of this button to this formula:

   ClearCollect(CitiesByCountryFiltered, Filter(CitiesByCountry, "e" in Country))

3. While holding down the Alt key, select the button that you added.

   You just created a third collection, named **CitiesByCountryFiltered**, that includes only those countries that have an "e" in their names (that is, not Spain or Italy).

Cities	Country
City / Population "London" / 8,615,000	"United Kingdom"
City / Population "Berlin" / 3,562,000 "Hamburg" / 1,760,000 "Munich" / 1,494,000	"Germany"
City / Population "Paris" / 2,273,000	"France"

4. Add one more button, and set its **Text** property so that the button shows **"Ungroup"**.

5. Set the **OnSelect** property of this button to this formula:

   ClearCollect(CityPopulationsUngrouped, Ungroup(CitiesByCountryFiltered, Cities))

   Which results in:

City	Country	Population
"London"	"United Kingdom"	8,615,000
"Berlin"	"Germany"	3,562,000
"Paris"	"France"	2,273,000
"Hamburg"	"Germany"	1,760,000
"Munich"	"Germany"	1,494,000

Aggregate results

Another operation we can perform on a grouped table is to compile the results. In this example, we'll sum the population of the major cities in each country/region.

1. Add another button, and set its **Text** property so that the button shows **"Sum"**.

2. Set the **OnSelect** property of the **"Sum"** button to this formula:

   ClearCollect(CityPopulationsSum, AddColumns(CitiesByCountry, 'Sum of City Populations', Sum(Cities, Population)))

   Which results in:

Cities	Country	Sum of City Populations
City: "London", Population: 8,615,000	"United Kingdom"	8,615,000
City: "Berlin", Population: 3,562,000 City: "Hamburg", Population: 1,760,000 City: "Munich", Population: 1,494,000	"Germany"	6,816,000
City: "Madrid", Population: 3,165,000 City: "Barcelona", Population: 1,602,000	"Spain"	4,767,000
City: "Rome", Population: 2,874,000 City: "Milan", Population: 1,344,000	"Italy"	4,218,000
City: "Paris", Population: 2,273,000	"France"	2,273,000

AddColumns starts with the base **CitiesByCountry** collection and adds a new column **Sum of City Populations**. This column's values are calculated row-by-row, based on the formula **Sum(Cities, Population)**. **AddColumns** provides the value of the **Cities** column (a table) for each row, and Sum adds up the **Population** for each row of this sub table.

Now that we have the sum that we want, we can use DropColumns to remove the sub tables.

3. Add another button, and set its Text property so that the button shows **"SumOnly"**.

4. Set the OnSelect property of the **"SumOnly"** button to this formula:

   ClearCollect(CityPopulationsSumOnly, DropColumns(CityPopulationsSum, Cities))

   Which results in:

Country	Sum of City Populations
"United Kingdom"	8,615,000
"Germany"	6,816,000
"Spain"	4,767,000
"Italy"	4,218,000
"France"	2,273,000

Note that we didn't need to ungroup this table.

GUID function

06/19/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions

Convert a GUID (globally unique identifier) string to a GUID value, or create a new GUID value.

Description

Use the **GUID** function to convert a string with the hexadecimal representation of a GUID into a GUID value you can pass to a database. Database systems like Microsoft Dataverse and SQL Server use GUID values as keys.

The string can have uppercase or lowercase letters, but it must be 32 hexadecimal digits in one of these formats:

- **"123e4567-e89b-12d3-a456-426655440000"** (hyphens in standard locations)
- **"123e4567e89b12d3a456426655440000"** (no hyphens)

If you don't specify an argument, the function creates a new GUID.

To convert a GUID value to a string, use it in a string context. The GUID value converts to a hexadecimal string with hyphens and lowercase letters.

When generating a new GUID, the function uses pseudo-random numbers to create a version 4 IETF RFC 4122 GUID. When converting a string to a GUID, the function supports any GUID version by accepting any string of 32 hexadecimal digits.

Volatile functions

GUID is a volatile function when used without an argument. Each time the function is evaluated, it returns a different value.

When you use a volatile function in a data-flow formula, it returns a different value only if the formula is reevaluated. If nothing else changes in the formula, it keeps the same value while your app is open.

For example, if you set the **Text** property of a label control to **GUID()**, it doesn't change while your app is active. You get a different value only when you close and reopen the app.

The function is reevaluated if it's part of a formula where something else changes. For example, if you set the **Text** property of a **Label** control to this formula, a GUID is generated each time the user changes the value of the **Text input** control:

TextInput1.Text & " " & GUID()

When you use **GUID** in a behavior formula, it's evaluated each time the formula is evaluated. For more information, see the examples later in this topic.

Syntax

GUID([*GUIDString*])

- *GUIDString* – Optional. A text string that has the hexadecimal representation of a GUID. If you don't supply a string, the function creates a new GUID.

GUID(*Dynamic*)

- *Dynamic* – Required. **Dynamic** value that represents a GUID. Acceptable values depend on the untyped provider. For **JSON**, the dynamic value is expected to be a GUID represented as a JSON string.

Examples

Basic usage

To return a GUID value based on the hexadecimal string representation:

```
Power Fx
GUID( "0f8fad5b-d9cb-469f-a165-70867728950e" )
```

You can also provide the GUID string without hyphens. This formula returns the same GUID value:

```
Power Fx
GUID( "0f8fad5bd9cb469fa16570867728950e" )
```

Used in context, to set the **Status** field of a new database record to a well-established value:

```
Power Fx
```

```
Patch( Products, Default( Products ), { Status: GUID( "F9168C5E-CEB2-4faa-B6BF-329BF39FA1E4" ) } )
```

You probably don't want to show GUIDs to users, but GUIDs can help you debug your app. To show the value of the **Status** field in the record you created in the previous example, set the **Text** property of a **Label** control to this formula:

Power Fx

```
First( Products ).Status
```

The **Label** control shows **f9168c5e-ceb2-4faa-b6bf-329bf39fa1e4**.

Create a table of GUIDs

1. Set the **OnSelect** property of a **Button** control to this formula:

   Power Fx

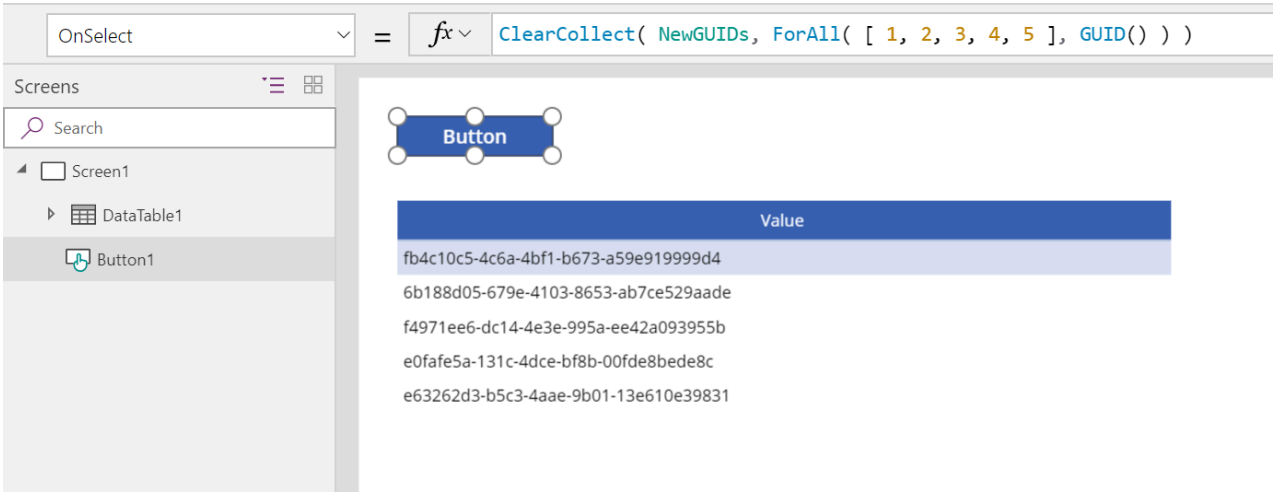
   ```
   ClearCollect( NewGUIDs, ForAll( Sequence(5), GUID() ) )
   ```

   This formula creates a single-column table that's used to iterate five times, resulting in five GUIDs.

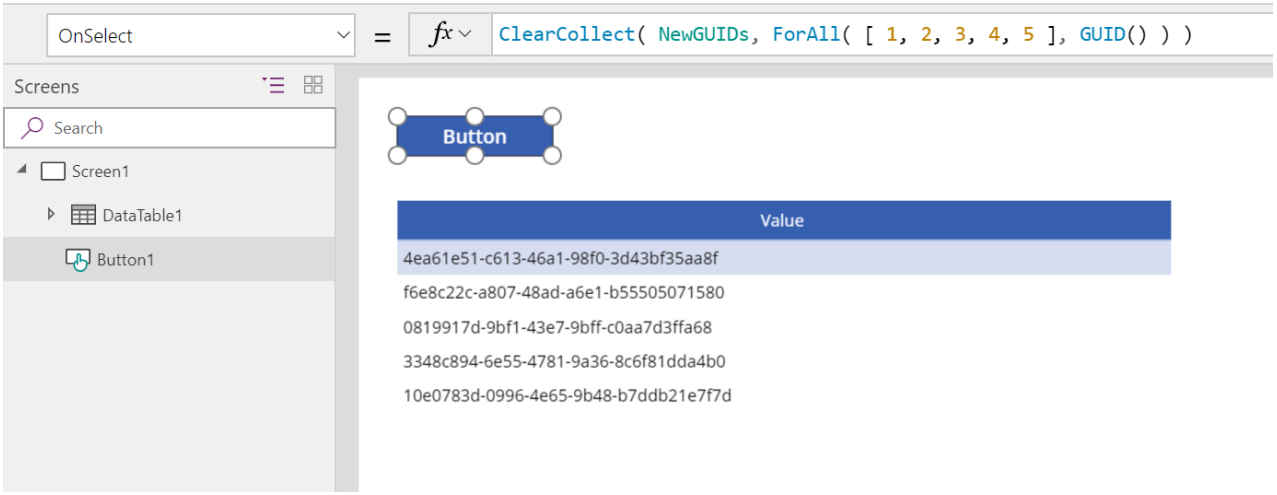
2. Add a **Data table** control, set its **Items** property to **NewGUIDs**, and show the **Value** field.

3. Hold down the Alt key and select the button.

   The data table shows a list of GUIDs:



4. Select the button again to show a new list of GUIDs:



To generate a single GUID instead of a table, use this formula:

Power Fx

```
Set( NewGUID, GUID() )
```

HashTags function

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Model-driven apps ✅ Power Pages

Extracts the hashtags (#strings) from a string of text.

Description

The **HashTags** function scans a string for hashtags. Hashtags start with a pound character (#), which is followed by any combination of:

- uppercase and lowercase letters
- numerals
- underscores
- currency symbols (such as $)

HashTags returns a one-column table that contains the hashtags in the string. If the string contains no hashtags, the function returns a one-column table that's empty.

Syntax

HashTags(*String*)

- *String* - Required. String to scan for hashtags.

Examples

Step by step

1. Add a **Text input** control, name it **Tweet**, and type this sentence into it:

   This #app is #AMAZING and can #coUnt123 or #123abc but not #1-23 or #$* (#@")

2. Add a vertical custom gallery, and set its **Items** property to this function:

   HashTags(Tweet.Text)

3. Add a **Label** control to the gallery template.

The gallery shows these hashtags:

- #app
- #AMAZING
- #coUnt123
- #123abc
- #1

Day, Month, Year, Hour, Minute, Second, and Weekday functions

Article • 06/10/2024

Applies to: Canvas apps Dataverse formula columns Desktop flows Model-driven apps Power Pages Power Platform CLI

Returns individual components of a Date/Time value.

Description

The **Day** function returns the day component of a Date/Time value, ranging from 1 to 31.

The **Month** function returns the month component of a Date/Time value, ranging from 1 to 12.

The **Year** function returns the year component of a Date/Time value, starting with 1900.

The **Hour** function returns the hour component of a Date/Time value, ranging from 0 (12:00 AM) to 23 (11:00 PM).

The **Minute** function returns the minute component of a Date/Time value, ranging from 0 to 59.

The **Second** function returns the second component of a Date/Time value, ranging from 0 to 59.

The **Weekday** function returns the weekday of a Date/Time value. By default, the result ranges from 1 (Sunday) to 7 (Saturday). You can specify a different range with a Microsoft Excel Weekday function code or a StartOfWeek enumeration value:

Expand table

Excel code	StartOfWeek enumeration	Description
1, 17	StartOfWeek.Sunday	Numbers 1 (Sunday) through 7 (Saturday). Default.
2, 11	StartOfWeek.Monday	Numbers 1 (Monday) through 7 (Sunday).
3	StartOfWeek.MondayZero	Numbers 0 (Monday) through 6 (Sunday).
12	StartOfWeek.Tuesday	Numbers 1 (Tuesday) through 7 (Monday).

Excel code	StartOfWeek enumeration	Description
13	**StartOfWeek.Wednesday**	Numbers 1 (Wednesday) through 7 (Tuesday).
14	**StartOfWeek.Thursday**	Numbers 1 (Thursday) through 7 (Wednesday).
15	**StartOfWeek.Friday**	Numbers 1 (Friday) through 7 (Thursday).
16	**StartOfWeek.Saturday**	Numbers 1 (Saturday) through 7 (Friday).

All functions return a number.

See working with dates and times for more information.

Syntax

Day(*DateTime*)
Month(*DateTime*)
Year(*DateTime*)
Hour(*DateTime*)
Minute(*DateTime*)
Second(*DateTime*)

- *DateTime* - Required. Date/Time value to operate on.

Weekday(*DateTime* [, *WeekdayFirst*])

- *DateTime* - Required. Date/Time value to operate on.
- *WeekdayFirst* - Optional. Excel code specifying which day starts the week. If not supplied, 1 (Sunday first) is used.

Examples

For the following example, the current time is **3:59:37 PM** on **Thursday, April 9, 2015**.

Expand table

Formula	Description	Result
Year(Now())	Returns the year component of the current time and date.	2015
Month(Now())	Returns the month component of the current time and date.	4

Formula	Description	Result
Day(Now())	Returns the day component of the current time and date.	9
Hour(Now())	Returns the hour component of the current time and date.	15
Minute(Now())	Returns the minute component of the current time and date.	59
Second(Now())	Returns the second component of the current time and date.	37
Weekday(Now())	Returns the weekday component of the current time and date, using the default start of the week as Sunday.	5
Weekday(Now(), 14)	Returns the weekday component of the current time and date, using an Excel code to specify the start of the week as Thursday.	1
Weekday(Now(), StartOfWeek.Wednesday)	Returns the weekday component of the current time and date, using a **StartOfWeek** enumeration to specify the start of the week as Wednesday.	2

Operators and Identifiers in Power Apps

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Some of these operators are dependent on the language of the author. For more information about language support in canvas apps, see Global apps.

Expand table

Symbol	Type	Example	Description
'...'	Identifier	**'Account Name'**	Identifiers that contain special characters, including spaces, are enclosed in single quotes
"..."	Text string	**"Hello, World"**	Text strings are enclosed in double quotes
$"..."	String interpolation	**$"Dear {FirstName},"**	Formulas embedded within a text string
.	Property Selector	**Slider1.Value** **Color.Red** **Acceleration.X**	Extracts a property from a table, control, signal, or enumeration. For backward compatibility, **!** may also be used.
. [language dependent]	Decimal separator	**1.23**	Separator between whole and fractional parts of a number. The character depends on the language.
( )	Parentheses	**Filter(T, A < 10)** **(1 + 2) * 3**	Enforces precedence order, and groups subexpressions in a larger expression
+	Arithmetic operators	**1 + 2**	Addition
-		**2 - 1**	Subtraction and sign
*		**2 * 3**	Multiplication
/		**2 / 3**	Division (also see the **Mod** function)
^		**2 ^ 3**	Exponentiation, equivalent to the **Power** function

Symbol	Type	Example	Description
%		**20%**	Percentage (equivalent to "* 1/100")
=	Comparison operators	**Price = 100**	Equal to
>		**Price > 100**	Greater than
>=		**Price >= 100**	Greater than or equal to
<		**Price < 100**	Less than
<=		**Price <= 100**	Less than or equal to
<>		**Price <> 100**	Not equal to
&	String concatenation operator	**"hello" & " " & "world"**	Makes multiple strings appear continuous
&& or **And**	Logical operators	**Price < 100 && Slider1.Value = 20** or **Price < 100 And Slider1.Value = 20**	Logical conjunction, equivalent to the **And** function
|| or **Or**		**Price < 100 || Slider1.Value = 20** or **Price < 100 Or Slider1.Value = 20**	Logical disjunction, equivalent to the **Or** function
! or **Not**		**!(Price < 100)** or **Not (Price < 100)**	Logical negation, equivalent to the **Not** function
exactin	Membership operators	**Gallery1.Selected exactin SavedItems**	Belonging to a collection or a table
exactin		**"Windows" exactin "To display windows in the Windows operating system..."**	Substring test (case-sensitive)
in		**Gallery1.Selected in SavedItems**	Belonging to a collection or a table
in		**"The" in "The keyboard and the monitor..."**	Substring test (case-insensitive)
@	Disambiguation operator	**MyTable[@fieldname]**	Field disambiguation
@		**[@MyVariable]**	Global disambiguation

Symbol	Type	Example	Description
, [language dependent]	List separator	**If(X < 10, "Low", "Good")** **{ X: 12, Y: 32 }** **[1, 2, 3]**	Separates: • arguments in function calls • fields in a record • records in a table This character depends on the language.
; [language dependent]	Formula chaining	**Collect(T, A); Navigate(S1, "")**	Separate invocations of functions in behavior properties. The chaining operator depends on the language.
As	As operator	**AllCustomers As Customer**	Overrides **ThisItem** and **ThisRecord** in galleries and record scope functions. **As** is useful for providing a better, specific name and is especially important in nested scenarios.
Self	Self operator	**Self.Fill**	Access to properties of the current control
Parent	Parent operator	**Parent.Fill**	Access to properties of a control container
ThisItem	ThisItem operator	**ThisItem.FirstName**	Access to fields of a Gallery or form control
ThisRecord	ThisRecord operator	**ThisRecord.FirstName**	Access to the complete record and individual fields of the record within **ForAll**, **Sum**, **With**, and other record scope functions. Can be overridden with the **As** operator.

> ⓘ Note
>
> The @ operator can also be used to validate the type of the record object against a data source. For example, `Collect(coll,Account@{'Account Number: 1111')`

in and exactin operators

Use the **in** and **exactin** operators to find a string in a data source, such as a collection or an imported table. The **in** operator identifies matches regardless of case, and the **exactin** operator identifies matches only if they're capitalized the same way. Here's an example:

1. Create or import a collection named **Inventory**, and show it in a gallery, as the first procedure in Show images and text in a gallery describes.

2. Set the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" in ProductName)

   The gallery shows all products except Callisto because the name of that product is the only one that doesn't contain the letter you specified.

3. Change the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" exactin ProductName)

   The gallery shows only Europa because only its name contains the letter that you specified in the case that you specified.

ThisItem, ThisRecord, and As operators

A few controls and functions apply formulas to individual records of a table. To refer to the individual record in a formula, use one of the following:

Expand table

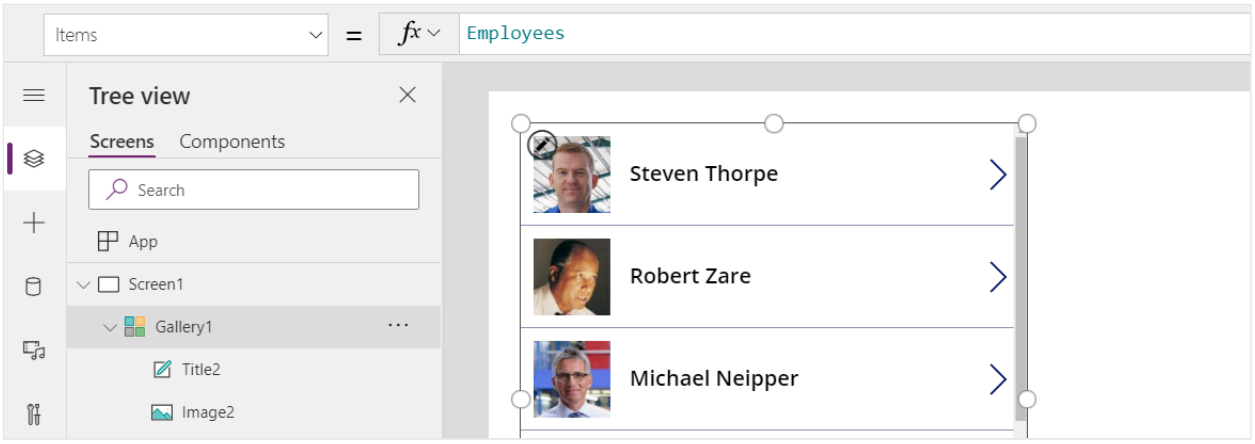
Operator	Applies to	Description
ThisItem	**Gallery** control **Edit form** control **Display form** control	The default name for the current record in a **Gallery** or form control.
ThisRecord	**ForAll**, **Filter**, **With**, **Sum** and other record scope functions	The default name for the current record in **ForAll** and other record scope functions.
As *name*	**Gallery** control **ForAll**, **Filter**, **With**, **Sum** and other record scope functions	Defines a *name* for the current record, replacing default **ThisItem** or **ThisRecord**. Use **As** to make formulas easier to understand and resolve ambiguity when nesting.

ThisItem operator

For example, in the following **Gallery** control, the **Items** property is set to the **Employees** data source (such as the **Employees** table included with the Northwind Traders sample):

Power Apps

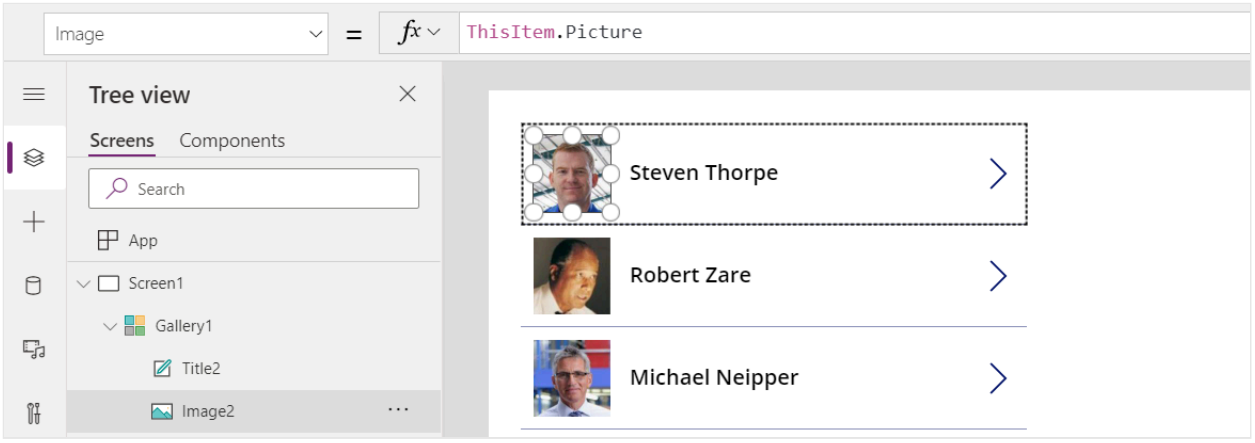
```
Employees
```



The first item in the gallery is a template that is replicated for each employee. In the template, the formula for the picture uses **ThisItem** to refer to the current item:

Power Apps

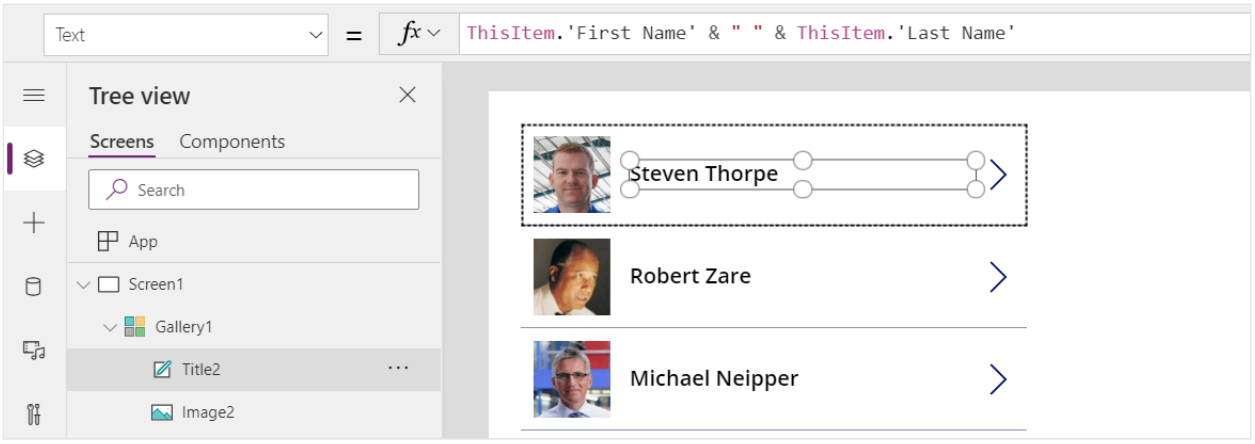
```
ThisItem.Picture
```



Likewise, the formula for the name also uses **ThisItem**:

Power Apps

```
ThisItem.'First Name' & " " & ThisItem.'Last Name'
```

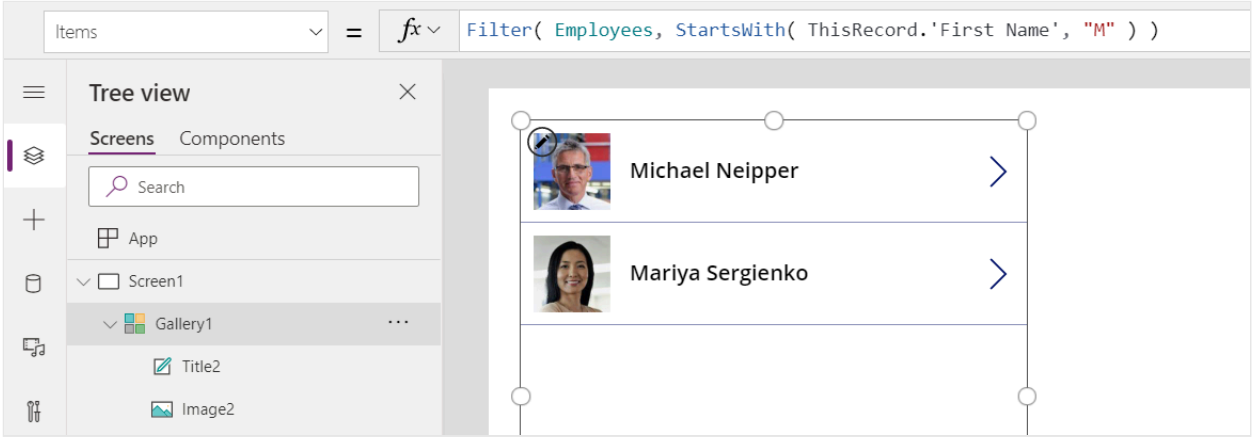


ThisRecord operator

ThisRecord is used in functions that have a record scope. For example, we can use the **Filter** function with our gallery's **Items** property to only show first names that being with *M*:

Power Apps

```
Filter( Employees, StartsWith( ThisRecord.Employee.'First Name', "M" ) )
```



ThisRecord is optional and implied by using the fields directly, for example, in this case, we could have written:

Power Apps

```
Filter( Employees, StartsWith( 'First Name', "M" ) )
```

Although optional, using **ThisRecord** can make formulas easier to understand and may be required in ambiguous situations where a field name may also be a relationship name. **ThisRecord** is optional while **ThisItem** is always required.

Use **ThisRecord** to reference the whole record with **Patch**, **Collect**, and other record scope functions. For example, the following formula sets the status for all inactive employees to active:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees,
              Patch( Employees, ThisRecord, { Status: 'Status
(Employees)'.Active } ) ) )
```

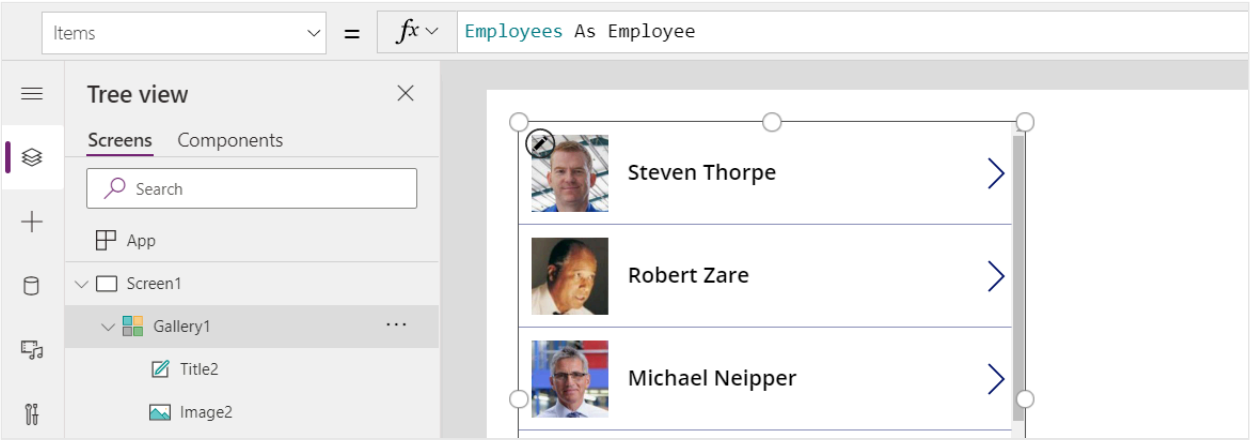
As operator

Use the **As** operator to name a record in a gallery or record scope function, overriding the default **ThisItem** or **ThisRecord**. Naming the record can make your formulas easier to understand and may be required in nested situations to access records in other scopes.

For example, you can modify the **Items** property of our gallery to use **As** to identify that we are working with an Employee:

Power Apps

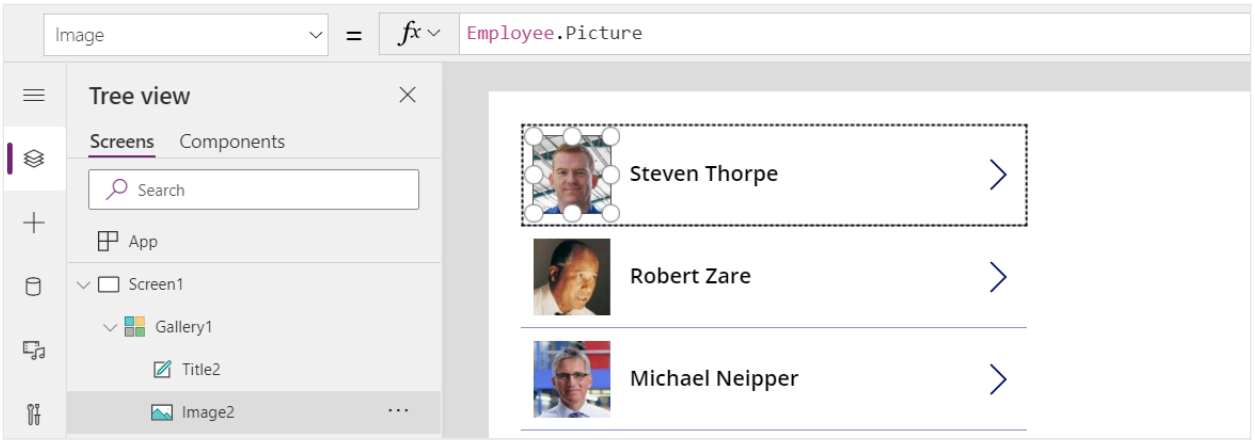
```
Employees As Employee
```



The formulas for the picture and name are adjusted to use this name for the current record:

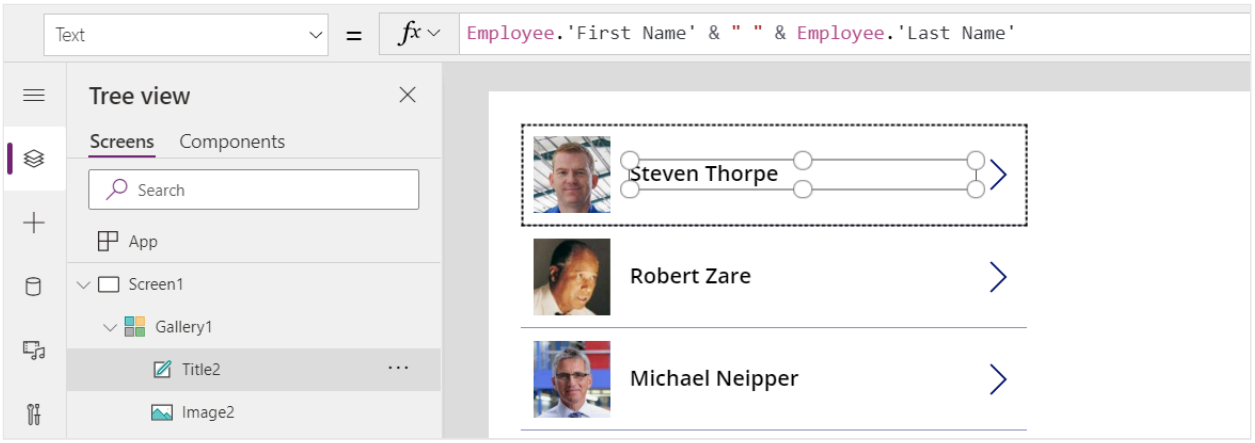
Power Apps

```
Employee.Picture
```



Power Apps

```
Employee.'First Name' & " " & Employee.'Last Name'
```



As can also be used with record scope functions to replace the default name **ThisRecord**. We can apply this to our previous example to clarify the record we're working with:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees As Employee,
              Patch( Employees, Employee, { Status: 'Status
(Employees)'.Active } ) ) )
```

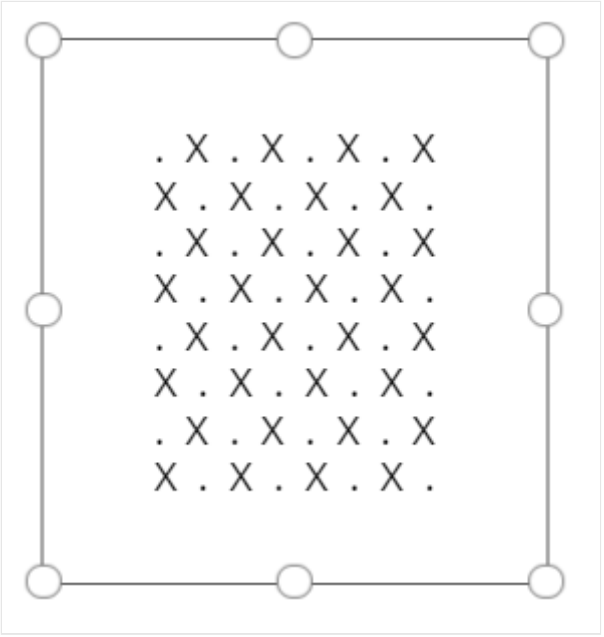
When nesting galleries and record scope functions, **ThisItem** and **ThisRecord** always refers to the inner most scope, leaving records in outer scopes unavailable. Use **As** to make all record scopes available by giving each a unique name.

For example, this formula produces a chessboard pattern as a text string by nesting two **ForAll** functions:

Power Apps

```
Concat(
    ForAll( Sequence(8) As Rank,
        Concat(
            ForAll( Sequence(8) As File,
                    If( Mod(Rank.Value + File.Value, 2) = 1, " X ", " . " )
            ),
            Value
        ) & Char(10)
    ),
    Value
)
```

Setting a **Label** control's **Text** property to this formula displays:



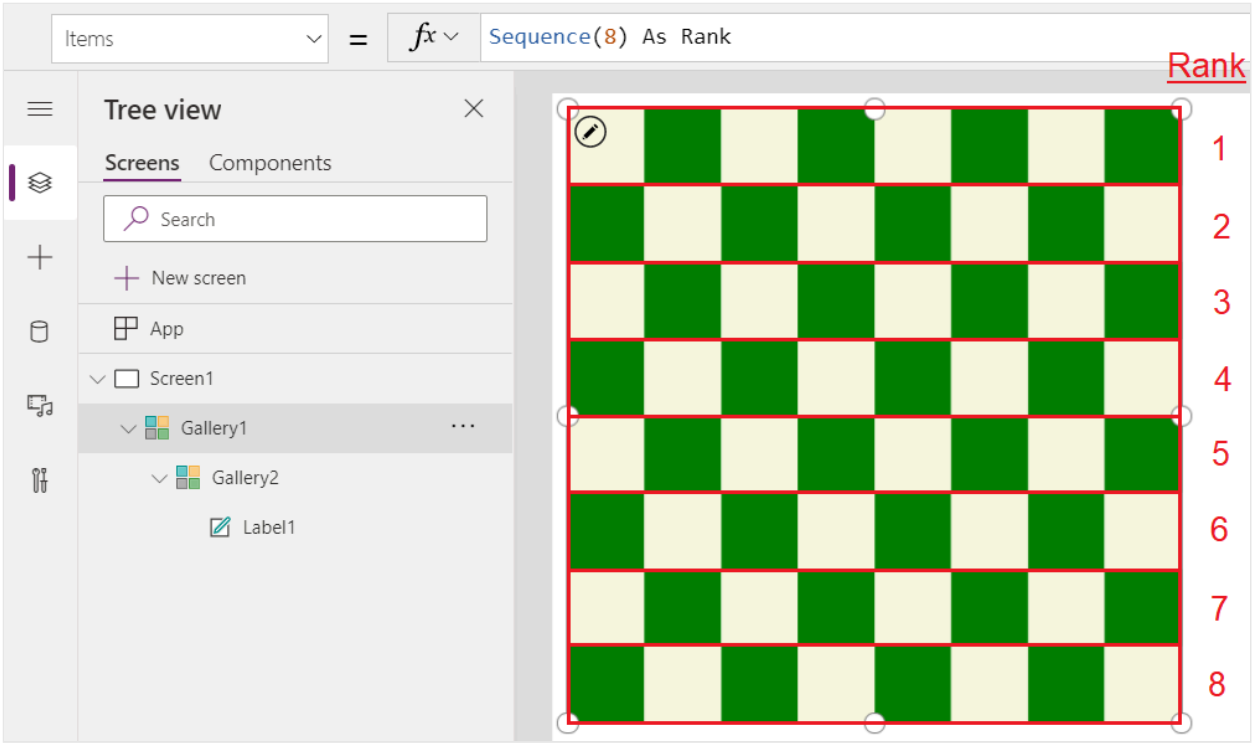
Let's unpack what is happening here:

- We start by iterating an unnamed table of 8 numbered records from the Sequence function. This loop is for each row of the board, which is commonly referred to as **Rank** and so we give it this name.
- For each row, we iterate another unnamed table of 8 columns, and we give the common name **File**.
- If **Rank.Value** + **File.Value** is an odd number, the square gets an **X**, otherwise a dot. This part of the formula is referencing both **ForAll** loops, made possible by using the **As** operator.
- Concat is used twice, first to assemble the columns and then the rows, with a Char(10) thrown in to create a new line.

A similar example is possible with nested **Gallery** controls instead of **ForAll** functions. Let's start with the vertical gallery for the **Rank**. This gallery control will have an **Items** formula of:

Power Apps

```
Sequence(8) as Rank
```



Within this gallery, we'll place a horizontal gallery for the **File**, that will be replicated for each **Rank**, with an **Items** property of:

Power Apps

```
Sequence(8) as File
```

And finally, within this gallery, we'll add a **Label** control that will be replicated for each **File** and each **Rank**. We'll size it to fill the entire space and use the **Fill** property to provide the color with this formula:

Power Apps

```
If( Mod( Rank.Value + File.Value, 2 ) = 1, Green, Beige )
```

Self and Parent operators

There are three ways to refer to a control and its properties within a formula:

Expand table

Method	Description
By control name	Any control can be referenced by name from anywhere within the app. For example, **Label1.Fill** refers to the fill property of the control who's name is **Label1**.
Self operator	It's often convenient to reference another property of the same control when writing a formula. Instead of using an absolute reference by name, it's easier and more portable to use a relative reference to one*self*. The **Self** operator provides that easy access to the current control. For example, **Self.Fill** refers to the fill color of the current control.

Method	Description
Parent operator	Some controls host other controls, such as the **Screen** and **Gallery** controls. The hosting control of the controls within it's called the *parent*. Like the **Self** operator, the **Parent** operator provides an easy relative reference to the container control. For example, **Parent.Fill** refers to the fill property of the control that is the container for the current control.

Self and **Parent** are operators and not properties on the controls themselves. Referring to **Parent.Parent**, **Self.Parent** or **Parent.Self** is not supported.

Identifier names

The names of variables, data sources, columns, and other objects can contain any Unicode.

Use single quotes around a name that contains a space or other special character. Use two single quotes together to represent one single quote in the name. Names that don't contain special characters don't require single quotes.

Here are some example column names you might encounter in a table, and how they're represented in a formula:

Expand table

Column name in a database	Column reference in a formula
SimpleName	`SimpleName`
NameWith123Numbers	`NameWith123Numbers`
Name with spaces	`'Name with spaces'`
Name with "double" quotes	`'Name with "double" quotes'`
Name with 'single' quotes	`'Name with ''single'' quotes'`
Name with an @ at sign	`'Name with an @ at sign'`

Double quotes are used to designate text strings.

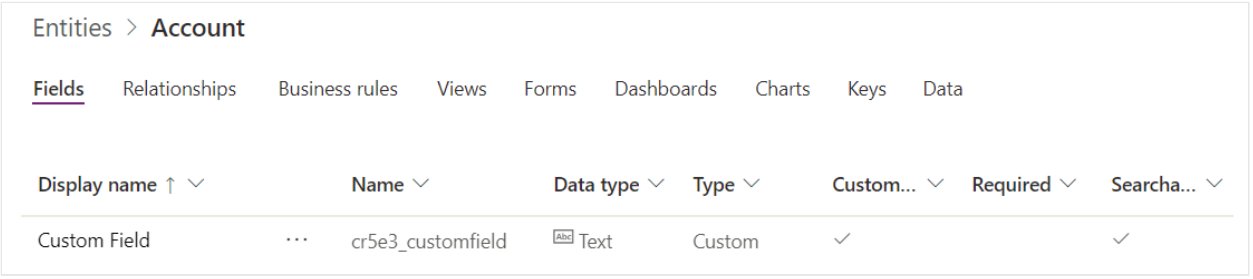
Display names and logical names

Some data sources such as SharePoint and Microsoft Dataverse have two different names to refer to the same table or column of data:

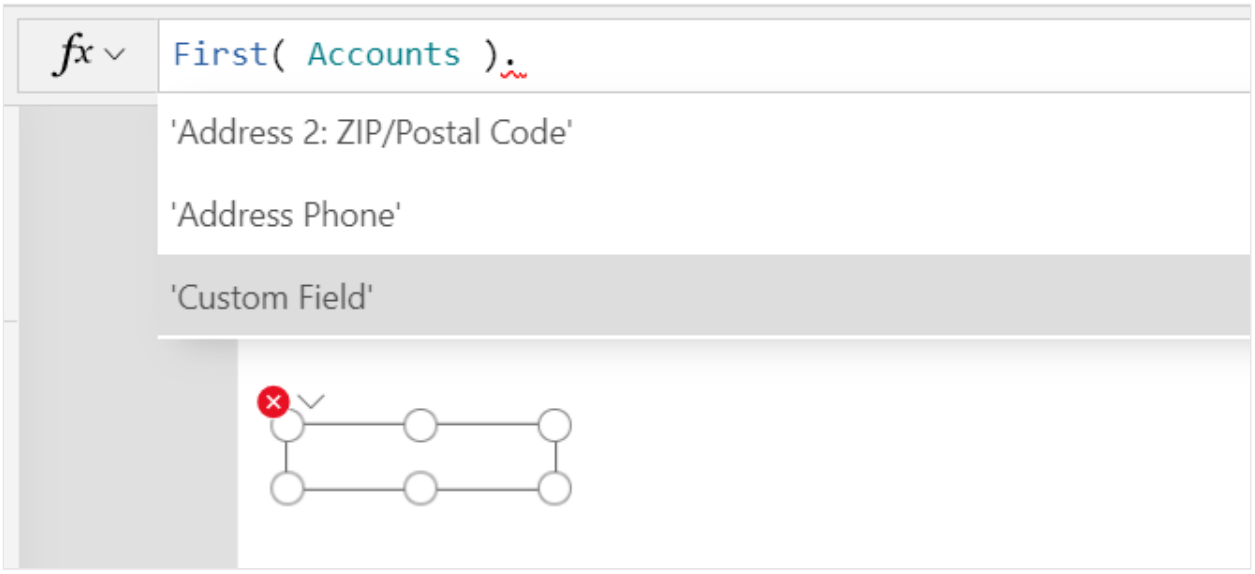
- **Logical name** - A name that is guaranteed to be unique, doesn't change after being created, usually doesn't allow spaces or other special characters, and isn't localized into different languages. As a result, the name can be cryptic. These names are used by professional developers. For example, **cra3a_customfield**. This name may also be referred to as **schema name** or just **name**.
- **Display name** - A name that is user-friendly and intended to be seen by end users. This name may not be unique, may change over time, may contain spaces and any Unicode character, and may be localized into different languages. Corresponding to the example above, the display name may be **Custom Field** with space in between the words.

Since display names are easier to understand, Canvas apps will suggest them as choices and not suggest logical names. Although logical names aren't suggested, they can still be used if typed indirectly.

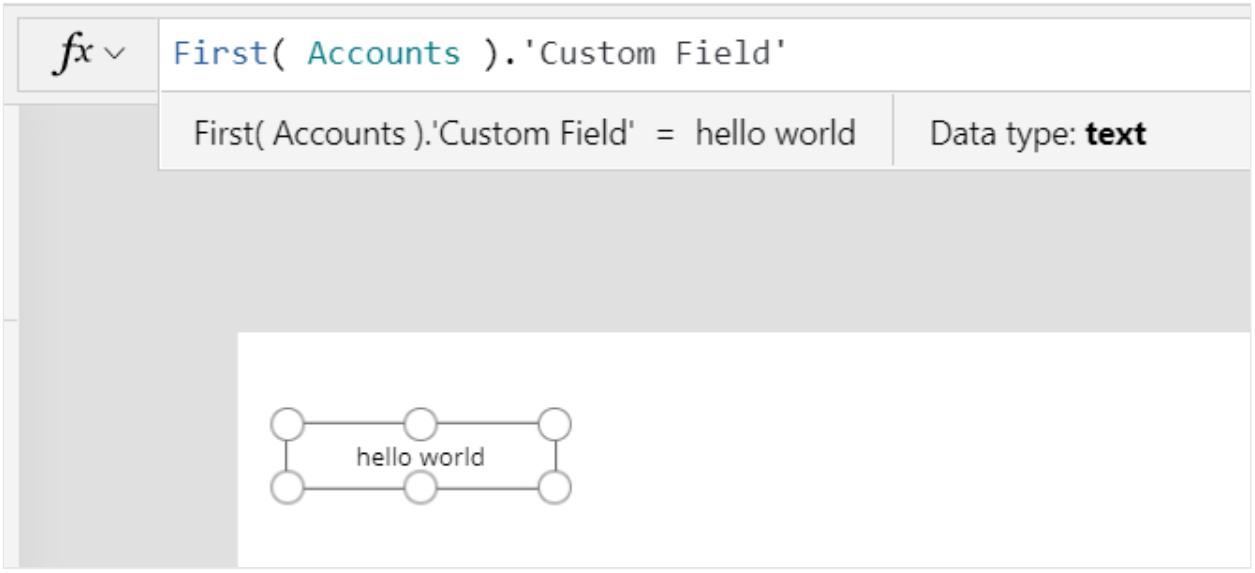
For example, imagine you've added a **Custom Field** to a table in Dataverse. A logical name will be assigned for you by the system, which you can modify only when creating the field. The result would look similar to:



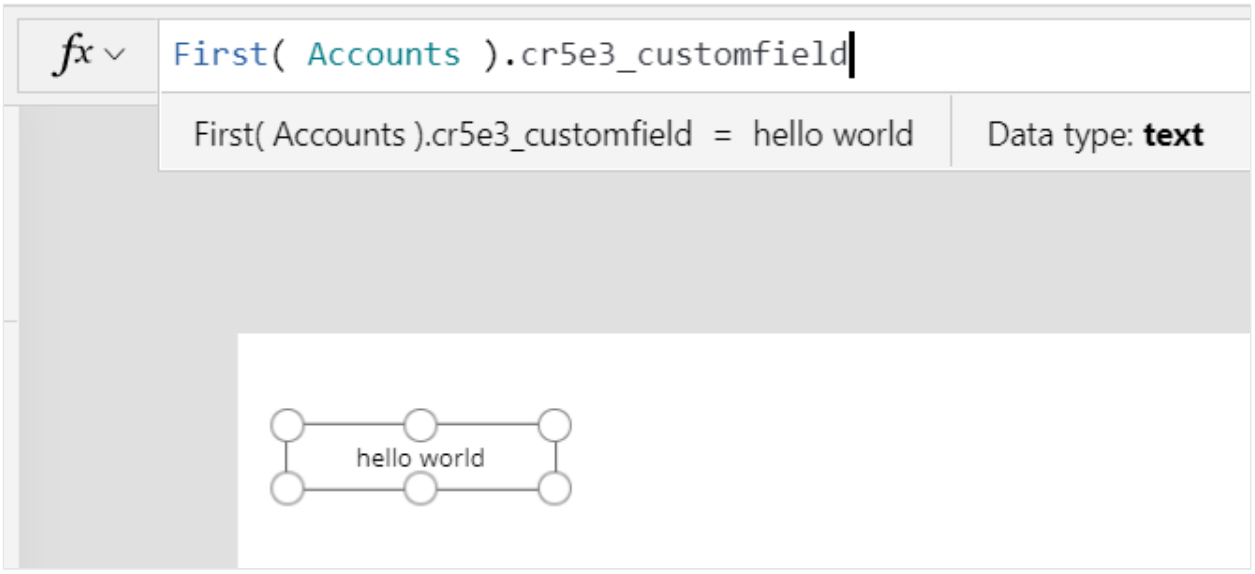
When authoring a reference to a field of Accounts, the suggestion will be made to use '**Custom Field**' since this is the display name. Single quotes must be used because this name has a space in it:



After selecting the suggestion, 'Custom Field' is shown in the formula bar and the data is retrieved:



Although it isn't suggested, we could also use the logical name for this field. This will result in the same data being retrieved. Single quotes are not required since this name doesn't contain spaces or special characters:

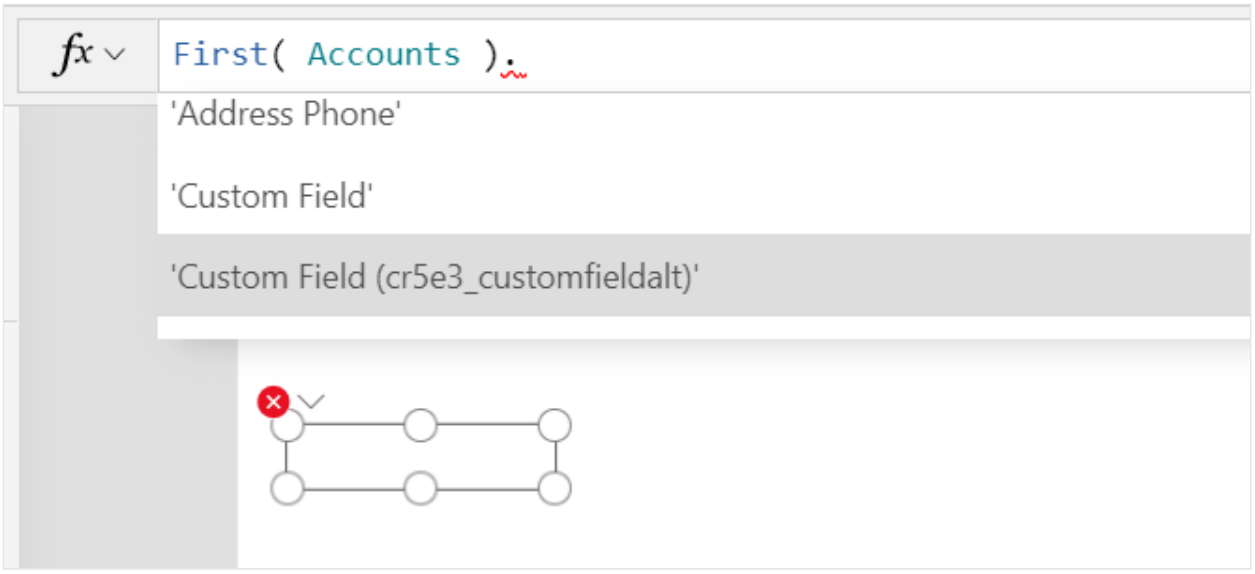


Behind the scenes, a mapping is maintained between the display names seen in formulas and the underlying logical names. Since logical names must be used to interact with the data source, this mapping is used to convert from the current display name to the logical name automatically and that is what is seen in the network traffic. This mapping is also used to convert back to logical names to switch into new display names, for example, if a display name changes or a maker in a different language edits the app.

> **Note**
>
> Logical names are not translated when moving an app between environments. For Dataverse system table and field names, this should not be a problem as logical names are consistent across environments. But any custom fields, such as **cra3a_customfield** in this example above, may have a different environment prefix (**cra3a** in this case). Display names are preferred as they can be matched against display names in the new environment.

Name disambiguation

Since display names aren't unique, the same display name may appear more than once in the same table. When this happens, the logical name will be added to the end of the display name in parentheses for one of more of the conflicting names. Building on the example above, if there was a second field with the same display name of **Custom Field** with a logical name of **cra3a_customfieldalt** then the suggestions would show:



Name disambiguation strings are added in other situations where name conflicts occur, such as the names of table, choices, and other Dataverse items.

Disambiguation operator

Some functions create record scopes for accessing the fields of table while processing each record, such as **Filter**, **AddColumns**, and **Sum**. Field names added with the record scope override the same names from elsewhere in the app. When this happens, you can still access values from outside the record scope with the @ disambiguation operator:

- To access values from nested record scopes, use the @ operator with the name of the table being operated upon using this pattern:
  Table[@*FieldName*]
- To access global values, such as data sources, collections, and context variables, use the pattern [@*ObjectName*] (without a table designation).

For more information and examples, see record scopes.

If and Switch functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Dataverse formula columns ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Determines whether any condition in a set is true (**If**) or the result of a formula matches any value in a set (**Switch**) and then returns a result or executes an action.

Description

The **If** function tests one or more conditions until a **true** result is found. If such a result is found, a corresponding value is returned. If no such result is found, a default value is returned. In either case, the returned value might be a string to show, a formula to evaluate, or another form of result.

The **Switch** function evaluates a formula and determines whether the result matches any value in a sequence that you specify. If a match is found, a corresponding value is returned. If no match is found, a default value is returned. In either case, the returned value might be a string to show, a formula to evaluate, or another form of result.

If and **Switch** are very similar, but you should use the best function for your situation:

- Use **If** to evaluate a single condition. The most common syntax for this function is **If**(*Condition*, *ThenResult*, *DefaultResult*), which provides the common "if ... then ... else ..." pattern seen in other programming tools.
- Use **If** to evaluate multiple unrelated conditions. In Power Apps (unlike Microsoft Excel), you can specify multiple conditions without having to nest **If** formulas.
- Use **Switch** to evaluate a single condition against multiple possible matches. You can also use **If** in this case, but you'd need to repeat the formula for each possible match.

You can use both of these functions in behavior formulas to branch between two or more actions. Only one branch will trigger an action. Conditions and matches are evaluated in order, and they stop if a condition is **true** or a match is found.

Blank is returned if no conditions are **true**, no matches are found, and you don't specify a default result.

Syntax

If(*Condition*, *ThenResult* [, *DefaultResult*])
If(*Condition1*, *ThenResult1* [, *Condition2*, *ThenResult2*, ... [, *DefaultResult*]])

- *Condition(s)* - Required. Formula(s) to test for **true**. Such formulas commonly contain comparison operators (such as <, >, and =) and test functions such as **IsBlank** and **IsEmpty**.
- *ThenResult(s)* - Required. The corresponding value to return for a condition that evaluates to **true**.
- *DefaultResult* - Optional. The value to return if no condition evaluates to **true**. If you don't specify this argument, *blank* is returned.

Switch(*Formula*, *Match1*, *Result1* [, *Match2*, *Result2*, ... [, *DefaultResult*]])

- *Formula* - Required. Formula to evaluate for matches. This formula is evaluated only once.
- *Match(s)* - Required. Values to compare with the result from *Formula*. If an exact match is found, the corresponding *Result* is returned.
- *Result(s)* - Required. The corresponding value to return when an exact match is found.
- *DefaultResult* - Optional. If an exact match isn't found, this value is returned. If you don't specify this argument, *blank* is returned.

Examples

Values in formulas

In the following examples, a **Slider** control (named **Slider1**) has a value of **25**.

Expand table

Formula	Description	Result
If(Slider1.Value = 25, "Result1")	The condition is **true**, and the corresponding result is returned.	"Result1"
If(Slider1.Value = 25, "Result1", "Result2")	The condition is **true**, and the corresponding result is returned.	"Result1"
If(Slider1.Value > 1000, "Result1")	The condition is **false**, and no *DefaultResult* was provided.	*blank*
If(Slider1.Value > 1000, "Result1", "Result2")	The condition is **false**, a *DefaultResult* was provided, and it's returned.	"Result2"

Formula	Description	Result
If(Slider1.Value = 25, "Result1", Slider1.Value > 0, "Result2")	The first condition is **true**, and the corresponding result is returned. The second condition is also **true**, but it isn't evaluated because it appears later in the argument list than a condition that evaluates to **true**.	"Result1"
If(IsBlank(Slider1.Value), "Result1", IsNumeric(Slider1.Value), "Result2")	The first condition is **false** because the slider isn't *blank*. The second condition is **true** because the slider's value is a number, and the corresponding result is returned.	"Result2"
If(Slider1.Value > 1000, "Result1", Slider1.Value > 50, "Result2", "Result3")	Both the first and second conditions are **false**, a *DefaultResult* was provided, and it's returned.	"Result3"
Switch(Slider1.Value, 25, "Result1")	The slider's value matches the first value to be checked, and the corresponding result is returned.	"Result1"
Switch(Slider1.Value, 20, "Result1", 25, "Result2", 30, "Result3")	The slider's value matches the second value to be checked, and the corresponding result is returned.	"Result2"
Switch(Slider1.Value, 20, "Result1", 10, "Result2", 0, "Result3", "DefaultResult")	The slider's value doesn't match any value to be checked. A *DefaultResult* was provided, so it's returned.	"DefaultResult"

Branching in behavior formulas

In these examples, a Text input control named **FirstName** has the value "John" typed into it.

Expand table

Formula	Description	Result
If(! IsBlank(FirstName.Text), Navigate(Screen1, ScreenTransition.None))	The condition is **true**, so the Navigate function runs. You can use the IsBlank function to test whether a required form field has been filled in. If **FirstName** were blank, this formula would have no effect.	**true** The display is changed to **Screen1**.
If(IsBlank(FirstName.Text), Navigate(Screen1,	Without the **!** operator, the condition is **false**, so the Navigate	**true**

Formula	Description	Result
ScreenTransition.None), Back())	function doesn't run. The **Back** function was provided as a *DefaultResult*, so it runs.	The display goes back to the screen that was previously shown.
Switch(FirstName.Text, "Carlos", Navigate(Screen1, ScreenTransition.None), "Kirstin", Navigate(Screen2, ScreenTransition.None), "John", Navigate(Screen3, ScreenTransition.None))	The value of **FirstName.Text** is compared against "Carlos", "Kirstin", and "John" in that order. A match is found with "John", so the app navigates to **Screen3**.	**true** The display is changed to **Screen3**.

Step by step

1. Add a **Text input** control, and name it **Text1** if it doesn't have that name by default.
2. In **Text1**, type **30**.
3. Add a **Label** control, and set its **Text** property to this formula:
   If(Value(Text1.Text) < 20, "Order MANY more!", Value(Text1.Text) < 40, "Order more!", Text1.Text)

   The **Label** control shows **Order more!** because the value of **Text1** is more than 20 but less than 40.
4. In **Text1**, type **15**.

   The **Label** control shows **Order MANY more!** because the value of **Text1** is less than 20.
5. In **Text1**, type **50**.

   The **Label** control shows the value that you typed because it's more than 40.

Error, IfError, IsError, IsBlankOrError functions

Article • 10/16/2024

Applies to: ✅ Canvas apps ✅ Dataverse formula columns ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Detects errors and provides an alternative value or takes action. Create a custom error or pass through an error.

> **Note**
>
> If an app has disabled the *Formula-level error management* feature under **Settings** > **Updates** > **Retired**, those functions will not work correctly.

IfError

The **IfError** function tests values until it finds an error. If the function discovers an error, the function evaluates and returns a corresponding replacement value and stops further evaluation. A default value can also be supplied for when no errors are found. The structure of **IfError** resembles that of the **If** function: **IfError** tests for errors, while **If** tests for **true**.

Use **IfError** to replace an error with a valid value so that downstream calculations can continue. For example, use this function if user input might result in a division by zero:

Power Apps

```
IfError( 1/x, 0 )
```

This formula returns `0` if the value of `x` is zero, as `1/x` produces an error. If `x` isn't zero, then `1/x` is returned.

Stopping further processing

When chaining formulas together in behavior formulas, such as:

Power Apps

```
Patch( DS1, ... );
Patch( DS2, ... )
```

The second Patch function to `DS2` will be attempted even if the **Patch** to `DS1` fails. The scope of an error is limited to each formula that is chained.

Use **IfError** to do an action and only continue processing if the action was successful. Applying **IfError** to this example:

Power Apps

```
IfError(
    Patch( DS1, ... ), Notify( "problem in the first action" ),
    Patch( DS2, ... ), Notify( "problem in the second action" )
)
```

If the **Patch** of `DS1` has a problem, the first **Notify** is executed. No further processing occurs including the second **Patch** of `DS2`. If the first **Patch** succeeds, the second **Patch** will execute.

If supplied, the optional *DefaultResult* argument is returned if no errors are discovered. Without this argument, the last *Value* argument is returned.

Building on the last example, the return value from **IfError** can be checked to determine if there were any problems:

Power Apps

```
IfError(
    Patch( DS1, ... ), Notify( "problem in the first action" );  false,
    Patch( DS2, ... ), Notify( "problem in the second action" ); false,
    true
)
```

Type compatibility

IfError returns the value of one of its arguments. The types of all values that might be returned by **IfError** must be compatible.

In the last example, **Patch** returns a record that isn't compatible with the Booleans used for the *Replacement* formulas or the *DefaultResult*. Which is fine, since there's no situation in which the return value from these **Patch** calls would be returned by **IfError**.

> ⓘ **Note**
>
> While the behavior in process for a change, the types of all arguments to **IfError** must be compatible currently.

In the simple example described earlier:

```
Power Apps
IfError( 1/x, 0 )
```

The types of `1/x` and `0` were compatible as both were numbers. If they're not, the second argument is coerced to match the type of the first argument.

Excel displays **#DIV/0!** when a division by zero occurs.

Consider **IfError** with the following instead:

```
Power Apps
IfError( 1/x, "#DIV/0!" )
```

The above formula won't work. The text string `"#DIV/0!"` is coerced to the type of the first argument to **IfError**, which is a number. The result of **IfError** is yet another error since the text string can't be coerced. As a fix, convert the first argument to a text string so that **IfError** always returns a text string:

```
Power Apps
IfError( Text( 1/x ), "#DIV/0!" )
```

As seen above, **IfError** can return an error if the *Replacement* or *DefaultResult* is an error.

FirstError / AllErrors

Within in the replacement formulas, information about the errors found is available through the **FirstError** record and **AllErrors** table. **AllErrors** is a table of error information records with **FirstError** being a shortcut to the first record of this table. **FirstError** always returns the same value as **First(AllErrors)**.

Error records include:

Expand table

Field	Type	Description
Kind	ErrorKind enum (number)	Category of the error.
Message	Text string	Message about the error, suitable to be displayed to the end user.
Source	Text string	Location in where the error originated, used for reporting. For example, for a formula bound to a control property, this value is in the form *ControlName.PropertyName*.
Observed	Text string	Location in where the error is surfaced to the user, used for reporting. For example, for a formula bound to a control property, this value is in the form *ControlName.PropertyName*.
Details	Record	Details about the error. Currently, details are provided only for network errors. This record includes **HttpStatusCode** which contains the HTTP status code and **HttpResponse** which contains the body of the response from the connector or service.

For example, consider the following formula as a **Button** control's **OnSelect** property:

Power Apps

```
Set( a, 1/0 )
```

And this formula on the **OnSelect** property of a second **Button** control:

Power Apps

```
IfError( a, Notify( "Internal error: originated on " & FirstError.Source &
", surfaced on " & FirstError.Observed ) )
```

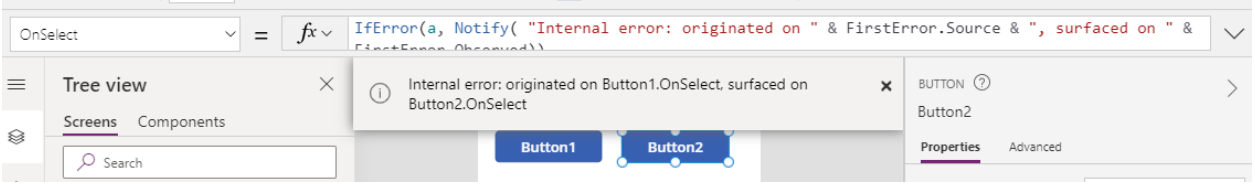
The example formula above would display the following banner when the two buttons are activated in sequence:



Typically, there will be only one error that **FirstError** can sufficiently work with. However, there are scenarios where multiple errors may be returned. For example, when using a formula chaining operator or the **Concurrent** function. Even in these situations,

reporting **FirstError** might be enough to reveal a problem instead overloading a user with multiple errors. If you still have a requirement to work with each error individually, you can use the **AllErrors** table.

IsError

The **IsError** function tests for an error value.

The return value is a Boolean *true* or *false*.

Using **IsError** prevents any further processing of the error.

IsBlankOrError

The **IsBlankOrError** function tests for either a blank value or an error value and is the equivalent of `Or( IsBlank( X ), IsError( X ) )`.

When enabling error handling for existing apps, consider replacing **IsBlank** with **IsBlankOrError** to preserve existing app behavior. Before the addition of error handling, a *blank* value was used to represent both null values from databases and error values. Error handling separates these two interpretations of *blank* which could change the behavior of existing apps that continue to use **IsBlank**.

The return value is a boolean *true* or *false*.

Using **IsBlankOrError** prevents any further processing of the error.

Use the **Error** function to create and report a custom error. For example, you might have logic to determine whether any given value is valid for your context or not—something not checked for a problem automatically. You can create and return your own error, complete with **Kind** and **Message**, using the same record described above for the **IfError** function.

In the context of **IfError**, use the **Error** function to rethrow or pass through an error. For example, your logic in **IfError** may decide that in some cases an error can be safely ignored, but in other cases the error is important to send through. Within **IfError** or **App.OnError**, use **Error(FirstError)** to pass through an error.

The **Error** function can also be passed a table of errors, as would be found in the **AllErrors** table. Use **Error(AllErrors)** to rethrow all the errors and not just the first.

A *blank* record or empty table passed to **Error** results in no error.

Syntax

Error(**ErrorRecord**)
Error(**ErrorTable**)

- *ErrorRecord* – Required. Error information record, including **Kind**, **Message**, and other fields. **Kind** is required. **FirstError** can be passed directly.
- *ErrorTable* – Required. Table of error information records. **AllErrors** can be passed directly.

IfError(*Value1*, *Replacement1* [, *Value2*, *Replacement2*, ... [, *DefaultResult*]])

- *Value(s)* – Required. Formula(s) to test for an error value.
- *Replacement(s)* – Required. The formulas to evaluate and values to return if matching *Value* arguments returned an error.
- *DefaultResult* – Optional. The formulas to evaluate if the formula doesn't find any errors.

IsError(*Value*)
IsBlankOrError(*Value*)

- *Value* – Required. Formula to test.

Examples

Simple IfError

Expand table

Formula	Description	Result
IfError(1, 2)	The first argument isn't an error. The function has no other errors to check and no default return value. The function returns the last *value* argument evaluated.	1
IfError(1/0, 2)	The first argument returns an error value (because of division by zero). The function evaluates the second argument and returns it as the result.	2
IfError(10, 20, 30)	The first argument isn't an error. The function has no other errors to check but does have a default return value. The function returns the *DefaultResult* argument.	30
IfError(10, 11, 20, 21, 300)	The first argument **10** isn't an error, so the function doesn't evaluate that argument's corresponding replacement **11**. The third argument	300

Formula	Description	Result
	20 isn't an error either, so the function doesn't evaluate that argument's corresponding replacement **21**. The fifth argument **300** has no corresponding replacement and is the default result. The function returns that result because the formula contains no errors.	
IfError(1/0, Notify("There was an internal problem"))	The first argument returns an error value (due to division by zero). The function evaluates the second argument and displays a message to the user. The return value of **IfError** is the return value of **Notify**, coerced to the same type as the first argument to **IfError** (a number).	1

Simple IsError

Expand table

Formula	Description	Result
IsError(1)	The argument isn't an error.	*false*
IsError(Blank())	The argument is a blank, but not an error.	*false*
IsError(1/0)	The argument is an error.	*true*
If(IsError(1/0), Notify("There was an internal problem"))	The argument to **IsError** returns an error value (because of division by zero). This function returns *true*, which causes the **If** to display a message to the user with the **Notify** function. The return value of **If** is the return value of **Notify**, coerced to the same type as the first argument to **If** (a boolean).	*true*

Simple IsBlankOrError

Expand table

Formula	Description	Result
IsBlankOrError(1)	The argument isn't an error or a blank.	*false*
IsBlankOrError(Blank())	The argument is a blank.	*true*
IsBlankOrError(1/0)	The argument is an error.	*true*

Simple Error

In this example, dates are validated relative to one another, resulting in an error if there is a problem.

Power Apps

```
If( StartDate > EndDate,
    Error( { Kind: ErrorKind.Validation, Message: "Start Date must be before
End Date" } ) )
```

In this example, some errors are allowed to pass through while others are suppressed and replaced with a value. In the first case, **b** is in an error state because the **Value** function has an invalid argument. Because this is unexpected by the formula writer, it is passed through so the user sees it. In the second case, with the same formula, **b** has the value 0, resulting in a division by zero. In this case, the formula writer may know that this is acceptable for this logic, suppress the error (no banner is shown), and return -1 instead.

Power Apps

```
With( {a: 1, b: Value("a")},
      IfError( a/b, If( FirstError.Kind <> ErrorKind.Div0, Error( FirstError
), -1 ) ) )
// returns an error with Kind = ErrorKind.InvalidArgument

With( {a: 1, b: 0} )
      IfError( a/b, If( FirstError.Kind <> ErrorKind.Div0, Error( FirstError
), -1 ) ) )
// returns -1
```

The **AllErrors** table can be filtered like any other table. Used with the **Error** function, expected errors can be removed and the remaining errors retained and reported. For example, if we knew that division by zero wasn't going to be a problem in a particular context, those errors could be filtered out, leaving all other errors intact with the following formula:

Power Apps

```
Error( Filter( AllErrors, Kind <> ErrorKind.Div0 ) )
```

Step by step

1. Add a Text input control, and name it **TextInput1** if it doesn't have that name by default.

2. Add a Label control, and name it **Label1** if it doesn't have that name by default.

3. Set the formula for **Label1**'s **Text** property to:

Power Apps

```
IfError( Value( TextInput1.Text ), -1 )
```

4. In **TextInput1**, enter **1234**.

   Label1 shows the value **1234** as this is a valid input to the Value function.

5. In **TextInput1**, enter **ToInfinity**.

   Label1 shows the value **-1** as this isn't a valid input to the Value function. Without wrapping the Value function with IfError, the label would show no value as the error value is treated as a *blank*.

Operators and Identifiers in Power Apps

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Some of these operators are dependent on the language of the author. For more information about language support in canvas apps, see Global apps.

Expand table

Symbol	Type	Example	Description
'...'	Identifier	**'Account Name'**	Identifiers that contain special characters, including spaces, are enclosed in single quotes
"..."	Text string	**"Hello, World"**	Text strings are enclosed in double quotes
$"..."	String interpolation	**$"Dear {FirstName},"**	Formulas embedded within a text string
.	Property Selector	**Slider1.Value** **Color.Red** **Acceleration.X**	Extracts a property from a table, control, signal, or enumeration. For backward compatibility, **!** may also be used.
. [language dependent]	Decimal separator	**1.23**	Separator between whole and fractional parts of a number. The character depends on the language.
( )	Parentheses	**Filter(T, A < 10)** **(1 + 2) * 3**	Enforces precedence order, and groups subexpressions in a larger expression
+	Arithmetic operators	**1 + 2**	Addition
-		**2 - 1**	Subtraction and sign
*		**2 * 3**	Multiplication
/		**2 / 3**	Division (also see the **Mod** function)
^		**2 ^ 3**	Exponentiation, equivalent to the **Power** function

Symbol	Type	Example	Description
%		**20%**	Percentage (equivalent to "* 1/100")
=	Comparison operators	**Price = 100**	Equal to
>		**Price > 100**	Greater than
>=		**Price >= 100**	Greater than or equal to
<		**Price < 100**	Less than
<=		**Price <= 100**	Less than or equal to
<>		**Price <> 100**	Not equal to
&	String concatenation operator	**"hello" & " " & "world"**	Makes multiple strings appear continuous
&& or **And**	Logical operators	**Price < 100 && Slider1.Value = 20** or **Price < 100 And Slider1.Value = 20**	Logical conjunction, equivalent to the **And** function
|| or **Or**		**Price < 100 || Slider1.Value = 20** or **Price < 100 Or Slider1.Value = 20**	Logical disjunction, equivalent to the **Or** function
! or **Not**		**!(Price < 100)** or **Not (Price < 100)**	Logical negation, equivalent to the **Not** function
exactin	Membership operators	**Gallery1.Selected exactin SavedItems**	Belonging to a collection or a table
exactin		**"Windows" exactin "To display windows in the Windows operating system..."**	Substring test (case-sensitive)
in		**Gallery1.Selected in SavedItems**	Belonging to a collection or a table
in		**"The" in "The keyboard and the monitor..."**	Substring test (case-insensitive)
@	Disambiguation operator	**MyTable[@fieldname]**	Field disambiguation
@		**[@MyVariable]**	Global disambiguation

Symbol	Type	Example	Description
, [language dependent]	List separator	**If(X < 10, "Low", "Good")** **{ X: 12, Y: 32 }** **[1, 2, 3]**	Separates: • arguments in function calls • fields in a record • records in a table This character depends on the language.
; [language dependent]	Formula chaining	**Collect(T, A); Navigate(S1, "")**	Separate invocations of functions in behavior properties. The chaining operator depends on the language.
As	As operator	**AllCustomers As Customer**	Overrides **ThisItem** and **ThisRecord** in galleries and record scope functions. **As** is useful for providing a better, specific name and is especially important in nested scenarios.
Self	Self operator	**Self.Fill**	Access to properties of the current control
Parent	Parent operator	**Parent.Fill**	Access to properties of a control container
ThisItem	ThisItem operator	**ThisItem.FirstName**	Access to fields of a Gallery or form control
ThisRecord	ThisRecord operator	**ThisRecord.FirstName**	Access to the complete record and individual fields of the record within **ForAll**, **Sum**, **With**, and other record scope functions. Can be overridden with the **As** operator.

> ⓘ Note
>
> The @ operator can also be used to validate the type of the record object against a data source. For example, `Collect(coll,Account@{'Account Number: 1111')`

in and exactin operators

Use the **in** and **exactin** operators to find a string in a data source, such as a collection or an imported table. The **in** operator identifies matches regardless of case, and the **exactin** operator identifies matches only if they're capitalized the same way. Here's an example:

1. Create or import a collection named **Inventory**, and show it in a gallery, as the first procedure in Show images and text in a gallery describes.

2. Set the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" in ProductName)

   The gallery shows all products except Callisto because the name of that product is the only one that doesn't contain the letter you specified.

3. Change the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" exactin ProductName)

   The gallery shows only Europa because only its name contains the letter that you specified in the case that you specified.

ThisItem, ThisRecord, and As operators

A few controls and functions apply formulas to individual records of a table. To refer to the individual record in a formula, use one of the following:

Expand table

Operator	Applies to	Description
ThisItem	**Gallery** control **Edit form** control **Display form** control	The default name for the current record in a **Gallery** or form control.
ThisRecord	**ForAll**, **Filter**, **With**, **Sum** and other record scope functions	The default name for the current record in **ForAll** and other record scope functions.
As *name*	**Gallery** control **ForAll**, **Filter**, **With**, **Sum** and other record scope functions	Defines a *name* for the current record, replacing default **ThisItem** or **ThisRecord**. Use **As** to make formulas easier to understand and resolve ambiguity when nesting.

ThisItem operator

For example, in the following **Gallery** control, the **Items** property is set to the **Employees** data source (such as the **Employees** table included with the Northwind Traders sample):

Power Apps

```
Employees
```

The first item in the gallery is a template that is replicated for each employee. In the template, the formula for the picture uses **ThisItem** to refer to the current item:

Power Apps

```
ThisItem.Picture
```

Likewise, the formula for the name also uses **ThisItem**:

Power Apps

```
ThisItem.'First Name' & " " & ThisItem.'Last Name'
```

ThisRecord operator

ThisRecord is used in functions that have a record scope. For example, we can use the **Filter** function with our gallery's **Items** property to only show first names that being with *M*:

Power Apps

```
Filter( Employees, StartsWith( ThisRecord.Employee.'First Name', "M" ) )
```

ThisRecord is optional and implied by using the fields directly, for example, in this case, we could have written:

Power Apps

```
Filter( Employees, StartsWith( 'First Name', "M" ) )
```

Although optional, using **ThisRecord** can make formulas easier to understand and may be required in ambiguous situations where a field name may also be a relationship name. **ThisRecord** is optional while **ThisItem** is always required.

Use **ThisRecord** to reference the whole record with **Patch**, **Collect**, and other record scope functions. For example, the following formula sets the status for all inactive employees to active:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees,
              Patch( Employees, ThisRecord, { Status: 'Status
(Employees)'.Active } ) ) )
```

As operator

Use the **As** operator to name a record in a gallery or record scope function, overriding the default **ThisItem** or **ThisRecord**. Naming the record can make your formulas easier to understand and may be required in nested situations to access records in other scopes.

For example, you can modify the **Items** property of our gallery to use **As** to identify that we are working with an Employee:

Power Apps

```
Employees As Employee
```

The formulas for the picture and name are adjusted to use this name for the current record:

Power Apps

```
Employee.Picture
```

Power Apps

```
Employee.'First Name' & " " & Employee.'Last Name'
```

As can also be used with record scope functions to replace the default name **ThisRecord**. We can apply this to our previous example to clarify the record we're working with:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees As Employee,
              Patch( Employees, Employee, { Status: 'Status
(Employees)'.Active } ) ) )
```

When nesting galleries and record scope functions, **ThisItem** and **ThisRecord** always refers to the inner most scope, leaving records in outer scopes unavailable. Use **As** to make all record scopes available by giving each a unique name.

For example, this formula produces a chessboard pattern as a text string by nesting two **ForAll** functions:

Power Apps

```
Concat(
    ForAll( Sequence(8) As Rank,
        Concat(
            ForAll( Sequence(8) As File,
                    If( Mod(Rank.Value + File.Value, 2) = 1, " X ", " . " )
            ),
            Value
        ) & Char(10)
    ),
    Value
)
```

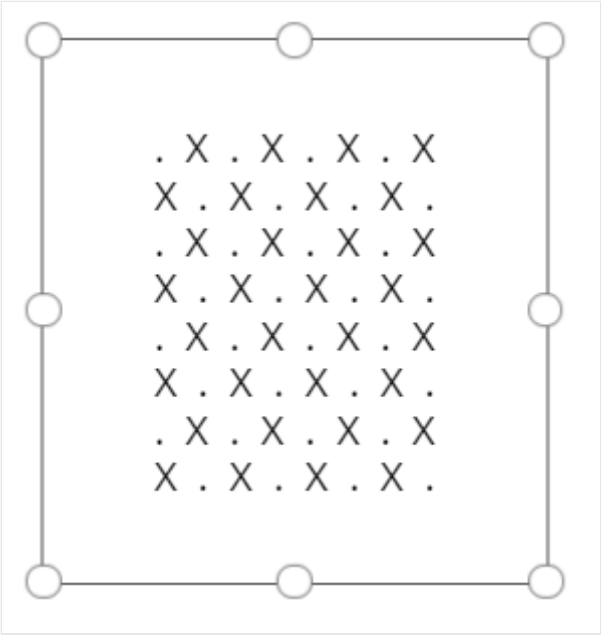
Setting a **Label** control's **Text** property to this formula displays:



Let's unpack what is happening here:

- We start by iterating an unnamed table of 8 numbered records from the Sequence function. This loop is for each row of the board, which is commonly referred to as **Rank** and so we give it this name.
- For each row, we iterate another unnamed table of 8 columns, and we give the common name **File**.
- If **Rank.Value** + **File.Value** is an odd number, the square gets an **X**, otherwise a dot. This part of the formula is referencing both **ForAll** loops, made possible by using the **As** operator.
- Concat is used twice, first to assemble the columns and then the rows, with a Char(10) thrown in to create a new line.

A similar example is possible with nested **Gallery** controls instead of **ForAll** functions. Let's start with the vertical gallery for the **Rank**. This gallery control will have an **Items** formula of:

Power Apps

```
Sequence(8) as Rank
```

Within this gallery, we'll place a horizontal gallery for the **File**, that will be replicated for each **Rank**, with an **Items** property of:

Power Apps

```
Sequence(8) as File
```

And finally, within this gallery, we'll add a **Label** control that will be replicated for each **File** and each **Rank**. We'll size it to fill the entire space and use the **Fill** property to provide the color with this formula:

Power Apps

```
If( Mod( Rank.Value + File.Value, 2 ) = 1, Green, Beige )
```

Self and Parent operators

There are three ways to refer to a control and its properties within a formula:

Expand table

Method	Description
By control name	Any control can be referenced by name from anywhere within the app. For example, **Label1.Fill** refers to the fill property of the control who's name is **Label1**.
Self operator	It's often convenient to reference another property of the same control when writing a formula. Instead of using an absolute reference by name, it's easier and more portable to use a relative reference to one*self*. The **Self** operator provides that easy access to the current control. For example, **Self.Fill** refers to the fill color of the current control.

Method	Description
Parent operator	Some controls host other controls, such as the **Screen** and **Gallery** controls. The hosting control of the controls within it's called the *parent*. Like the **Self** operator, the **Parent** operator provides an easy relative reference to the container control. For example, **Parent.Fill** refers to the fill property of the control that is the container for the current control.

Self and **Parent** are operators and not properties on the controls themselves. Referring to **Parent.Parent**, **Self.Parent** or **Parent.Self** is not supported.

Identifier names

The names of variables, data sources, columns, and other objects can contain any Unicode.

Use single quotes around a name that contains a space or other special character. Use two single quotes together to represent one single quote in the name. Names that don't contain special characters don't require single quotes.

Here are some example column names you might encounter in a table, and how they're represented in a formula:

Expand table

Column name in a database	Column reference in a formula
SimpleName	`SimpleName`
NameWith123Numbers	`NameWith123Numbers`
Name with spaces	`'Name with spaces'`
Name with "double" quotes	`'Name with "double" quotes'`
Name with 'single' quotes	`'Name with ''single'' quotes'`
Name with an @ at sign	`'Name with an @ at sign'`

Double quotes are used to designate text strings.

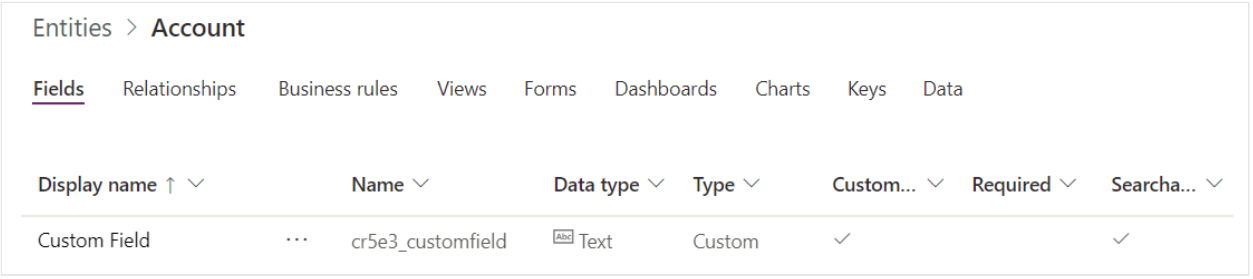
Display names and logical names

Some data sources such as SharePoint and Microsoft Dataverse have two different names to refer to the same table or column of data:

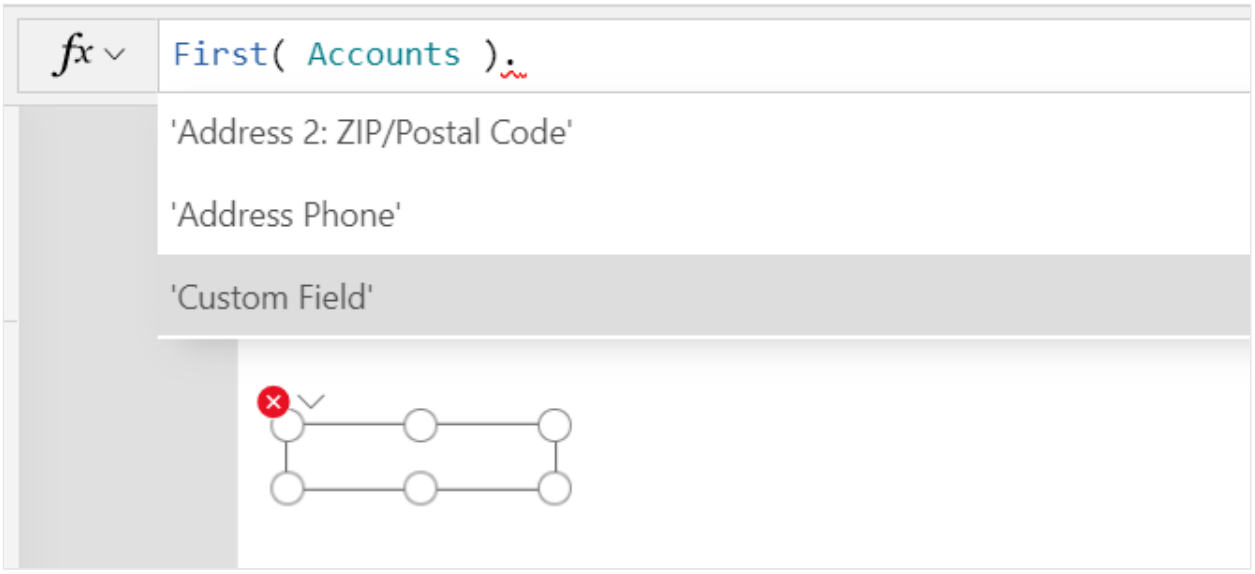
- **Logical name** - A name that is guaranteed to be unique, doesn't change after being created, usually doesn't allow spaces or other special characters, and isn't localized into different languages. As a result, the name can be cryptic. These names are used by professional developers. For example, **cra3a_customfield**. This name may also be referred to as **schema name** or just **name**.
- **Display name** - A name that is user-friendly and intended to be seen by end users. This name may not be unique, may change over time, may contain spaces and any Unicode character, and may be localized into different languages. Corresponding to the example above, the display name may be **Custom Field** with space in between the words.

Since display names are easier to understand, Canvas apps will suggest them as choices and not suggest logical names. Although logical names aren't suggested, they can still be used if typed indirectly.

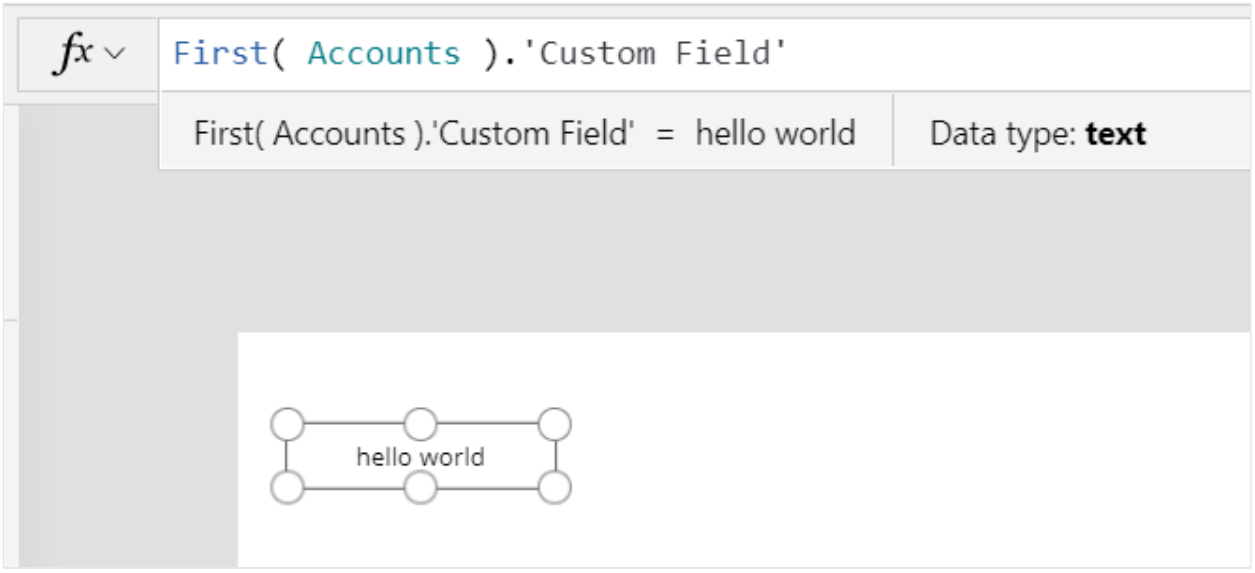
For example, imagine you've added a **Custom Field** to a table in Dataverse. A logical name will be assigned for you by the system, which you can modify only when creating the field. The result would look similar to:



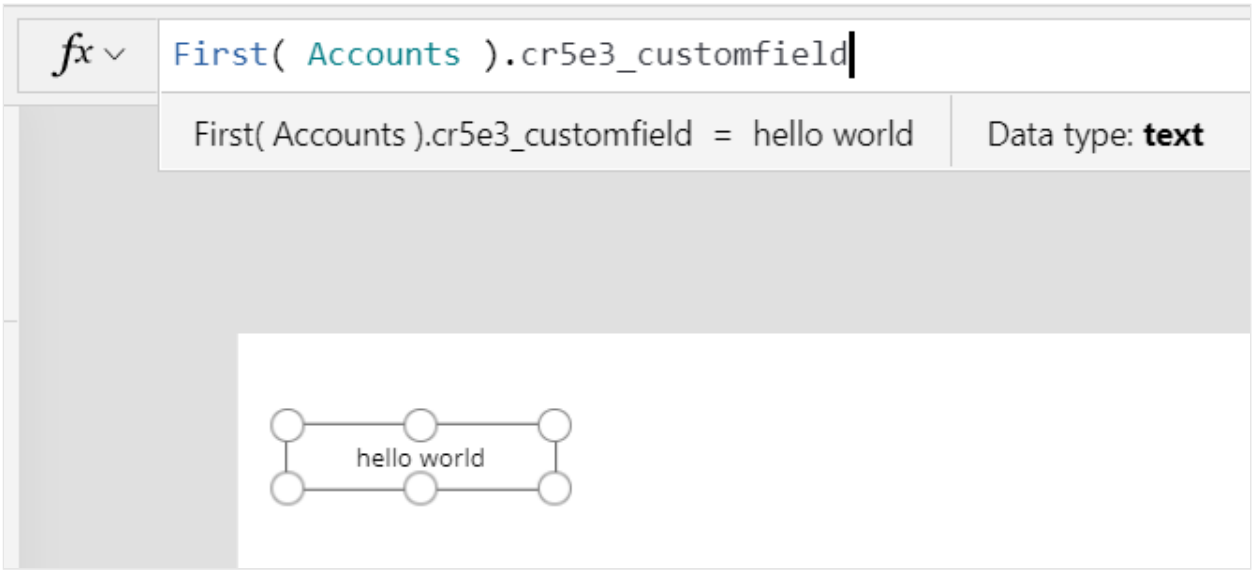
When authoring a reference to a field of Accounts, the suggestion will be made to use '**Custom Field**' since this is the display name. Single quotes must be used because this name has a space in it:



After selecting the suggestion, 'Custom Field' is shown in the formula bar and the data is retrieved:



Although it isn't suggested, we could also use the logical name for this field. This will result in the same data being retrieved. Single quotes are not required since this name doesn't contain spaces or special characters:

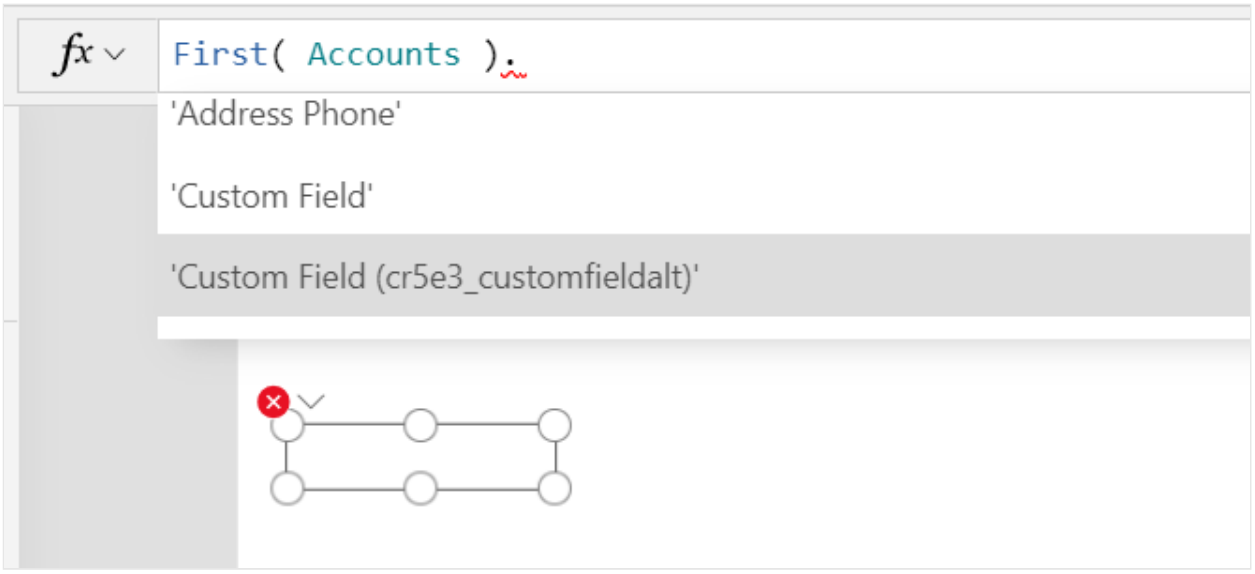


Behind the scenes, a mapping is maintained between the display names seen in formulas and the underlying logical names. Since logical names must be used to interact with the data source, this mapping is used to convert from the current display name to the logical name automatically and that is what is seen in the network traffic. This mapping is also used to convert back to logical names to switch into new display names, for example, if a display name changes or a maker in a different language edits the app.

> **Note**
>
> Logical names are not translated when moving an app between environments. For Dataverse system table and field names, this should not be a problem as logical names are consistent across environments. But any custom fields, such as **cra3a_customfield** in this example above, may have a different environment prefix (**cra3a** in this case). Display names are preferred as they can be matched against display names in the new environment.

Name disambiguation

Since display names aren't unique, the same display name may appear more than once in the same table. When this happens, the logical name will be added to the end of the display name in parentheses for one of more of the conflicting names. Building on the example above, if there was a second field with the same display name of **Custom Field** with a logical name of **cra3a_customfieldalt** then the suggestions would show:



Name disambiguation strings are added in other situations where name conflicts occur, such as the names of table, choices, and other Dataverse items.

Disambiguation operator

Some functions create record scopes for accessing the fields of table while processing each record, such as **Filter**, **AddColumns**, and **Sum**. Field names added with the record scope override the same names from elsewhere in the app. When this happens, you can still access values from outside the record scope with the @ disambiguation operator:

- To access values from nested record scopes, use the @ operator with the name of the table being operated upon using this pattern:
  Table[@*FieldName*]
- To access global values, such as data sources, collections, and context variables, use the pattern [@*ObjectName*] (without a table designation).

For more information and examples, see record scopes.

First, FirstN, Index, Last, and LastN functions

04/20/2025

Applies to: ✅ Canvas apps ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Returns the first, last, or a specific record, or a set of first or last records, from a table.

Description

The **First** function returns the first record of a table.

The **FirstN** function returns the first set of records of a table; the second argument specifies the number of records to return.

The **Last** function returns the last record of a table.

The **LastN** function returns the last set of records of a table; the second argument specifies the number of records to return.

The **Index** function returns a record of a table based on its ordered position in the table. Record numbering begins with 1 so `First( table )` returning the same record as `Index( table, 1 )`. **Index** returns an error if the requested record index is less than 1, greater than the number of records in the table, or the table is empty.

First, **Index**, and **Last** return a single record. **FirstN** and **LastN** return a table, even if you specify only a single record.

Delegation

When used with a data source, these functions can't be delegated. Only the first portion of the data source will be retrieved and then the function applied. The result may not represent the complete story. A warning may appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

For example, when used with a data source containing a large table with 1 million records, **Last** will be subject to the non-delegation limit and will not return the last record of the entire data source. Likewise, using **Index** to request a record in the middle of 1 million records will result in an error because the index is out of range based on the non-delegation limit.

Syntax

First(*Table*)
Last(*Table*)

- *Table* - Required. Table to operate on.

FirstN(*Table* [, *NumberOfRecords*])
LastN(*Table* [, *NumberOfRecords*])

- *Table* - Required. Table to operate on.
- *NumberOfRecords* - Optional. Number of records to return. If you don't specify this argument, the function returns one record.

Index(*Table*, *RecordIndex*)

- *Table* - Required. Table to operate on.
- *RecordIndex* - Required. The index of the record to return. Record numbering begins with 1.

Examples

For the following examples, we'll use the **IceCream** data source, which contains the data in this table:

Flavor	Quantity
"Chocolate"	100
"Vanilla"	200
"Strawberry"	300
"Mint Chocolate"	60
"Pistachio"	200

This table can be placed in a collection with this formula (put in the OnStart formula for a Button control and press the button):

Power Fx

```
Collect( IceCream, Table( { Flavor: "Chocolate", Quantity: 100 },
                          { Flavor: "Vanilla", Quantity: 200 },
                          { Flavor: "Strawberry", Quantity: 300 },
                          { Flavor: "Mint Chocolate", Quantity: 60 },
                          { Flavor: "Pistachio", Quantity: 200 } ) )
```

Expand table

Formula	Description	Result
First(IceCream)	Returns the first record of **IceCream**.	{ Flavor: "Chocolate", Quantity: 100 }
Last(IceCream)	Returns the last record of **IceCream**.	{ Flavor: "Pistachio", Quantity: 200 }
Index(IceCream, 3)	Returns the third record of **IceCream**.	{ Flavor: "Strawberry", Quantity: 300 }
FirstN(IceCream, 2)	Returns a table containing the first two records of **IceCream**.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Chocolate"</td><td>100</td></tr><tr><td>"Vanilla"</td><td>200</td></tr></table>
LastN(IceCream, 2)	Returns a table containing the last two records of **IceCream**.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Mint Chocolate"</td><td>60</td></tr><tr><td>"Pistachio"</td><td>200</td></tr></table>
Index(IceCream, 4).Quantity	Returns the fourth record of the table, and extracts the Quantity column.	60
Index(IceCream, 10)	Returns an error since the record requested is beyond the bounds of the table.	*Error*

Int, Round, RoundDown, RoundUp, and Trunc functions

Article • 04/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Rounds a number.

Round, RoundDown, and RoundUp

The **Round**, **RoundDown**, and **RoundUp** functions round a number to the specified number of decimal places:

- **Round** rounds up if the next digit is 5 or higher. Otherwise, this function rounds down.
- **RoundDown** always rounds down to the previous lower number, towards zero.
- **RoundUp** always rounds up to the next higher number, away from zero.

The number of decimal places can be specified for these functions:

Expand table

Decimal places	Description	Example
Greater than 0	The number is rounded to the right of the decimal separator.	`Round( 12.37, 1 )` returns 12.4.
0	The number is rounded to the nearest integer.	`Round( 12.37, 0 )` returns 12.
Less than 0	The number is rounded to the left of the decimal separator.	`Round( 12.37, -1 )` returns 10.

Int and Trunc

The **Int** and **Trunc** functions round a number to an integer (whole number without a decimal):

- **Int** rounds down to the nearest integer.
- **Trunc** truncates the number to just the integer portion by removing any decimal portion.

The difference between **Int** and **Trunc** is in the handling of negative numbers. For example, for an argument of `-4.3`, **Int** will return the integer further away from zero, `-5`, while **Trunc** will return the integer closer to zero, `-4`. **Int** returns values that are unique amongst the five rounding functions, while **Trunc** returns the same values as **RoundDown**.

Use **Trunc** to extract the decimal portion of a number by subtracting it from the original, for example `X - Trunc(X)`.

Decimal places cannot be specified with **Trunc** as it can with Microsoft Excel. Use **RoundDown** instead when this is needed.

Single-column tables

These functions support single-column tables. If you pass a single number, the return value is the rounded version of that number. If you pass a single-column table that contains numbers, the return value is a single-column table of rounded numbers. The *DecimalPlaces* parameter can be a single value or a single-column table. If the single-column table has less values that the *Number*, zero is used for the remaining values. Use **ShowColumns** and other table shaping functions to extract a single-column table from a larger table.

Syntax

Round(*Number*, *DecimalPlaces*)
RoundDown(*Number*, *DecimalPlaces*)
RoundUp(*Number*, *DecimalPlaces*)

- *Number* - Required. The number to round.
- *DecimalPlaces* - Required. Number of decimal places to round to. Use a positive value to indicate decimal places right of the decimal separator, a negative value to the left, and zero for a whole number.

Int(*Number*)
Trunc(*Number*)

- *Number* - Required. The number to be rounded to an integer.

Examples

Rounding to a whole number.

Expand table

X	Round(X, 0)	RoundUp(X, 0)	RoundDown(X, 0)	Int(X)	Trunc(X)
7.9	8	8	7	7	7
-7.9	-8	-8	-7	-8	-7
7.5	8	8	7	7	7
-7.5	-8	-8	-7	-8	-7
7.1	7	8	7	7	7
-7.1	-7	-8	-7	-8	-7

Rounding to two decimal places to the right of the decimal separator (0.01).

Expand table

X	Round(X, 2)	RoundUp(X, 2)	RoundDown(X, 2)
430.123	430.12	430.13	430.12
430.125	430.13	430.13	430.12
430.128	430.13	430.13	430.12

Rounding to two decimal places to the left of the decimal separator (100).

Expand table

X	Round(X, -2)	RoundUp(X, -2)	RoundDown(X, -2)
430.123	400	500	400

IsBlank	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Tests whether a value is blank or a table contains no records, and provides a way to create *blank* values.

Overview

Blank is a placeholder for "no value" or "unknown value." For example, a **Combo box** control's **Selected** property is *blank* if the user hasn't made a selection. Many data sources can store and return NULL values, which are represented in Power Apps as *blank*.

Any property or calculated value in Power Apps can be *blank*. For example, a Boolean value normally has one of two values: **true** or **false**. But in addition to these two, it can also be *blank* indicating that the state is not known. This is similar to Microsoft Excel, where a worksheet cell starts out as blank with no contents but can hold the values **TRUE** or **FALSE** (among others). At any time, the contents of the cell can again be cleared, returning it to a *blank* state.

Empty string refers to a string that contains no characters. The **Len** function returns zero for such a string and it can be written in a formulas as two double quotes with nothing in between `""`. Some controls and data sources use an empty string to indicate a "no value" condition. To simplify app creation, the **IsBlank** and **Coalesce** functions test for both *blank* values or empty strings.

In the context of the **IsEmpty** function, *empty* is specific to tables that contain no records. The table structure may be intact, complete with column names, but no data is in the table. A table

may start as empty, take on records and no longer be empty, and then have the records removed and again be empty.

Blank

The **Blank** function returns a *blank* value. Use this to store a NULL value in a data source that supports these values, effectively removing any value from the field.

IsBlank

The **IsBlank** function tests for a *blank* value or an empty string. The test includes empty strings to ease app creation since some data sources and controls use an empty string when there is no value present. To test specifically for a *blank* value use `if( Value = Blank(), ...` instead of **IsBlank**. The **IsBlank** function considers empty tables as not blank, and **IsEmpty** should be used to test a table.

When enabling error handling for existing apps, consider replacing **IsBlank** with IsBlankOrError to preserve existing app behavior. Prior to the addition of error handling, a *blank* value was used to represent both null values from databases and error values. Error handling separates these two interpretations of *blank* which could change the behavior of existing apps that continue to use **IsBlank**.

The return value for **IsBlank** is a boolean **true** or **false**.

Coalesce

The **Coalesce** function evaluates its arguments in order and returns the first value that isn't *blank* or an empty string. Use this function to replace a *blank* value or empty string with a different value but leave non-*blank* and non-empty string values unchanged. If all the arguments are *blank* or empty strings then the function returns *blank*, making **Coalesce** a good way to convert empty strings to *blank* values.

`Coalesce( value1, value2 )` is the more concise equivalent of `If( Not IsBlank( value1 ), value1, Not IsBlank( value2 ), value2 )` and doesn't require **value1** and **value2** to be evaluated twice. The **If** function returns *blank* if there is no "else" formula as is the case here.

All arguments to **Coalesce** must be of the same type; for example, you can't mix numbers with text strings. The return value from **Coalesce** is of this common type.

IsEmpty

The **IsEmpty** function tests whether a table contains any records. It's equivalent to using the CountRows function and checking for zero. You can check for data-source errors by combining **IsEmpty** with the Errors function.

The return value for **IsEmpty** is a Boolean **true** or **false**.

Syntax

Blank()

Coalesce(*Value1* [, *Value2*, ...])

- *Value(s)* – Required. Values to test. Each value is evaluated in order until a value that is not *blank* and not an empty string is found. Values after this point are not evaluated.

IsBlank(*Value*)

- *Value* – Required. Value to test for a *blank* value or empty string.

IsEmpty(*Table*)

- *Table* - Required. Table to test for records.

Examples

Blank

1. Create an app from scratch, and add a **Button** control.
2. Set the button's OnSelect property to this formula:

   ```
   Power Fx
   ClearCollect( Cities, { Name: "Seattle", Weather: "Rainy" } )
   ```

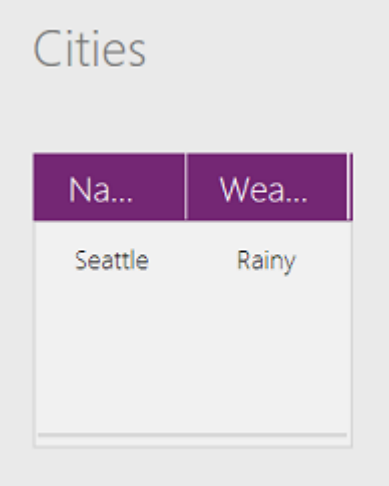
3. Preview your app, click or tap the button that you added, and then close Preview.
4. On the **File** menu, click or tap **Collections**.

   The **Cities** collection appears, showing one record with "Seattle" and "Rainy":



5. Click or tap the back arrow to return to the default workspace.

6. Add a **Label** control, and set its **Text** property to this formula:

```
Power Fx
IsBlank( First( Cities ).Weather )
```

   The label shows **false** because the **Weather** field contains a value ("Rainy").

7. Add a second button, and set its **OnSelect** property to this formula:

```
Power Fx
Patch( Cities, First( Cities ), { Weather: Blank() } )
```

8. Preview your app, click or tap the button that you added, and then close Preview.

   The **Weather** field of the first record in **Cities** is replaced with a *blank*, removing the "Rainy" that was there previously.

   The label shows **true** because the **Weather** field no longer contains a value.

Coalesce

Expand table

Formula	Description	Result
Coalesce(Blank(), 1)	Tests the return value from the **Blank** function, which always returns a *blank* value. Because the first argument is *blank*, evaluation continues with the next argument until a non-*blank* value and non-empty string is found.	**1**
Coalesce("", "2")	Tests the first argument which is an empty string. Because the first argument is an empty string, evaluation continues with the next argument until a non-*blank* value and non-empty string is found.	**2**
Coalesce(Blank(), "", Blank(), "", "3", "4")	**Coalesce** starts at the beginning of the argument list and evaluates each argument in turn until a non-*blank* value and non-empty string is found. In this case, the first four arguments all return *blank* or an empty string, so evaluation continues to the fifth argument. The fifth argument is non-*blank* and non-empty string, so evaluation stops here. The value of the fifth argument is returned, and the sixth argument isn't evaluated.	**3**
Coalesce("")	Tests the first argument which is an empty string. Because the first argument is an empty string, and there are no more arguments, the function returns *blank*.	*blank*

IsBlank

1. Create an app from scratch, add a text-input control, and name it **FirstName**.
2. Add a label, and set its **Text** property to this formula:

   ```
   Power Fx
   ```

   ```
   If( IsBlank( FirstName.Text ), "First Name is a required field." )
   ```

   By default, the **Text** property of a text-input control is set to **"Text input"**. Because the property contains a value, it isn't blank, and the label doesn't display any message.
3. Remove all the characters from the text-input control, including any spaces.

   Because the **Text** property no longer contains any characters, it's an empty string, and **IsBlank(FirstName.Text)** will be **true**. The required field message is displayed.

For information about how to perform validation by using other tools, see the **Validate** function and working with data sources.

Other examples:

Expand table

Formula	Description	Result
IsBlank(Blank())	Tests the return value from the **Blank** function, which always returns a *blank* value.	**true**
IsBlank("")	A string that contains no characters.	**true**
IsBlank("Hello")	A string that contains one or more characters.	**false**
IsBlank(*AnyCollection*)	Because the collection exists, it isn't blank, even if it doesn't contain any records. To check for an empty collection, use **IsEmpty** instead.	**false**
IsBlank(Mid("Hello", 17, 2))	The starting character for **Mid** is beyond the end of the string. The result is an empty string.	**true**
IsBlank(If(false, false))	An **If** function with no *ElseResult*. Because the condition is always **false**, this **If** always returns *blank*.	**true**

IsEmpty

1. Create an app from scratch, and add a **Button** control.
2. Set the button's **OnSelect** property to this formula:

   Collect(IceCream, { Flavor: "Strawberry", Quantity: 300 }, { Flavor: "Chocolate", Quantity: 100 })
3. Preview your app, click or tap the button that you added, and then close Preview.

   A collection named **IceCream** is created and contains this data:

Flavor	Quantity
"Strawberry"	300
"Chocolate"	100

   This collection has two records and isn't empty. **IsEmpty(IceCream)** returns **false**, and **CountRows(IceCream)** returns **2**.
4. Add a second button, and set its **OnSelect** property to this formula:

   Clear(IceCream)
5. Preview your app, click or tap the second button, and then close Preview.

The collection is now empty:

Flavor	Quantity

The Clear function removes all the records from a collection, resulting in an empty collection. **IsEmpty(IceCream)** returns **true**, and **CountRows(IceCream)** returns **0**.

You can also use **IsEmpty** to test whether a calculated table is empty, as these examples show:

Expand table

Formula	Description	Result
IsEmpty([1, 2, 3])	The single-column table contains three records and, therefore, isn't empty.	**false**
IsEmpty([ ])	The single-column table contains no records and is empty.	**true**
IsEmpty(Filter([1, 2, 3], Value > 5))	The single-column table contains no values that are greater than 5. The result from the filter doesn't contain any records and is empty.	**true**

Error, IfError, IsError, IsBlankOrError functions

Article • 10/16/2024

Applies to: ✅ Canvas apps ✅ Dataverse formula columns ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Detects errors and provides an alternative value or takes action. Create a custom error or pass through an error.

> **Note**
>
> If an app has disabled the *Formula-level error management* feature under **Settings** > **Updates** > **Retired**, those functions will not work correctly.

IfError

The **IfError** function tests values until it finds an error. If the function discovers an error, the function evaluates and returns a corresponding replacement value and stops further evaluation. A default value can also be supplied for when no errors are found. The structure of **IfError** resembles that of the **If** function: **IfError** tests for errors, while **If** tests for **true**.

Use **IfError** to replace an error with a valid value so that downstream calculations can continue. For example, use this function if user input might result in a division by zero:

Power Apps

```
IfError( 1/x, 0 )
```

This formula returns `0` if the value of `x` is zero, as `1/x` produces an error. If `x` isn't zero, then `1/x` is returned.

Stopping further processing

When chaining formulas together in behavior formulas, such as:

Power Apps

```
Patch( DS1, ... );
Patch( DS2, ... )
```

The second Patch function to `DS2` will be attempted even if the **Patch** to `DS1` fails. The scope of an error is limited to each formula that is chained.

Use **IfError** to do an action and only continue processing if the action was successful. Applying **IfError** to this example:

Power Apps

```
IfError(
    Patch( DS1, ... ), Notify( "problem in the first action" ),
    Patch( DS2, ... ), Notify( "problem in the second action" )
)
```

If the **Patch** of `DS1` has a problem, the first **Notify** is executed. No further processing occurs including the second **Patch** of `DS2`. If the first **Patch** succeeds, the second **Patch** will execute.

If supplied, the optional *DefaultResult* argument is returned if no errors are discovered. Without this argument, the last *Value* argument is returned.

Building on the last example, the return value from **IfError** can be checked to determine if there were any problems:

Power Apps

```
IfError(
    Patch( DS1, ... ), Notify( "problem in the first action" );  false,
    Patch( DS2, ... ), Notify( "problem in the second action" ); false,
    true
)
```

Type compatibility

IfError returns the value of one of its arguments. The types of all values that might be returned by **IfError** must be compatible.

In the last example, **Patch** returns a record that isn't compatible with the Booleans used for the *Replacement* formulas or the *DefaultResult*. Which is fine, since there's no situation in which the return value from these **Patch** calls would be returned by **IfError**.

> ⓘ **Note**
>
> While the behavior in process for a change, the types of all arguments to **IfError** must be compatible currently.

In the simple example described earlier:

```
Power Apps
IfError( 1/x, 0 )
```

The types of `1/x` and `0` were compatible as both were numbers. If they're not, the second argument is coerced to match the type of the first argument.

Excel displays **#DIV/0!** when a division by zero occurs.

Consider **IfError** with the following instead:

```
Power Apps
IfError( 1/x, "#DIV/0!" )
```

The above formula won't work. The text string `"#DIV/0!"` is coerced to the type of the first argument to **IfError**, which is a number. The result of **IfError** is yet another error since the text string can't be coerced. As a fix, convert the first argument to a text string so that **IfError** always returns a text string:

```
Power Apps
IfError( Text( 1/x ), "#DIV/0!" )
```

As seen above, **IfError** can return an error if the *Replacement* or *DefaultResult* is an error.

FirstError / AllErrors

Within in the replacement formulas, information about the errors found is available through the **FirstError** record and **AllErrors** table. **AllErrors** is a table of error information records with **FirstError** being a shortcut to the first record of this table. **FirstError** always returns the same value as **First(AllErrors)**.

Error records include:

Expand table

Field	Type	Description
Kind	ErrorKind enum (number)	Category of the error.
Message	Text string	Message about the error, suitable to be displayed to the end user.
Source	Text string	Location in where the error originated, used for reporting. For example, for a formula bound to a control property, this value is in the form *ControlName.PropertyName*.
Observed	Text string	Location in where the error is surfaced to the user, used for reporting. For example, for a formula bound to a control property, this value is in the form *ControlName.PropertyName*.
Details	Record	Details about the error. Currently, details are provided only for network errors. This record includes **HttpStatusCode** which contains the HTTP status code and **HttpResponse** which contains the body of the response from the connector or service.

For example, consider the following formula as a **Button** control's **OnSelect** property:

Power Apps

```
Set( a, 1/0 )
```

And this formula on the **OnSelect** property of a second **Button** control:

Power Apps

```
IfError( a, Notify( "Internal error: originated on " & FirstError.Source &
", surfaced on " & FirstError.Observed ) )
```

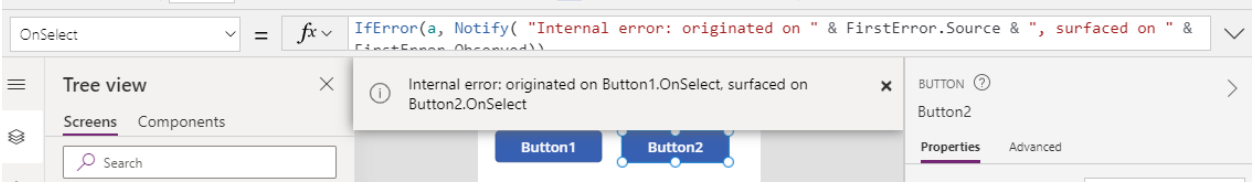
The example formula above would display the following banner when the two buttons are activated in sequence:



Typically, there will be only one error that **FirstError** can sufficiently work with. However, there are scenarios where multiple errors may be returned. For example, when using a formula chaining operator or the **Concurrent** function. Even in these situations,

reporting **FirstError** might be enough to reveal a problem instead overloading a user with multiple errors. If you still have a requirement to work with each error individually, you can use the **AllErrors** table.

IsError

The **IsError** function tests for an error value.

The return value is a Boolean *true* or *false*.

Using **IsError** prevents any further processing of the error.

IsBlankOrError

The **IsBlankOrError** function tests for either a blank value or an error value and is the equivalent of `Or( IsBlank( X ), IsError( X ) )`.

When enabling error handling for existing apps, consider replacing **IsBlank** with **IsBlankOrError** to preserve existing app behavior. Before the addition of error handling, a *blank* value was used to represent both null values from databases and error values. Error handling separates these two interpretations of *blank* which could change the behavior of existing apps that continue to use **IsBlank**.

The return value is a boolean *true* or *false*.

Using **IsBlankOrError** prevents any further processing of the error.

Use the **Error** function to create and report a custom error. For example, you might have logic to determine whether any given value is valid for your context or not—something not checked for a problem automatically. You can create and return your own error, complete with **Kind** and **Message**, using the same record described above for the **IfError** function.

In the context of **IfError**, use the **Error** function to rethrow or pass through an error. For example, your logic in **IfError** may decide that in some cases an error can be safely ignored, but in other cases the error is important to send through. Within **IfError** or **App.OnError**, use **Error(FirstError)** to pass through an error.

The **Error** function can also be passed a table of errors, as would be found in the **AllErrors** table. Use **Error(AllErrors)** to rethrow all the errors and not just the first.

A *blank* record or empty table passed to **Error** results in no error.

Syntax

Error(**ErrorRecord**)
Error(**ErrorTable**)

- *ErrorRecord* – Required. Error information record, including **Kind**, **Message**, and other fields. **Kind** is required. **FirstError** can be passed directly.
- *ErrorTable* – Required. Table of error information records. **AllErrors** can be passed directly.

IfError(*Value1*, *Replacement1* [, *Value2*, *Replacement2*, ... [, *DefaultResult*]])

- *Value(s)* – Required. Formula(s) to test for an error value.
- *Replacement(s)* – Required. The formulas to evaluate and values to return if matching *Value* arguments returned an error.
- *DefaultResult* – Optional. The formulas to evaluate if the formula doesn't find any errors.

IsError(*Value*)
IsBlankOrError(*Value*)

- *Value* – Required. Formula to test.

Examples

Simple IfError

Expand table

Formula	Description	Result
IfError(1, 2)	The first argument isn't an error. The function has no other errors to check and no default return value. The function returns the last *value* argument evaluated.	1
IfError(1/0, 2)	The first argument returns an error value (because of division by zero). The function evaluates the second argument and returns it as the result.	2
IfError(10, 20, 30)	The first argument isn't an error. The function has no other errors to check but does have a default return value. The function returns the *DefaultResult* argument.	30
IfError(10, 11, 20, 21, 300)	The first argument **10** isn't an error, so the function doesn't evaluate that argument's corresponding replacement **11**. The third argument	300

Formula	Description	Result
	20 isn't an error either, so the function doesn't evaluate that argument's corresponding replacement **21**. The fifth argument **300** has no corresponding replacement and is the default result. The function returns that result because the formula contains no errors.	
IfError(1/0, Notify("There was an internal problem"))	The first argument returns an error value (due to division by zero). The function evaluates the second argument and displays a message to the user. The return value of **IfError** is the return value of **Notify**, coerced to the same type as the first argument to **IfError** (a number).	1

Simple IsError

Expand table

Formula	Description	Result
IsError(1)	The argument isn't an error.	*false*
IsError(Blank())	The argument is a blank, but not an error.	*false*
IsError(1/0)	The argument is an error.	*true*
If(IsError(1/0), Notify("There was an internal problem"))	The argument to **IsError** returns an error value (because of division by zero). This function returns *true*, which causes the **If** to display a message to the user with the **Notify** function. The return value of **If** is the return value of **Notify**, coerced to the same type as the first argument to **If** (a boolean).	*true*

Simple IsBlankOrError

Expand table

Formula	Description	Result
IsBlankOrError(1)	The argument isn't an error or a blank.	*false*
IsBlankOrError(Blank())	The argument is a blank.	*true*
IsBlankOrError(1/0)	The argument is an error.	*true*

Simple Error

In this example, dates are validated relative to one another, resulting in an error if there is a problem.

Power Apps

```
If( StartDate > EndDate,
    Error( { Kind: ErrorKind.Validation, Message: "Start Date must be before
End Date" } ) )
```

In this example, some errors are allowed to pass through while others are suppressed and replaced with a value. In the first case, **b** is in an error state because the **Value** function has an invalid argument. Because this is unexpected by the formula writer, it is passed through so the user sees it. In the second case, with the same formula, **b** has the value 0, resulting in a division by zero. In this case, the formula writer may know that this is acceptable for this logic, suppress the error (no banner is shown), and return -1 instead.

Power Apps

```
With( {a: 1, b: Value("a")},
      IfError( a/b, If( FirstError.Kind <> ErrorKind.Div0, Error( FirstError
), -1 ) ) )
// returns an error with Kind = ErrorKind.InvalidArgument

With( {a: 1, b: 0} )
      IfError( a/b, If( FirstError.Kind <> ErrorKind.Div0, Error( FirstError
), -1 ) ) )
// returns -1
```

The **AllErrors** table can be filtered like any other table. Used with the **Error** function, expected errors can be removed and the remaining errors retained and reported. For example, if we knew that division by zero wasn't going to be a problem in a particular context, those errors could be filtered out, leaving all other errors intact with the following formula:

Power Apps

```
Error( Filter( AllErrors, Kind <> ErrorKind.Div0 ) )
```

Step by step

1. Add a Text input control, and name it **TextInput1** if it doesn't have that name by default.

2. Add a Label control, and name it **Label1** if it doesn't have that name by default.

3. Set the formula for **Label1**'s **Text** property to:

Power Apps

```
IfError( Value( TextInput1.Text ), -1 )
```

4. In **TextInput1**, enter **1234**.

   Label1 shows the value **1234** as this is a valid input to the Value function.

5. In **TextInput1**, enter **ToInfinity**.

   Label1 shows the value **-1** as this isn't a valid input to the Value function. Without wrapping the Value function with IfError, the label would show no value as the error value is treated as a *blank*.

Tests whether a value is blank or a table contains no records, and provides a way to create *blank* values.

Overview

Blank is a placeholder for "no value" or "unknown value." For example, a **Combo box** control's **Selected** property is *blank* if the user hasn't made a selection. Many data sources can store and return NULL values, which are represented in Power Apps as *blank*.

Any property or calculated value in Power Apps can be *blank*. For example, a Boolean value normally has one of two values: **true** or **false**. But in addition to these two, it can also be *blank* indicating that the state is not known. This is similar to Microsoft Excel, where a worksheet cell starts out as blank with no contents but can hold the values **TRUE** or **FALSE** (among others). At any time, the contents of the cell can again be cleared, returning it to a *blank* state.

Empty string refers to a string that contains no characters. The **Len** function returns zero for such a string and it can be written in a formulas as two double quotes with nothing in between `""`. Some controls and data sources use an empty string to indicate a "no value" condition. To simplify app creation, the **IsBlank** and **Coalesce** functions test for both *blank* values or empty strings.

In the context of the **IsEmpty** function, *empty* is specific to tables that contain no records. The table structure may be intact, complete with column names, but no data is in the table. A table

may start as empty, take on records and no longer be empty, and then have the records removed and again be empty.

Blank

The **Blank** function returns a *blank* value. Use this to store a NULL value in a data source that supports these values, effectively removing any value from the field.

IsBlank

The **IsBlank** function tests for a *blank* value or an empty string. The test includes empty strings to ease app creation since some data sources and controls use an empty string when there is no value present. To test specifically for a *blank* value use `if( Value = Blank(), ...` instead of **IsBlank**. The **IsBlank** function considers empty tables as not blank, and **IsEmpty** should be used to test a table.

When enabling error handling for existing apps, consider replacing **IsBlank** with IsBlankOrError to preserve existing app behavior. Prior to the addition of error handling, a *blank* value was used to represent both null values from databases and error values. Error handling separates these two interpretations of *blank* which could change the behavior of existing apps that continue to use **IsBlank**.

The return value for **IsBlank** is a boolean **true** or **false**.

Coalesce

The **Coalesce** function evaluates its arguments in order and returns the first value that isn't *blank* or an empty string. Use this function to replace a *blank* value or empty string with a different value but leave non-*blank* and non-empty string values unchanged. If all the arguments are *blank* or empty strings then the function returns *blank*, making **Coalesce** a good way to convert empty strings to *blank* values.

`Coalesce( value1, value2 )` is the more concise equivalent of `If( Not IsBlank( value1 ), value1, Not IsBlank( value2 ), value2 )` and doesn't require **value1** and **value2** to be evaluated twice. The **If** function returns *blank* if there is no "else" formula as is the case here.

All arguments to **Coalesce** must be of the same type; for example, you can't mix numbers with text strings. The return value from **Coalesce** is of this common type.

IsEmpty

The **IsEmpty** function tests whether a table contains any records. It's equivalent to using the CountRows function and checking for zero. You can check for data-source errors by combining **IsEmpty** with the Errors function.

The return value for **IsEmpty** is a Boolean **true** or **false**.

Syntax

Blank()

Coalesce(*Value1* [, *Value2*, ...])

- *Value(s)* – Required. Values to test. Each value is evaluated in order until a value that is not *blank* and not an empty string is found. Values after this point are not evaluated.

IsBlank(*Value*)

- *Value* – Required. Value to test for a *blank* value or empty string.

IsEmpty(*Table*)

- *Table* - Required. Table to test for records.

Examples

Blank

1. Create an app from scratch, and add a **Button** control.
2. Set the button's OnSelect property to this formula:

   ```
   Power Fx
   ClearCollect( Cities, { Name: "Seattle", Weather: "Rainy" } )
   ```

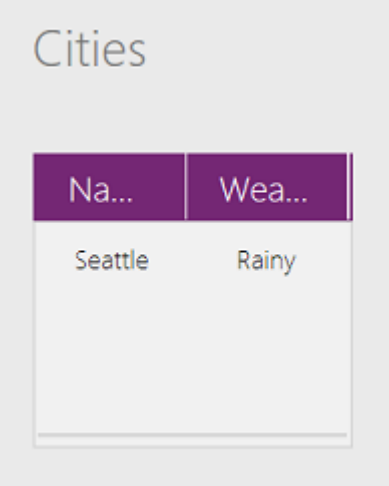
3. Preview your app, click or tap the button that you added, and then close Preview.
4. On the **File** menu, click or tap **Collections**.

   The **Cities** collection appears, showing one record with "Seattle" and "Rainy":



5. Click or tap the back arrow to return to the default workspace.

6. Add a **Label** control, and set its **Text** property to this formula:

```
Power Fx
IsBlank( First( Cities ).Weather )
```

   The label shows **false** because the **Weather** field contains a value ("Rainy").

7. Add a second button, and set its **OnSelect** property to this formula:

```
Power Fx
Patch( Cities, First( Cities ), { Weather: Blank() } )
```

8. Preview your app, click or tap the button that you added, and then close Preview.

   The **Weather** field of the first record in **Cities** is replaced with a *blank*, removing the "Rainy" that was there previously.

   The label shows **true** because the **Weather** field no longer contains a value.

Coalesce

Expand table

Formula	Description	Result
Coalesce(Blank(), 1)	Tests the return value from the **Blank** function, which always returns a *blank* value. Because the first argument is *blank*, evaluation continues with the next argument until a non-*blank* value and non-empty string is found.	**1**
Coalesce("", "2")	Tests the first argument which is an empty string. Because the first argument is an empty string, evaluation continues with the next argument until a non-*blank* value and non-empty string is found.	**2**
Coalesce(Blank(), "", Blank(), "", "3", "4")	**Coalesce** starts at the beginning of the argument list and evaluates each argument in turn until a non-*blank* value and non-empty string is found. In this case, the first four arguments all return *blank* or an empty string, so evaluation continues to the fifth argument. The fifth argument is non-*blank* and non-empty string, so evaluation stops here. The value of the fifth argument is returned, and the sixth argument isn't evaluated.	**3**
Coalesce("")	Tests the first argument which is an empty string. Because the first argument is an empty string, and there are no more arguments, the function returns *blank*.	*blank*

IsBlank

1. Create an app from scratch, add a text-input control, and name it **FirstName**.
2. Add a label, and set its **Text** property to this formula:

   ```
   Power Fx
   ```

   ```
   If( IsBlank( FirstName.Text ), "First Name is a required field." )
   ```

   By default, the **Text** property of a text-input control is set to **"Text input"**. Because the property contains a value, it isn't blank, and the label doesn't display any message.
3. Remove all the characters from the text-input control, including any spaces.

   Because the **Text** property no longer contains any characters, it's an empty string, and **IsBlank(FirstName.Text)** will be **true**. The required field message is displayed.

For information about how to perform validation by using other tools, see the **Validate** function and working with data sources.

Other examples:

Expand table

Formula	Description	Result
IsBlank(Blank())	Tests the return value from the **Blank** function, which always returns a *blank* value.	**true**
IsBlank("")	A string that contains no characters.	**true**
IsBlank("Hello")	A string that contains one or more characters.	**false**
IsBlank(*AnyCollection*)	Because the collection exists, it isn't blank, even if it doesn't contain any records. To check for an empty collection, use **IsEmpty** instead.	**false**
IsBlank(Mid("Hello", 17, 2))	The starting character for **Mid** is beyond the end of the string. The result is an empty string.	**true**
IsBlank(If(false, false))	An **If** function with no *ElseResult*. Because the condition is always **false**, this **If** always returns *blank*.	**true**

IsEmpty

1. Create an app from scratch, and add a **Button** control.
2. Set the button's **OnSelect** property to this formula:

   Collect(IceCream, { Flavor: "Strawberry", Quantity: 300 }, { Flavor: "Chocolate", Quantity: 100 })
3. Preview your app, click or tap the button that you added, and then close Preview.

   A collection named **IceCream** is created and contains this data:

Flavor	Quantity
"Strawberry"	300
"Chocolate"	100

   This collection has two records and isn't empty. **IsEmpty(IceCream)** returns **false**, and **CountRows(IceCream)** returns **2**.
4. Add a second button, and set its **OnSelect** property to this formula:

   Clear(IceCream)
5. Preview your app, click or tap the second button, and then close Preview.

The collection is now empty:

Flavor	Quantity

The Clear function removes all the records from a collection, resulting in an empty collection. **IsEmpty(IceCream)** returns **true**, and **CountRows(IceCream)** returns **0**.

You can also use **IsEmpty** to test whether a calculated table is empty, as these examples show:

Expand table

Formula	Description	Result
IsEmpty([1, 2, 3])	The single-column table contains three records and, therefore, isn't empty.	**false**
IsEmpty([ ])	The single-column table contains no records and is empty.	**true**
IsEmpty(Filter([1, 2, 3], Value > 5))	The single-column table contains no values that are greater than 5. The result from the filter doesn't contain any records and is empty.	**true**

Error, IfError, IsError, IsBlankOrError functions

Article • 10/16/2024

Applies to: ✅ Canvas apps ✅ Dataverse formula columns ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Detects errors and provides an alternative value or takes action. Create a custom error or pass through an error.

> **Note**
>
> If an app has disabled the *Formula-level error management* feature under **Settings** > **Updates** > **Retired**, those functions will not work correctly.

IfError

The **IfError** function tests values until it finds an error. If the function discovers an error, the function evaluates and returns a corresponding replacement value and stops further evaluation. A default value can also be supplied for when no errors are found. The structure of **IfError** resembles that of the **If** function: **IfError** tests for errors, while **If** tests for **true**.

Use **IfError** to replace an error with a valid value so that downstream calculations can continue. For example, use this function if user input might result in a division by zero:

Power Apps

```
IfError( 1/x, 0 )
```

This formula returns `0` if the value of `x` is zero, as `1/x` produces an error. If `x` isn't zero, then `1/x` is returned.

Stopping further processing

When chaining formulas together in behavior formulas, such as:

Power Apps

```
Patch( DS1, ... );
Patch( DS2, ... )
```

The second Patch function to `DS2` will be attempted even if the **Patch** to `DS1` fails. The scope of an error is limited to each formula that is chained.

Use **IfError** to do an action and only continue processing if the action was successful. Applying **IfError** to this example:

Power Apps

```
IfError(
    Patch( DS1, ... ), Notify( "problem in the first action" ),
    Patch( DS2, ... ), Notify( "problem in the second action" )
)
```

If the **Patch** of `DS1` has a problem, the first **Notify** is executed. No further processing occurs including the second **Patch** of `DS2`. If the first **Patch** succeeds, the second **Patch** will execute.

If supplied, the optional *DefaultResult* argument is returned if no errors are discovered. Without this argument, the last *Value* argument is returned.

Building on the last example, the return value from **IfError** can be checked to determine if there were any problems:

Power Apps

```
IfError(
    Patch( DS1, ... ), Notify( "problem in the first action" );  false,
    Patch( DS2, ... ), Notify( "problem in the second action" ); false,
    true
)
```

Type compatibility

IfError returns the value of one of its arguments. The types of all values that might be returned by **IfError** must be compatible.

In the last example, **Patch** returns a record that isn't compatible with the Booleans used for the *Replacement* formulas or the *DefaultResult*. Which is fine, since there's no situation in which the return value from these **Patch** calls would be returned by **IfError**.

> ⓘ **Note**
>
> While the behavior in process for a change, the types of all arguments to **IfError** must be compatible currently.

In the simple example described earlier:

```
Power Apps
IfError( 1/x, 0 )
```

The types of `1/x` and `0` were compatible as both were numbers. If they're not, the second argument is coerced to match the type of the first argument.

Excel displays **#DIV/0!** when a division by zero occurs.

Consider **IfError** with the following instead:

```
Power Apps
IfError( 1/x, "#DIV/0!" )
```

The above formula won't work. The text string `"#DIV/0!"` is coerced to the type of the first argument to **IfError**, which is a number. The result of **IfError** is yet another error since the text string can't be coerced. As a fix, convert the first argument to a text string so that **IfError** always returns a text string:

```
Power Apps
IfError( Text( 1/x ), "#DIV/0!" )
```

As seen above, **IfError** can return an error if the *Replacement* or *DefaultResult* is an error.

FirstError / AllErrors

Within in the replacement formulas, information about the errors found is available through the **FirstError** record and **AllErrors** table. **AllErrors** is a table of error information records with **FirstError** being a shortcut to the first record of this table. **FirstError** always returns the same value as **First(AllErrors)**.

Error records include:

Expand table

Field	Type	Description
Kind	ErrorKind enum (number)	Category of the error.
Message	Text string	Message about the error, suitable to be displayed to the end user.
Source	Text string	Location in where the error originated, used for reporting. For example, for a formula bound to a control property, this value is in the form *ControlName.PropertyName*.
Observed	Text string	Location in where the error is surfaced to the user, used for reporting. For example, for a formula bound to a control property, this value is in the form *ControlName.PropertyName*.
Details	Record	Details about the error. Currently, details are provided only for network errors. This record includes **HttpStatusCode** which contains the HTTP status code and **HttpResponse** which contains the body of the response from the connector or service.

For example, consider the following formula as a **Button** control's **OnSelect** property:

Power Apps

```
Set( a, 1/0 )
```

And this formula on the **OnSelect** property of a second **Button** control:

Power Apps

```
IfError( a, Notify( "Internal error: originated on " & FirstError.Source &
", surfaced on " & FirstError.Observed ) )
```

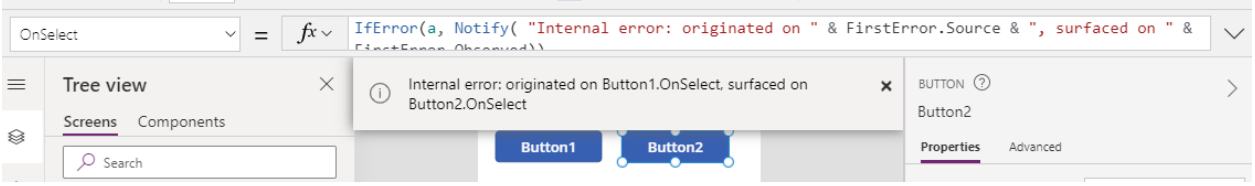
The example formula above would display the following banner when the two buttons are activated in sequence:



Typically, there will be only one error that **FirstError** can sufficiently work with. However, there are scenarios where multiple errors may be returned. For example, when using a formula chaining operator or the **Concurrent** function. Even in these situations,

reporting **FirstError** might be enough to reveal a problem instead overloading a user with multiple errors. If you still have a requirement to work with each error individually, you can use the **AllErrors** table.

IsError

The **IsError** function tests for an error value.

The return value is a Boolean *true* or *false*.

Using **IsError** prevents any further processing of the error.

IsBlankOrError

The **IsBlankOrError** function tests for either a blank value or an error value and is the equivalent of `Or( IsBlank( X ), IsError( X ) )`.

When enabling error handling for existing apps, consider replacing **IsBlank** with **IsBlankOrError** to preserve existing app behavior. Before the addition of error handling, a *blank* value was used to represent both null values from databases and error values. Error handling separates these two interpretations of *blank* which could change the behavior of existing apps that continue to use **IsBlank**.

The return value is a boolean *true* or *false*.

Using **IsBlankOrError** prevents any further processing of the error.

Use the **Error** function to create and report a custom error. For example, you might have logic to determine whether any given value is valid for your context or not—something not checked for a problem automatically. You can create and return your own error, complete with **Kind** and **Message**, using the same record described above for the **IfError** function.

In the context of **IfError**, use the **Error** function to rethrow or pass through an error. For example, your logic in **IfError** may decide that in some cases an error can be safely ignored, but in other cases the error is important to send through. Within **IfError** or **App.OnError**, use **Error(FirstError)** to pass through an error.

The **Error** function can also be passed a table of errors, as would be found in the **AllErrors** table. Use **Error(AllErrors)** to rethrow all the errors and not just the first.

A *blank* record or empty table passed to **Error** results in no error.

Syntax

Error(**ErrorRecord**)
Error(**ErrorTable**)

- *ErrorRecord* – Required. Error information record, including **Kind**, **Message**, and other fields. **Kind** is required. **FirstError** can be passed directly.
- *ErrorTable* – Required. Table of error information records. **AllErrors** can be passed directly.

IfError(*Value1*, *Replacement1* [, *Value2*, *Replacement2*, ... [, *DefaultResult*]])

- *Value(s)* – Required. Formula(s) to test for an error value.
- *Replacement(s)* – Required. The formulas to evaluate and values to return if matching *Value* arguments returned an error.
- *DefaultResult* – Optional. The formulas to evaluate if the formula doesn't find any errors.

IsError(*Value*)
IsBlankOrError(*Value*)

- *Value* – Required. Formula to test.

Examples

Simple IfError

Expand table

Formula	Description	Result
IfError(1, 2)	The first argument isn't an error. The function has no other errors to check and no default return value. The function returns the last *value* argument evaluated.	1
IfError(1/0, 2)	The first argument returns an error value (because of division by zero). The function evaluates the second argument and returns it as the result.	2
IfError(10, 20, 30)	The first argument isn't an error. The function has no other errors to check but does have a default return value. The function returns the *DefaultResult* argument.	30
IfError(10, 11, 20, 21, 300)	The first argument **10** isn't an error, so the function doesn't evaluate that argument's corresponding replacement **11**. The third argument	300

Formula	Description	Result
	20 isn't an error either, so the function doesn't evaluate that argument's corresponding replacement **21**. The fifth argument **300** has no corresponding replacement and is the default result. The function returns that result because the formula contains no errors.	
IfError(1/0, Notify("There was an internal problem"))	The first argument returns an error value (due to division by zero). The function evaluates the second argument and displays a message to the user. The return value of **IfError** is the return value of **Notify**, coerced to the same type as the first argument to **IfError** (a number).	1

Simple IsError

Expand table

Formula	Description	Result
IsError(1)	The argument isn't an error.	*false*
IsError(Blank())	The argument is a blank, but not an error.	*false*
IsError(1/0)	The argument is an error.	*true*
If(IsError(1/0), Notify("There was an internal problem"))	The argument to **IsError** returns an error value (because of division by zero). This function returns *true*, which causes the **If** to display a message to the user with the **Notify** function. The return value of **If** is the return value of **Notify**, coerced to the same type as the first argument to **If** (a boolean).	*true*

Simple IsBlankOrError

Expand table

Formula	Description	Result
IsBlankOrError(1)	The argument isn't an error or a blank.	*false*
IsBlankOrError(Blank())	The argument is a blank.	*true*
IsBlankOrError(1/0)	The argument is an error.	*true*

Simple Error

In this example, dates are validated relative to one another, resulting in an error if there is a problem.

Power Apps

```
If( StartDate > EndDate,
    Error( { Kind: ErrorKind.Validation, Message: "Start Date must be before
End Date" } ) )
```

In this example, some errors are allowed to pass through while others are suppressed and replaced with a value. In the first case, **b** is in an error state because the **Value** function has an invalid argument. Because this is unexpected by the formula writer, it is passed through so the user sees it. In the second case, with the same formula, **b** has the value 0, resulting in a division by zero. In this case, the formula writer may know that this is acceptable for this logic, suppress the error (no banner is shown), and return -1 instead.

Power Apps

```
With( {a: 1, b: Value("a")},
      IfError( a/b, If( FirstError.Kind <> ErrorKind.Div0, Error( FirstError
), -1 ) ) )
// returns an error with Kind = ErrorKind.InvalidArgument

With( {a: 1, b: 0} )
      IfError( a/b, If( FirstError.Kind <> ErrorKind.Div0, Error( FirstError
), -1 ) ) )
// returns -1
```

The **AllErrors** table can be filtered like any other table. Used with the **Error** function, expected errors can be removed and the remaining errors retained and reported. For example, if we knew that division by zero wasn't going to be a problem in a particular context, those errors could be filtered out, leaving all other errors intact with the following formula:

Power Apps

```
Error( Filter( AllErrors, Kind <> ErrorKind.Div0 ) )
```

Step by step

1. Add a Text input control, and name it **TextInput1** if it doesn't have that name by default.

2. Add a Label control, and name it **Label1** if it doesn't have that name by default.

3. Set the formula for **Label1**'s **Text** property to:

Power Apps

```
IfError( Value( TextInput1.Text ), -1 )
```

4. In **TextInput1**, enter **1234**.

   Label1 shows the value **1234** as this is a valid input to the Value function.

5. In **TextInput1**, enter **ToInfinity**.

   Label1 shows the value **-1** as this isn't a valid input to the Value function. Without wrapping the Value function with IfError, the label would show no value as the error value is treated as a *blank*.

IsMatch, Match, and MatchAll functions

06/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Tests for a match or extracts parts of a text string based on a pattern.

Description

The **IsMatch** function tests whether a text string matches a pattern that can comprise ordinary characters, predefined patterns, or a regular expression. The **Match** and **MatchAll** functions return what was matched, including submatches.

Use **IsMatch** to validate what a user typed in a **Text input** control. For example, confirm whether the user entered a valid email address before the result is saved to your data source. If the entry doesn't match your criteria, add other controls that prompt the user to fix the entry.

Use **Match** to extract the first text string that matches a pattern and **MatchAll** to extract all text strings that match. Extract submatches to parse complex strings.

Match returns a record of information for the first match found, and **MatchAll** returns a table of records for every match found. The record or records contain:

Expand table

Column	Type	Description
named sub-match or sub-matches	Text	Each named submatch has its own column. Create a named submatch by using **(?<*name*>...)** in the regular expression. If a named submatch has the same name as one of the predefined columns, the submatch takes precedence, and a warning is generated. Rename the submatch to avoid this warning.
FullMatch	Text	All of the text string that was matched.
StartMatch	Number	The starting position of the match within the input text string. The first character of the string returns 1.
SubMatches, only if **MatchOptions.NumberedSubMatches** is used.	Single-column table of	The table of numbered submatches in the order in which they appear in the regular expression. Generally, named submatches are

Column	Type	Description
	Text (column **Value**)	easier to work with and are encouraged. Use the ForAll function or Index function to work with an individual sub-match. If no submatches are defined in the regular expression, this table will be present but empty.

These functions support MatchOptions. By default:

- These functions perform a case-sensitive match. Use **MatchOptions.IgnoreCase** to perform case-insensitive matches.
- **IsMatch** matches the entire text string (**Complete** MatchOption), while **Match** and **MatchAll** search for a match anywhere in the text string (**Contains** MatchOption). Use **Complete**, **Contains**, **BeginsWith**, or **EndsWith** as appropriate for your scenario.

IsMatch returns *true* if the text string matches the pattern or *false* if it doesn't. **Match** returns *blank* if no match is found that can be tested with the IsBlank function. **MatchAll** returns an empty table if no match is found that can be tested with the IsEmpty function.

If you use **MatchAll** to split a text string, consider using the Split function, which is simpler and faster.

Patterns

The key to using these functions is in describing the pattern to match. You describe the pattern in a text string as a combination of:

- Ordinary characters, such as "**abc**" or "**123**".
- Predefined patterns, such as **Letter**, **MultipleDigits**, or **Email**. (The **Match** enum defines these patterns.)
- Regular-expression codes, such as "**\d+\s+\d+**" or "**[a-z]+**".

Combine these elements using the string-concatenation operator &. For example, "**abc**" & **Digit** & "**\s+**" is a valid pattern that matches the characters "a", "b", and "c", followed by a digit from 0 to 9, followed by at least one whitespace character.

Ordinary characters

The simplest pattern is a sequence of ordinary characters that match exactly.

For example, when used with the **IsMatch** function, the string "Hello" matches the pattern "**Hello**" exactly. No more and no less. The string `"hello!"` doesn't match the pattern because

of the exclamation point on the end and because the case is wrong for the letter "h". (See Match options for ways to modify this behavior.)

In the pattern language, the characters `. ? * + ( ) [ ] ^ $ | \` are reserved for special purposes. To use these characters, either prefix the character with a **** (backslash) to indicate that the character should be taken literally, or use one of the predefined patterns. For example, you can match the string `"Hello?"` by using the pattern `"Hello\\?"` with a backslash before the question mark.

Predefined patterns

Predefined patterns provide a simple way to match either one of a set of characters or a sequence of multiple characters. Use the string-concatenation operator **&** to combine your own text strings with members of the **Match** enum:

Expand table

Match enum	Description	Regular expression
Any	Matches any character.	`.`
Comma	Matches a comma `,`.	`,`
Digit	Matches a single digit ("0" through "9").	`\d`
Email	Matches an email address that contains an "at" symbol ("@") and a domain name that contains a dot (".")	*See note*
Hyphen	Matches a hyphen.	`-` *See note*
LeftParen	Matches a left parenthesis `(`.	`\(`
Letter	Matches a letter.	`\p{L}`
MultipleDigits	Matches one or more digits.	`\d+`
MultipleLetters	Matches one or more letters.	`\p{L}+`
MultipleNonSpaces	Matches one or more characters that don't add whitespace (not space, tab, or newline).	`\S+`
MultipleSpaces	Matches one or more characters that add whitespace (space, tab, or newline).	`\s+`
NonSpace	Matches a single character that doesn't add whitespace.	`\S`
OptionalDigits	Matches zero, one, or more digits.	`\d*`

Match enum	Description	Regular expression
OptionalLetters	Matches zero, one, or more letters.	`\p{L}*`
OptionalNonSpaces	Matches zero, one, or more characters that don't add whitespace.	`\S*`
OptionalSpaces	Matches zero, one, or more characters that add whitespace.	`\s*`
Period	Matches a period or dot `.`.	`\.`
RightParen	Matches a right parenthesis `)`.	`\)`
Space	Matches a character that adds whitespace.	`\s`
Tab	Matches a tab character.	`\t`

For example, the pattern **"A" & MultipleDigits** matches the letter "A" followed by one or more digits.

Power Apps uses a different definition for **Match.EMail** and **Match.Hyphen**. Evaluate `Text( Match.Email )` to see the regular expression used by your host.

Regular expressions

The pattern they these functions use is called a regular expression. Power Fx's specific dialect of regular expressions is detailed in Regular expressions in Power Fx.

Regular expressions are powerful and serve a wide variety of purposes. They can also look like a random sequence of punctuation marks. This article doesn't describe all aspects of regular expressions, but a wealth of information, tutorials, and tools are available online.

Regular expressions have a long history and are available in many programming languages. Every programming language has its own dialect of regular expressions, and there are few standards. We strive to ensure the same regular expression gives the same result across all Power Fx implementations. Compatibility isn't easy to accomplish as Power Fx runs on top of JavaScript and .NET which have significant differences. To accommodate running on different platforms, Power Fx regular expressions are limited to a subset of features that are widely supported across the industry.

As a result, some regular expressions that may work in other environments may be blocked or require a tweak in Power Fx. Authoring time errors are reported as unsupported features are encountered. This is one of the reasons that the regular expression and options must be an authoring time constant and not dynamic (for example, provided in a variable).

> **Note**
>
> Power Apps uses an earlier version of Power Fx regular expressions that has fewer limitations but also fewer features. **MatchOptions.DotAll** and **MatchOptions.FreeSpacing** aren't available and the definitions of **Match.Email** and **Match.Hyphen** are different. Unicode surrogate pairs aren't treated as a single character. **MatchOptions.NumberedSubMatches** is the default. The version of regular expressions described here will be available in Power Apps soon, under a "Power Fx V1.0 compatibility" switch.

Here are some basic elements of regular expressions that build up complexity in parsing a number.

Expand table

Feature	Example	Description
Predfined character class	`\d`	This regular expression matches a single number, such as `1`. A character class matches a set of characters and `\d` matches the standard digits `0` to `9` and also digits defined in the Unicode character category "Nd". There are character classes for letters and numbers with `\w` and spaces including newlines with `\s`. There are also inverse character classes that are capitalized: `\D` matches everything that `\d` does not.
One or More	`\d+`	This regular expression matches one or more numbers, such as `123`. A `+` after an element says "one or more" of the last element.
Zero or One	`\+?\d`	This regular expression matches an optional `+` sign followed by one ore more numbers, such as `+123` as well as just `123`. A `?` after an element says "this is optional, it can occur zero or one time". The `+` has a backslash before it to distinguish it as a literal character rather than the "one or more" usage.
Grouping and alternation	`(-|\+)?\d+`	This regular expression matches either an `+` sign or a `-`, optionally, and then a series of numbers, such as `-123`, `+123`, and `123`. We are introducing two concepts here that are often used together. First, we have the parenthesis that group as set of elements together, for the `?` to act upon. Second, we have `|` which says "either this or that".
Custom character class	`(-|\+)?\d+[eE][\-\+]?\d+`	This regular expression adds an exponent to the mix with two character classes, matching `+123e-12`. A character class is like `|` alternation providing a "match one of these things" in a more

Feature	Example	Description
		compact form. As with the `+`, `-` has special meaning in regular expression character classes so we need to escape it.
Zero or More	`(-|\+)?\d+\.?\d*[eE][\-\+]?\d+`	This regular expression adds the decimal after the integer portion of the number, such as `-123.456e-89` or `-123.E+32`. The `\d` after the decimal point has a `*` quantifier that says "zero or more times" for decimal digits after the `.`
Capture groups	`(?<number>(-|\+)?\d+\.?\d*)[eE](?<exponent>[\-\+]?\d+)`	Finally, we add capture groups for `number` and `exponent`. Not only can a regular expression match the entire string, it can also extract portions for use in your formulas, in this case the part before the `e` (or `E`) and the part after.

These examples only give a small taste of what regular expressions can do. They are commonly used to validate ID numbers, email addresses, phone numbers, dates and times, and to extract information from all kinds of text files. Continue your journey by reading Regular expressions in Power Fx, experiment, and use the web to learn more.

Match options

Modify the behavior of these functions by specifying one or more options, which you combine using the string- concatenation operator (**&**).

Expand table

MatchOptions enum	Description	Impact on a regular expression
MatchOptions.BeginsWith	The pattern must match from the beginning of the text.	Adds a ^ to the start of the regular expression.
MatchOptions.Complete	Default for **IsMatch** on Power Apps. The pattern matches the entire string of text, from beginning to end.	Adds a ^ to the start and a $ to the end of the regular expression.
MatchOptions.Contains	Default for **Match** and **MatchAll**, and **IsMatch** outside of Power Apps. The pattern must appear somewhere in the text but doesn't need to begin or end it.	Doesn't modify the regular expression.
MatchOptions.DotAll	Changes the behavior of the `.` (dot) operator to match all characters,	Doesn't modify the regular expression.

MatchOptions enum	Description	Impact on a regular expression
	including newline characters. Not available in Power Apps.	This option is the equivalent of the standard "s" modifier for regular expressions.
MatchOptions.EndsWith	The pattern must match the end of the string of text.	Adds a **$** to the end of the regular expression.
MatchOptions.FreeSpacing	Whitespace characters, including newlines, are ignored in the regular expression. End-of-line comments beginning with a `#` are ignored. Not available in Power Apps.	Only changes how the regular expression syntax. This option is the equivalent of the standard "x" modifier for regular expressions.
MatchOptions.IgnoreCase	Treats uppercase and lowercase letters as identical. By default, matching is case sensitive.	Doesn't modify the regular expression. This option is the equivalent of the standard "i" modifier for regular expressions.
MatchOptions.Multiline	Changes the behavior of `^` and `$` to match at the end of aline.	Doesn't modify the regular expression. This option is the equivalent of the standard "m" modifier for regular expressions.
MatchOptions.NumberedSubMatches	Named captures are preferred because they are easier to understand and maintain. Performance also improves as unneeded captures aren't retained. But for older regular expressions, treats each set of parenthesis as a numbered capture that is included with the **SubMatches** table in the result. Default in Power Apps.	Doesn't modify the regular expression. Named captures are disabled and `\1` style back references are enabled.

Using **MatchAll** is the same as using the standard "g" modifier for regular expressions.

Syntax

IsMatch(*Text*, *Pattern* [, *Options*])

- *Text* – Required. The text string to test.
- *Pattern* – Required. The pattern to test as a text string. Concatenate predefined patterns that the **Match** enum defines or provide a regular expression. *Pattern* must be a constant formula without variables, data sources, or other dynamic references that change as the app runs. Note, that the formula must be expressed as "Match.PredefinedPattern" e.g. Match.Email
- *Options* – Optional. A text-string combination of **MatchOptions** enum values. By default, **MatchOptions.Complete** is used. *Options* must be a constant formula without variables, data sources, or other dynamic references that change as the app runs.

Match(*Text*, *Pattern* [, *Options*])

- *Text* – Required. The text string to match.
- *Pattern* – Required. The pattern to match as a text string. Concatenate predefined patterns that the **Match** enum defines, or provide a regular expression. *Pattern* must be a constant formula without any variables, data sources, or other dynamic references that change as the app runs.
- *Options* – Optional. A text-string combination of **MatchOptions** enum values. By default, **MatchOptions.Contains** is used. *Options* must be a constant formula without any variables, data sources, or other dynamic references that change as the app runs.

MatchAll(*Text*, *Pattern* [, *Options*])

- *Text* – Required. The text string to match.
- *Pattern* – Required. The pattern to match as a text string. Concatenate predefined patterns that the **Match** enum defines or provide a regular expression. *Pattern* must be a constant formula without variables, data sources, or other dynamic references that change as the app runs.
- *Options* – Optional. A text-string combination of **MatchOptions** enum values. By default, **MatchOptions.Contains** is used. *Options* must be a constant formula without variables, data sources, or other dynamic references that change as the app runs.

IsMatch examples

Ordinary characters

Imagine your app has a **Text input** control named **TextInput1**. Users enter values into this control to store them in a database.

Users type **Hello world** into **TextInput1**.

Expand table

Formula	Description	Result
`IsMatch( TextInput1.Text, "Hello world" )`	Tests whether the user's input matches, exactly, the string "Hello world".	**true**
`IsMatch( TextInput1.Text, "Good bye" )`	Tests whether the user's input matches, exactly, the string "Good bye".	**false**
`IsMatch( TextInput1.Text, "hello", Contains )`	Tests whether the user's input contains the word "hello" (case sensitive).	**false**
`IsMatch( TextInput1.Text, "hello", Contains & IgnoreCase )`	Tests whether the user's input contains the word "hello" (case insensitive).	**true**

Predefined patterns

Expand table

Formula	Description	Result
`IsMatch( "123-45-7890", Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit )`	Matches a United States Social Security Number	**true**
`IsMatch( "joan@contoso.com", Match.Email )`	Matches an email address	**true**
`IsMatch( "123.456", Match.MultipleDigits & Match.Period & Match.OptionalDigits )`	Matches a sequence of digits, a period, and then zero or more digits.	**true**
`IsMatch( "123", Match.MultipleDigits & Match.Period & Match.OptionalDigits )`	Matches a sequence of digits, a period, and then zero or more digits. A period doesn't appear in the text to match, so this pattern isn't matched.	**false**

Regular expressions

Expand table

Formula	Description	Result
`IsMatch( "986", "\d+" )`	Matches an integer greater than zero.	**true**

Formula	Description	Result
`IsMatch( "1.02", "\d+(\.\d\d)?" )`	Matches a positive currency amount. If the input contains a decimal point, the input must also contain two numeric characters after the decimal point. For example, 3.00 is valid, but 3.1 isn't.	**true**
`IsMatch( "-4.95", "(-)?\d+(\.\d\d)?" )`	Matches a positive or negative currency amount. If the input contains a decimal point, the input must also contain two numeric characters after the decimal point.	**true**
`IsMatch( "111-11-1111", "\d{3}-\d{2}-\d{4}" )`	Matches a United States Social Security number. Validates the format, type, and length of the supplied input field. The string to match must consist of three numeric characters followed by a dash, then two numeric characters followed by a dash, and then four numeric characters.	**true**
`IsMatch( "111-111-111", "\d{3}-\d{2}-\d{4}" )`	Same as the previous example, but one of the hyphens is out of place in the input.	**false**
`IsMatch( "AStrongPasswordNot", "(?!^[0-9]\*$)(?!^[a-zA-Z]\*$)([a-zA-Z0-9]{8,10})" )`	Validates a strong password that must contain eight, nine, or 10 characters, at least one digit, and at least one alphabetic character. The string can't contain special characters.	**false**

Match and MatchAll examples

Expand table

Formula	Description	Result

`Match( "Bob Jones <bob.jones@contoso.com>", "<(?<email>" & Match.Email & ")>")`	Extracts only the email portion of the contact information.	{
		email: "bob.jones@contoso.com",
		FullMatch: "<bob.jones@contoso.com>",
		StartMatch: 11
		}

`Match( "Bob Jones <InvalidEmailAddress>", "<(?<email>" & Match.Email & ")>"`	Extracts only the email portion of the contact information. No legal address is found (there is no @ sign), so the function returns *blank*.	*blank*
`Match( Language(), "(<language>\w{2})(?:-(?<script>\w{4}))?(?:-(?<region>\w{2}))?" )`	Extracts the language, script, and region portions of the language tag that the Language function returns. These results reflect the	{ language: "en", script: *blank*, region: "US",

Formula	Description	Result
	United States; see the Language function documentation for more examples. The **(?:** operator groups characters without creating another sub-match.	FullMatch: "en-US", StartMatch: 1 }

`Match( "PT2H1M39S", "PT(?:(?<hours>\d+)H)?(?:(?<minutes>\d+)M)?(?:(?<seconds>\d+)S)?" )`	Extracts the hours, minutes, and seconds from an ISO 8601 duration value. The extracted numbers are still in a text string; use the Value function to convert it to a number before mathematical operations are performed on it.	{
		hours: "2",
		minutes: "1",
		seconds: "39",
		FullMatch: "PT2H1M39S",
		StartMatch: 1
		}

Let's drill into that last example. If you wanted to convert this string to a date/time value using the Time function, you must pass in the named submatches individually. To do this, use the With function operating on the record that **Match** returns:

Power Fx

```
With(
    Match( "PT2H1M39S", "PT(?:(?<hours>\d+)H)?(?:(?<minutes>\d+)M)?(?:(?<seconds>\d+)S)?" ),
   Time( Value( hours ), Value( minutes ), Value( seconds ) )
)
```

For these examples, add a Button control, set its **OnSelect** property to this formula, and then select the button:

Power Fx

```
Set( pangram, "The quick brown fox jumps over the lazy dog." )
```

Expand table

Formula	Description	Result

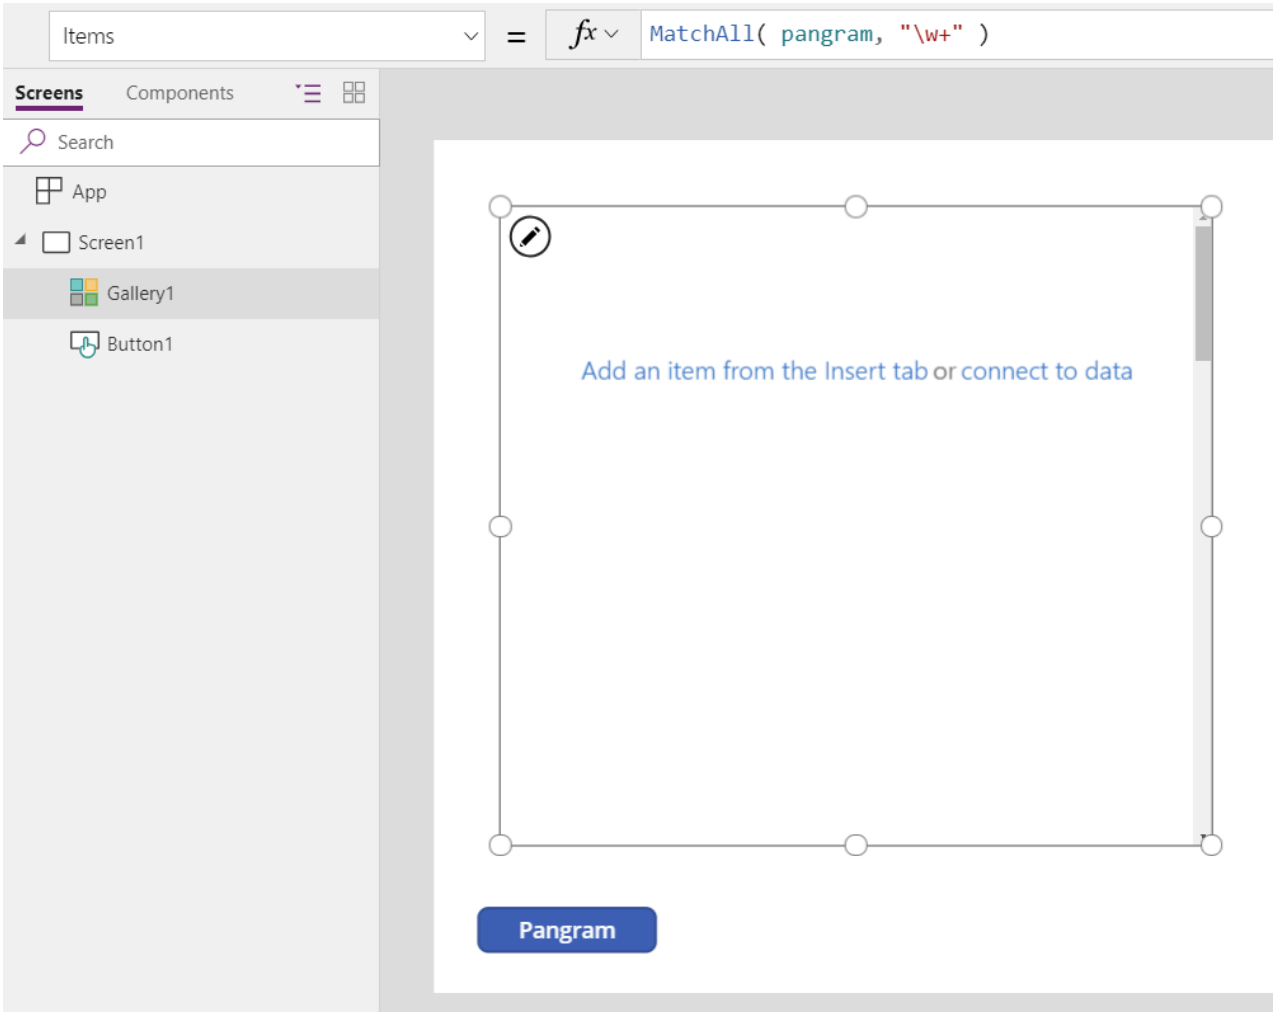
`Match( pangram, "THE", IgnoreCase )`	Find all matches of "THE" in the text string that the **pangram** variable contains. The string contains two matches, but only the first is returned because	{
		FullMatch: "The",
		StartMatch: 32
		}

<table>
<tr><th>Formula</th><th>Description</th><th>Result</th></tr>
<tr><td></td><td>you're using Match and not MatchAll.</td><td></td></tr>
<tr><td><code>MatchAll(pangram, "the")</code></td><td>Find all matches of "the" in the text string that the pangram variable contains. The test is case sensitive, so only the second instance of "the" is found.</td><td><table><tr><th>FullMatch</th><th>SubMatches</th><th>StartMatch</th></tr><tr><td>"the"</td><td>[ ]</td><td>32</td></tr></table></td></tr>
<tr><td><code>MatchAll(pangram, "the", IgnoreCase)</code></td><td>Find all matches of "the" in the text string that the pangram variable contains. In this case, the test is case insensitive, so both instances of the word are found.</td><td><table><tr><th>FullMatch</th><th>SubMatches</th><th>StartMatch</th></tr><tr><td>"The"</td><td>[ ]</td><td>1</td></tr><tr><td>"the"</td><td>[ ]</td><td>32</td></tr></table></td></tr>
<tr><td><code>MatchAll(pangram, "\b\wo\w\b")</code></td><td>Finds all three-letter words with an "o" in the middle. "brown" is excluded because it's not a three-letter word and, therefore, fails to match "\b" (word boundary).</td><td><table><tr><th>FullMatch</th><th>SubMatches</th><th>StartMatch</th></tr><tr><td>"fox"</td><td>[ ]</td><td>17</td></tr><tr><td>"dog"</td><td>[ ]</td><td>41</td></tr></table></td></tr>
<tr><td><code>Match(pangram, "\b\wo\w\b\s*(?<between>\w.+\w)\s*\b\wo\w\b")</code></td><td>Matches all the characters between "fox" and "dog".</td><td>{
between: "jumps over the lazy",
FullMatch: "fox jumps over the lazy dog",
StartMatch: 17
}</td></tr>
</table>

To see the results of **MatchAll** in a gallery:

1. In an empty screen, insert a blank vertical gallery control.
2. Set the gallery's **Items** property to **MatchAll(pangram, "\w+")** or **MatchAll(pangram, MultipleLetters)**.



3. Select "Add an item from the Insert tab" in the middle of the gallery control to select the template of the gallery.

4. Add a Label control to the gallery's template.

5. Set the label's **Text** property to **ThisItem.FullMatch**.

   The gallery is filled with each word in our example text. To see all the words on one screen, resize the gallery's template and the label control.

IsNumeric function

06/21/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Tests whether a value is numeric.

Description

The **IsNumeric** function tests whether a value is numeric. Other kinds of values include Boolean, string, table, and record.

The return value is a Boolean **true** or **false**.

Syntax

IsNumeric(*Value*)

Examples

Expand table

Formula	Description	Result
IsNumeric(1)	Evaluates if the number 1 is a number	*true*
IsNumeric("1")	Evaluates if the text "1" is a number	*true*
IsNumeric("A")	Evaluates if the text A is a number	*false*
IsNumeric(1+1)	Evaluates if the outcome of 1+1 is a number	*true*
IsNumeric("1+1")	Evaluates if the text 1+1 is a number	*false*

WeekNum and ISOWeekNum functions

Article • 04/20/2025

Expand table

Function	Applies to
ISOWeekNum	✅ Canvas apps ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Pages
WeekNum	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Returns the week number of a specific date.

Description

Use the **WeekNum** and **ISOWeekNum** functions to determine the week number of a date.

These functions differ in how they determine the first week of the year (week 1):

- **WeekNum** uses the week containing January 1 as the first week of the year. The result from this function can range from 1 to 54.
- **ISOWeekNum** uses the week containing the first Thursday of the year as the first week of the year. This follows the ISO 8601 date and time standard definition for week numbering. The result from this function can range from 1 to 53. It is possible that 52 or 53 may be returned for the first days of January since the dates could belong to the last week of the previous year.

Use the second parameter to **WeekNum** to specify which day begins a week. You can provide either an Excel code number or use the StartOfWeek enumeration:

Expand table

Excel code	StartOfWeek enumeration	Description
1, 17	**StartOfWeek.Sunday**	Week begins on Sunday. Default.
2, 11	**StartOfWeek.Monday**	Week begins on Monday.
12	**StartOfWeek.Tuesday**	Week begins on Tuesday.
13	**StartOfWeek.Wednesday**	Week begins on Wednesday.

Excel code	StartOfWeek enumeration	Description
14	**StartOfWeek.Thursday**	Week begins on Thursday.
15	**StartOfWeek.Friday**	Week begins on Friday.
16	**StartOfWeek.Saturday**	Week begins on Saturday.

ISOWeekNum always uses Monday as the start of the week. In Excel, the **WeekNum** function supports an addition code **21** that is not supported here; use **ISOWeekNum** instead.

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

Syntax

WeekNum(*DateTime* [, *StartOfWeek*])

- *DateTime* - Required. Date/Time value to operate on.
- *StartOfWeek* - Optional. Excel code or StartOfWeek enumeration that determines which day the week begins.

ISOWeekNum(*DateTime*)

- *DateTime* - Required. Date/Time value to operate on. The week always begins on Monday.

Examples

First and last calendar weeks of 2021

Expand table

Date	WeekNum(Date)	ISOWeekNum(Date)	WeekNum(Date, StartOfWeek.Wednesday)
Friday, January 1, 2021	1	53	1
Saturday, January 2, 2021	1	53	1
Sunday, January 3, 2021	2	53	1
Monday, January 4, 2021	2	1	1
Tuesday, January 5, 2021	2	1	1

Date	WeekNum(Date)	ISOWeekNum(Date)	WeekNum(Date, StartOfWeek.Wednesday)
Wednesday, January 6, 2021	2	1	2
Thursday, January 7, 2021	2	1	2
Saturday, December 25, 2021	52	51	52
Sunday, December 26, 2021	53	51	52
Monday, December 27, 2021	53	52	52
Tuesday, December 28, 2021	53	52	52
Wednesday, December 29, 2021	53	52	53
Thursday, December 30, 2021	53	52	53
Friday, December 31, 2021	53	52	53

Now, Today, IsToday, UTCNow, UTCToday, IsUTCToday functions

Article • 04/20/2025

Expand table

Functions	Applies to
Now	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Today **IsToday**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
UTCNow **UTCToday**	✅ Dataverse formula columns ✅ Power Pages

Returns the current date and time, and tests whether a date/time value is today.

> ⓘ Note
>
> PAC CLI pac power-fx commands do not support the **UTCNow**, **UTCToday**, and **IsUTCToday** functions.

Description

The **Now** function returns the current date and time as a date/time value.

The **Today** function returns the current date as a date/time value. The time portion is midnight. **Today** has the same value throughout a day, from midnight today to midnight tomorrow.

The **IsToday** function tests whether a date/time value is between midnight today and midnight tomorrow. This function returns a Boolean (**true** or **false**) value.

Now, **Today**, and **IsToday** functions work with the local time of the current user.

UTCNow, **UTCToday**, and **IsUTCToday** functions are the same as their non-UTC counterparts but work with time zone independent values and use Coordinated Universal Time (UTC).

> ⓘ Note

- **UTCNow**, **UTCToday**, and **IsUTCToday** are only available in Microsoft Dataverse for Teams formula columns, and only for time-independent fields and values.
- **Now**, **Today**, and **IsToday** are not available in Dataverse for Teams formula columns as evaluations are done without the knowledge of the current user's local time zone. More information: Work with formula table columns in Dataverse for Teams

See Date, Time, and DateTime in the data types documentation and working with dates and times for more information.

Volatile Functions

Now, **Today**, **UTCNow**, and **UTCToday** are volatile functions. These functions return a different value for each evaluation.

When used in a data flow formula, a volatile function will only return a different value if the formula in which it appears is reevaluated. If nothing else changes in the formula then it will have the same value throughout the execution of your app.

For example, a label control with **Label1.Text = Now()** will not change while your app is active. Only closing and reopening the app will result in a new value.

The function will be reevaluated if it is part of a formula in which something else has changed. For example, if we change our example to involve a slider control with **Label1.Text = DateAdd(Now(), Slider1.Value, Minutes)** then the current time is retrieved each time the Slider control's value changes and the label's text property is reevaluated.

When used in a behavior formula, volatile functions will be evaluated each time the behavior formula is evaluated. See below for an example.

Syntax

Using the user's local time

Now()

Today()

IsToday(*DateTime*)

- *DateTime* - Required. The date/time value to test.

Using Coordinated Universal Time (UTC)

UTCNow()

UTCToday()

IsUTCToday(*TimeZoneIndependentTime*)

- *TimeZoneIndependentDateTime* - Required. The time zone independent date/time value to test.

Examples

For the examples in this section, the current time is **8:58 PM** on **July 11, 2021** in the Pacific Time Zone (UTC-8) and the language is **en-us**.

Expand table

Formula	Description	Result
Text(Now(), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date and time in the user's time zone, and displays it as a string.	"07/11/2021 20:58:00"
Text(Today(), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date only, leaving the time portion as midnight, and displays it as a string.	"07/12/2021 00:00:00"
IsToday(Now())	Tests whether the current date and time is between midnight today and midnight tomorrow.	**true**
IsToday(Today())	Tests whether the current date is between midnight today and midnight tomorrow.	**true**
Text(DateAdd(Now(), 12), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date and time, adds 12 days to the result, and displays it as a string.	"07/23/2021 20:58:00"
Text(DateAdd(Today(), 12), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date, adds 12 days to the result, and displays it as a string.	"07/23/2021 00:00:00"
IsToday(DateAdd(Now(), 12))	Tests whether the current date and time, plus 12 days, is between midnight today and midnight tomorrow.	**false**
IsToday(DateAdd(Today(), 12))	Tests whether the current date, plus 12 days, is between midnight today and midnight tomorrow.	**false**
Hour(UTCNow())	Retrieves the current date and time in UTC and extracts the hour only, which is 8 hours ahead of local time.	4

Formula	Description	Result
Day(UTCToday())	Retrieves the current date only in UTC and extracts the day, which is 1 day ahead of local time.	12
IsUTCToday(UTCNow())	Tests whether the current date and time is between midnight today and midnight tomorrow, all in UTC time.	**true**
IsUTCToday(UTCToday())	Tests whether the current date is between midnight today and midnight tomorrow, all in UTC time.	**true**

Display a clock that updates in real time

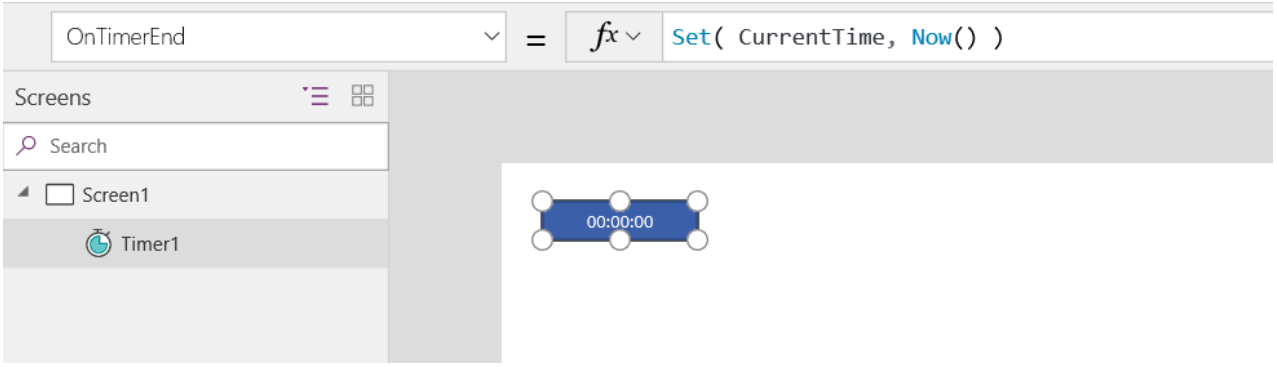
1. Add a Timer control, set its **Duration** property to **1000**, and set its **Repeat** property to **true**.

   The timer will run for one second, automatically start over, and continue that pattern.

2. Set the control's **OnTimerEnd** property to this formula:

   Set(CurrentTime, Now())

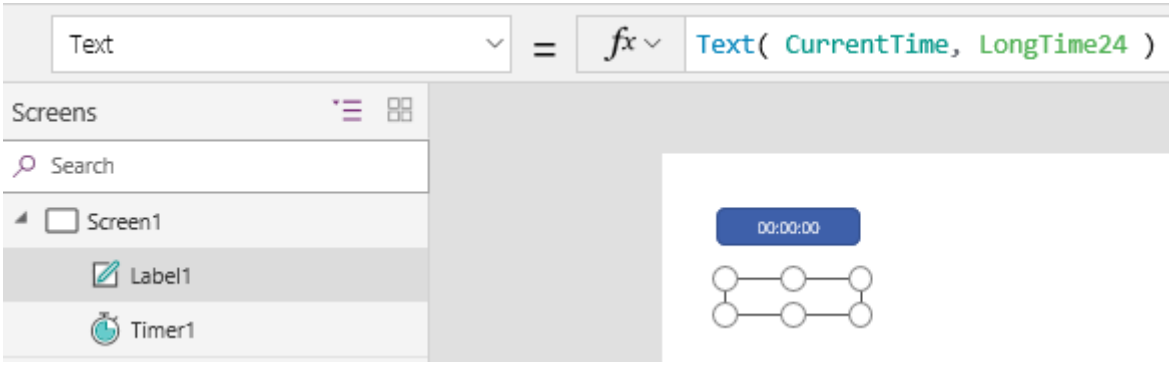
   Whenever the timer starts over (after each second), this formula sets the **CurrentTime** global variable to the current value of the **Now** function.

3. Add a Label control, and set its **Text** property to this formula:

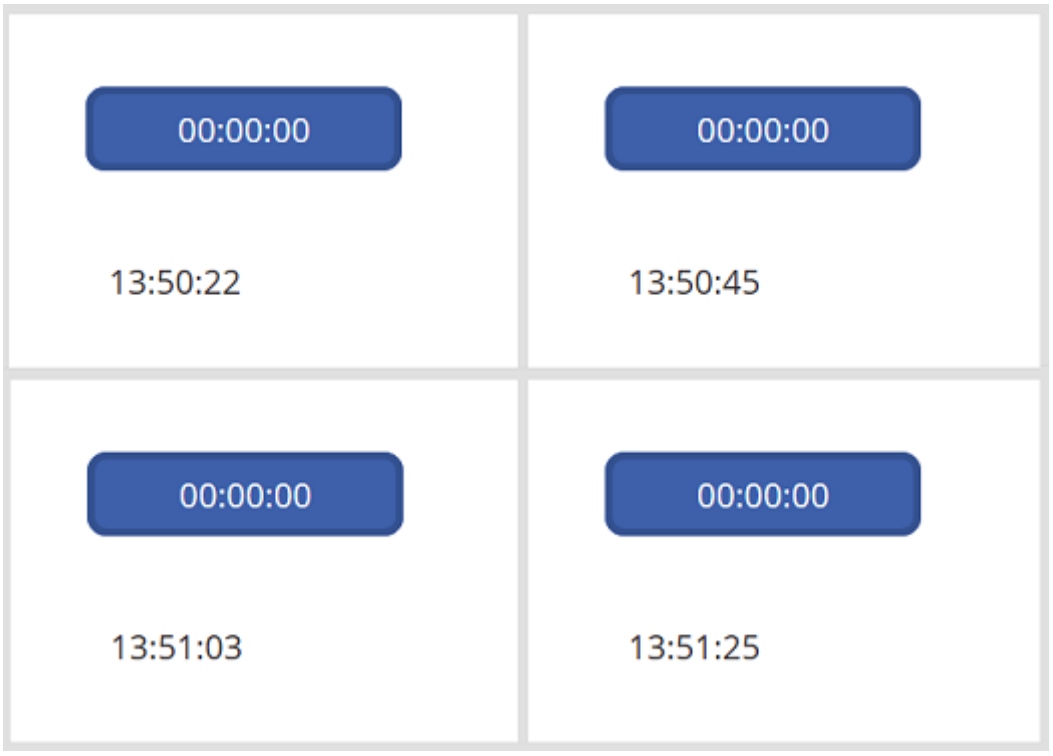
   Text(CurrentTime, LongTime24)

   Use the Text function to format the date and time however you want, or set this property to just **CurrentTime** to show hours and minutes but not seconds.



4. Preview the app by pressing F5, and then start the timer by clicking or tapping it.

   The label continually shows the current time, down to the second.



5. Set the timer's **AutoStart** property to **true** and its **Visible** property to **false**.

   The timer is invisible and starts automatically.

6. Set the screen's OnStart property so that the **CurrentTime** variable has a valid value, as in this example:

   Set(CurrentTime, Now())

   The label appears as soon as the app starts (before the timer runs for a full second).

AsType and IsType functions

06/19/2025

Expand table

Function	Applies to
AsType	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
IsType	✅ Canvas apps ✅ Copilot Studio ✅ Model-driven apps ✅ Dataverse functions ✅ Power Pages

Checks if a record reference is a specific table type (**IsType**) and treats the reference as that type (**AsType**).

> ⓘ **Note**
>
> PAC CLI pac power-fx commands don't support **IsType**.

Description

The **AsType** and **IsType** functions can be used to convert record references (for example polymorphic lookups in Dataverse) and dynamic values to typed values that can be used directly.

Record References

Read Understand record references and polymorphic lookups for a broader introduction and more details.

A lookup field usually refers to records in a particular table. Because the table type is well established, access the fields of the lookup using simple dot notation. For example, **First(Accounts).'Primary Contact'.'Full Name'** walks from the **Accounts** table to the **Primary Contact** record in the **Contacts** table and extracts the **Full Name** field.

Microsoft Dataverse also supports polymorphic lookup fields, which can refer to records from a set of tables, as in these examples.

Expand table

Lookup field	Can refer to
Owner	**Users** or **Teams**
Customer	**Accounts** or **Contacts**
Regarding	**Accounts**, **Contacts**, **Knowledge Articles**, etc.

In canvas-app formulas, use record references to work with polymorphic lookups. Because a record reference can refer to different tables, you can't know which fields are available at runtime when you write a formula. The *Record.Field* notation isn't available. These formulas need to adapt to the records that the app encounters when it runs.

The **IsType** function checks if a record reference refers to a specific table type. The function returns a Boolean TRUE or FALSE.

The **AsType** function treats a record reference as a specific table type, also called *casting*. You use the result as if it's a record of the table and use the *Record.Field* notation to access all the fields of that record. If the reference isn't of the specific type, an error occurs.

Use these functions together to first check the table type of a record and then treat it as a record of that type so the fields are available:

Power Fx

```
If( IsType( First( Accounts ).Owner, Users ),
    AsType( First( Accounts ).Owner, Users ).'Full Name',
    AsType( First( Accounts ).Owner, Teams ).'Team Name'
)
```

You need these functions only if you access the fields of a record reference. For example, you use record references in the **Filter** function without **IsType** or **AsType**:

Power Fx

```
Filter( Accounts, Owner = First( Users ) )
```

Similarly, you can use record references with the **Patch** function:

Power Fx

```
Patch( Accounts, First( Accounts ), { Owner: First( Teams ) } )
```

When you use these functions in a record context, such as within a **Gallery** or **Edit form** control, you might need the global disambiguation operator to reference the table type. For

example, this formula works for a gallery that displays a list of contacts where **Company Name** is a **Customer** lookup:

```
Power Fx
```

```
If( IsType( ThisItem.'Company Name', Accounts ),
    AsType( ThisItem.'Company Name', Accounts ).'Account Name',
    AsType( ThisItem.'Company Name', Contacts ).'Full Name'
)
```

For both functions, specify the type by using the name of the data source connected to the table. For the formula to work, add a data source to the app for any types you want to check or cast. For example, add the **Users** table as a data source if you want to use **IsType** and **AsType** with an **Owner** lookup and records from that table. Add only the data sources you use in your app; you don't need to add all the tables that a lookup could reference.

If the record reference is *blank*, **IsType** returns FALSE, and **AsType** returns *blank*. All fields of a *blank* record are also *blank*.

Dynamic values

> **Important**
>
> - Using **AsType** and **IsType** with **Dynamic** values is an experimental feature.
> - Experimental features aren't meant for production use and might not be complete. These features are available before an official release so that you can get early access and provide feedback. More information: Understand experimental, preview, and retired features in canvas apps
> - The behavior that this article describes is available only when the **User-defined types** experimental feature in Settings > Upcoming features > Experimental is turned on (it's off by default).
> - Your feedback is valuable to us. Let us know what you think in the Power Apps experimental features community forum.

A **Dynamic** value from a web API or the [**ParseJSON** function] needs to be converted to a specific typed value before you can use it in Power Fx. Here are some options:

1. Implicitly type the field at the point you use it. For example, an object converts to a number if you use it with the `+` operator, if it can be converted to a number. This option can cause unexpected conversions and can't convert records and tables as a whole.

2. Explicitly type each field individually with the **Decimal**, **Text**, **DateTime**, **GUID**, and other type constructor functions. This option is the most invasive to your formulas because you need to do each field separately.
3. Explicitly type JSON with the second argument to the **ParseJSON** function. This option is easy and avoids needing the **Dynamic** value.
4. Explicitly type a **Dynamic** value using the **AsType** function. You can also check the type before you try the conversion with the **IsType** function.

Syntax

AsType(*RecordReference*, *TableType*)

- *RecordReference* - Required. A record reference, often a lookup field that refers to a record in any of several tables.
- *TableType* - Required. The specific table to cast the record to.

AsType(*DynamicValue*, *TypeSpecification*)

- *DynamicValue* - Required. A dynamic value from the **ParseJSON** function or API call.
- *TypeSpecification* - Required. A type name or type specification you define with the **Type** function.

IsType(*RecordReference*, *TableType*)

- *RecordReference* - Required. A record reference, often a lookup field that can refer to a record in any of multiple tables.
- *TableType* - Required. The specific table to test for.

IsType(*DynamicValue*, *TypeSpecification*)

- *DynamicValue* - Required. A dynamic value from the **ParseJSON** function or an API call.
- *TypeSpecification* - Required. A type name or type specification defined with the **Type** function.

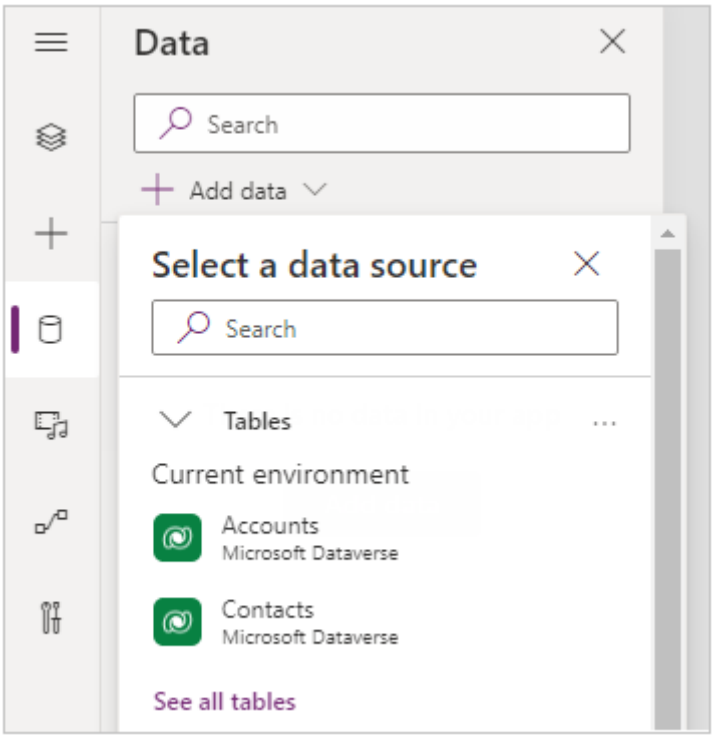
Examples

Record References

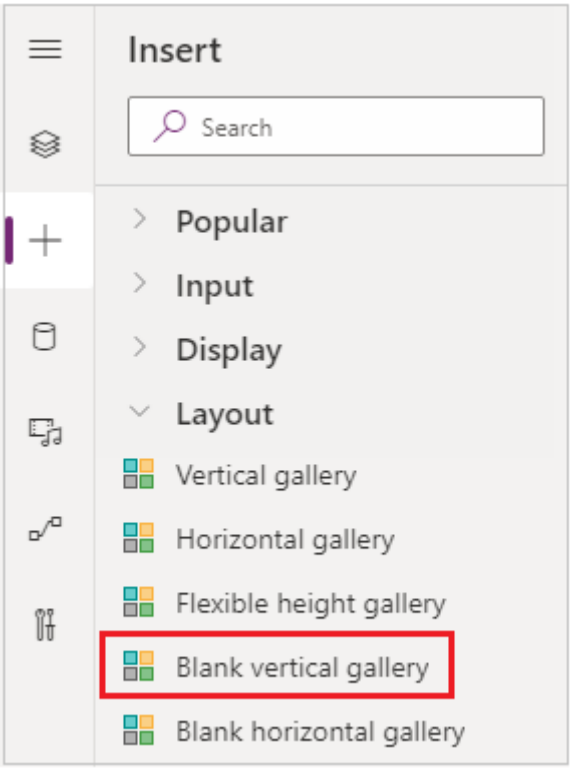
Understand record references and polymorphic lookups contains extensive examples.

1. Create a blank canvas app for tablets.

2. On the left pane, select **Data** > **Add data**, and then add **Accounts** and **Contacts** tables.

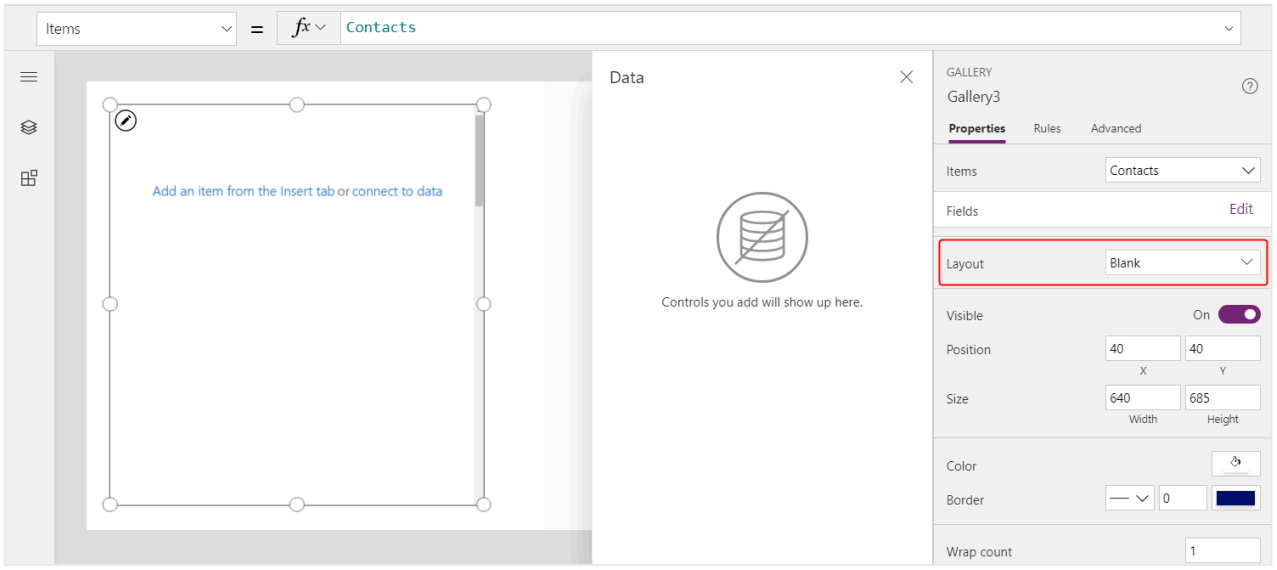


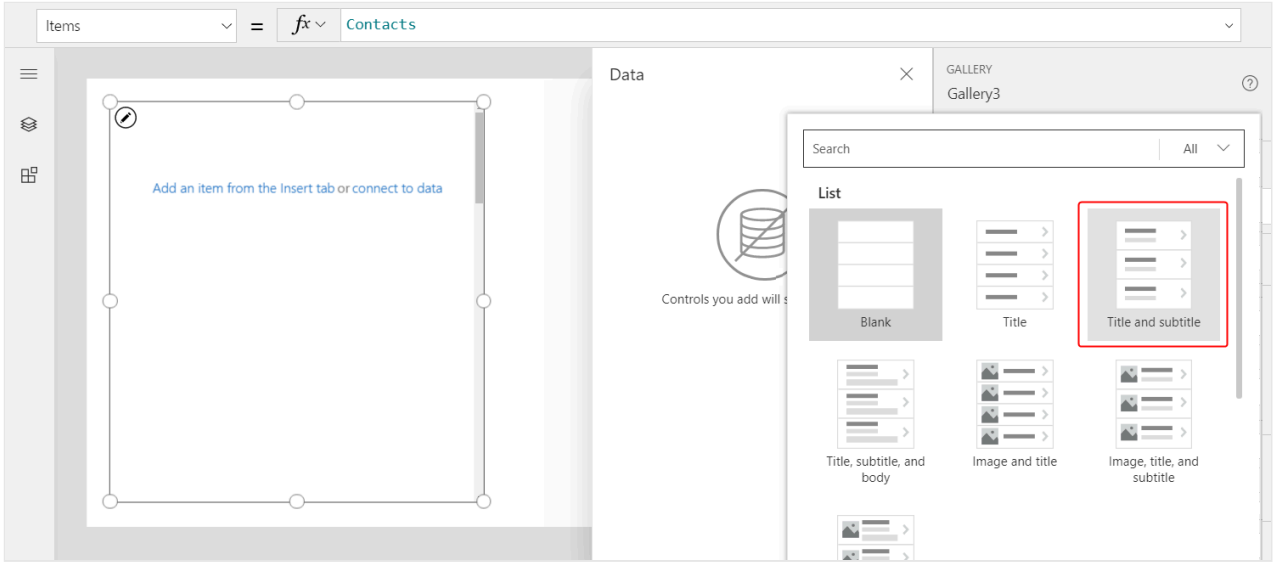
3. On the left pane, select + (Insert) > **Layout** > **Blank vertical gallery**.



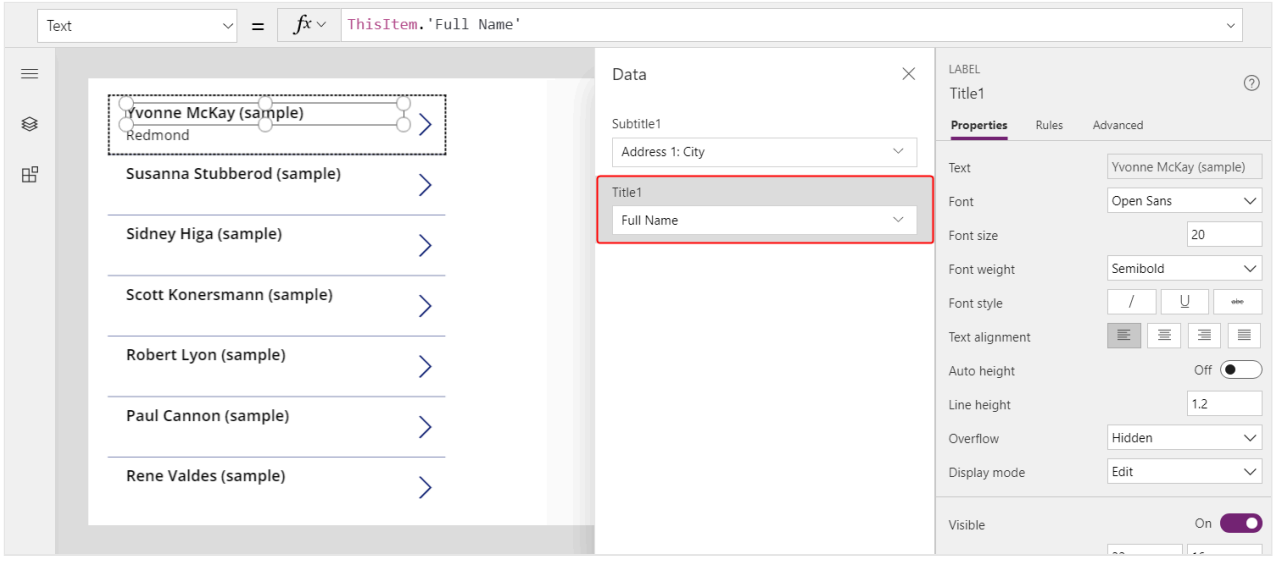
4. Select **Connect to data**, and then select **Contacts** as the data source.

5. Set the gallery layout to **Title and subtitle**.

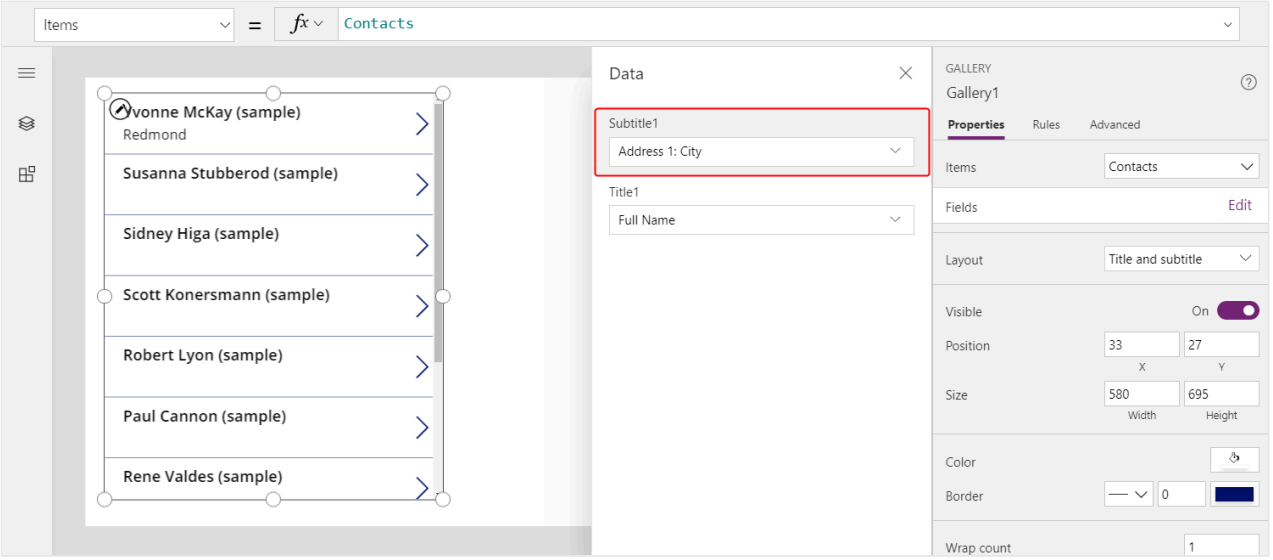




6. In the **Data** pane, open the **Title1** list, and then select **Full Name**.



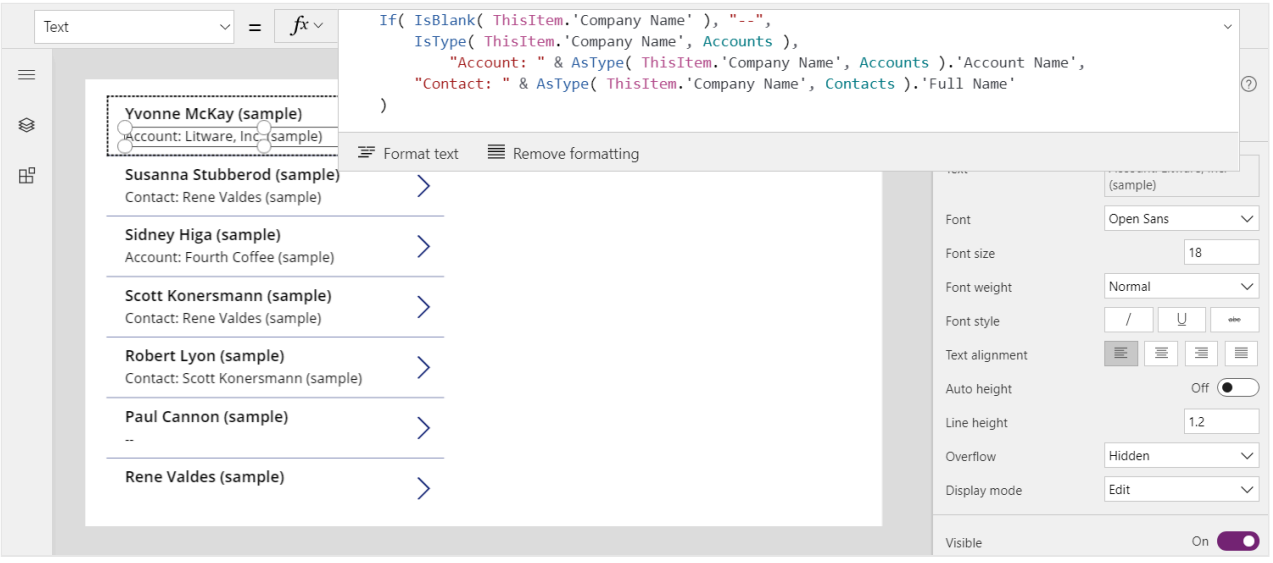
7. Select the **Subtitle1** label control.



8. Set the **Text** property of **Subtitle1** to this formula:

Power Fx

```
If( IsBlank( ThisItem.'Company Name' ), "--",
    IsType( ThisItem.'Company Name', Accounts ),
        "Account: " & AsType( ThisItem.'Company Name', Accounts ).'Account
Name',
    "Contact: " & AsType( ThisItem.'Company Name', Contacts ).'Full Name'
)
```



The subtitle in the gallery shows these values:

- "--" if the '**Company Name**' is *blank*.
- "Account: " and the **Account Name** field from the **Accounts** table if the **Company Name** field refers to an account.
- "Contact: " and the **Full Name** field from the **Contacts** table if the **Company Name** field refers to a contact.

Your results can differ because the sample data can be modified to show more types of results.

Dynamic values

The following examples show a simple JSON record interpreted in various ways by **ParseJSON**, **AsType**, and **IsType** in the Pac CLI Power Fx REPL.

In this first example, no type information is provided to **ParseJSON**, so it returns a dynamic value.

Power Apps

```
>> Set( rec, ParseJSON( "{""a"":1}" ) )
rec: <Dynamic: Use Value, Text, Boolean, or other functions to establish the type>
```

The field is implicitly converted to a number when used in a numerical context.

Power Apps

```
>> 1 + rec.a
2
```

As an alternative, this example explicitly converts the record to a typed Power Fx record with the second argument to **ParseJSON**.

Power Apps

```
>> ParseJSON( "{""a"":1}", Type( {a: Number} ) )
{a:1}
```

And another alternative, this example explicitly converts the record to a typed Power Fx record using **AsType**.

Power Apps

```
>> AsType( ParseJSON( "{""a"":1}" ), Type( {a: Number} ) )
{a:1}
```

Finally, if you aren't sure, this example tests the type before converting it with the **IsType** function.

Power Apps

```
>> IsType( ParseJSON( "{""a"":1}" ), Type( {a: Number} ) )
true
```

Now, Today, IsToday, UTCNow, UTCToday, IsUTCToday functions

Article • 04/20/2025

Expand table

Functions	Applies to
Now	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Today **IsToday**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
UTCNow **UTCToday**	✅ Dataverse formula columns ✅ Power Pages

Returns the current date and time, and tests whether a date/time value is today.

> ⓘ Note
>
> PAC CLI pac power-fx commands do not support the **UTCNow**, **UTCToday**, and **IsUTCToday** functions.

Description

The **Now** function returns the current date and time as a date/time value.

The **Today** function returns the current date as a date/time value. The time portion is midnight. **Today** has the same value throughout a day, from midnight today to midnight tomorrow.

The **IsToday** function tests whether a date/time value is between midnight today and midnight tomorrow. This function returns a Boolean (**true** or **false**) value.

Now, **Today**, and **IsToday** functions work with the local time of the current user.

UTCNow, **UTCToday**, and **IsUTCToday** functions are the same as their non-UTC counterparts but work with time zone independent values and use Coordinated Universal Time (UTC).

> ⓘ Note

- **UTCNow**, **UTCToday**, and **IsUTCToday** are only available in Microsoft Dataverse for Teams formula columns, and only for time-independent fields and values.
- **Now**, **Today**, and **IsToday** are not available in Dataverse for Teams formula columns as evaluations are done without the knowledge of the current user's local time zone. More information: Work with formula table columns in Dataverse for Teams

See Date, Time, and DateTime in the data types documentation and working with dates and times for more information.

Volatile Functions

Now, **Today**, **UTCNow**, and **UTCToday** are volatile functions. These functions return a different value for each evaluation.

When used in a data flow formula, a volatile function will only return a different value if the formula in which it appears is reevaluated. If nothing else changes in the formula then it will have the same value throughout the execution of your app.

For example, a label control with **Label1.Text = Now()** will not change while your app is active. Only closing and reopening the app will result in a new value.

The function will be reevaluated if it is part of a formula in which something else has changed. For example, if we change our example to involve a slider control with **Label1.Text = DateAdd(Now(), Slider1.Value, Minutes)** then the current time is retrieved each time the Slider control's value changes and the label's text property is reevaluated.

When used in a behavior formula, volatile functions will be evaluated each time the behavior formula is evaluated. See below for an example.

Syntax

Using the user's local time

Now()

Today()

IsToday(*DateTime*)

- *DateTime* - Required. The date/time value to test.

Using Coordinated Universal Time (UTC)

UTCNow()

UTCToday()

IsUTCToday(*TimeZoneIndependentTime*)

- *TimeZoneIndependentDateTime* - Required. The time zone independent date/time value to test.

Examples

For the examples in this section, the current time is **8:58 PM** on **July 11, 2021** in the Pacific Time Zone (UTC-8) and the language is **en-us**.

Expand table

Formula	Description	Result
Text(Now(), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date and time in the user's time zone, and displays it as a string.	"07/11/2021 20:58:00"
Text(Today(), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date only, leaving the time portion as midnight, and displays it as a string.	"07/12/2021 00:00:00"
IsToday(Now())	Tests whether the current date and time is between midnight today and midnight tomorrow.	**true**
IsToday(Today())	Tests whether the current date is between midnight today and midnight tomorrow.	**true**
Text(DateAdd(Now(), 12), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date and time, adds 12 days to the result, and displays it as a string.	"07/23/2021 20:58:00"
Text(DateAdd(Today(), 12), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date, adds 12 days to the result, and displays it as a string.	"07/23/2021 00:00:00"
IsToday(DateAdd(Now(), 12))	Tests whether the current date and time, plus 12 days, is between midnight today and midnight tomorrow.	**false**
IsToday(DateAdd(Today(), 12))	Tests whether the current date, plus 12 days, is between midnight today and midnight tomorrow.	**false**
Hour(UTCNow())	Retrieves the current date and time in UTC and extracts the hour only, which is 8 hours ahead of local time.	4

Formula	Description	Result
Day(UTCToday())	Retrieves the current date only in UTC and extracts the day, which is 1 day ahead of local time.	12
IsUTCToday(UTCNow())	Tests whether the current date and time is between midnight today and midnight tomorrow, all in UTC time.	**true**
IsUTCToday(UTCToday())	Tests whether the current date is between midnight today and midnight tomorrow, all in UTC time.	**true**

Display a clock that updates in real time

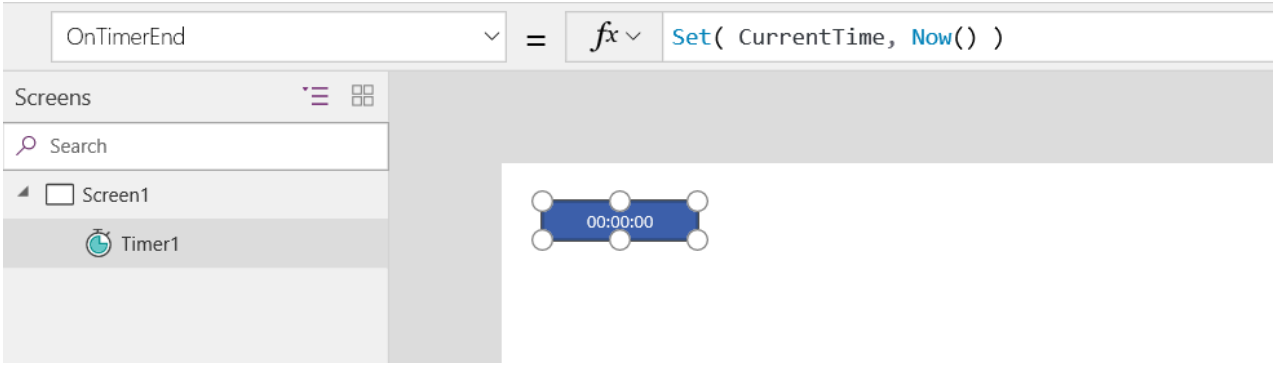
1. Add a Timer control, set its **Duration** property to **1000**, and set its **Repeat** property to **true**.

   The timer will run for one second, automatically start over, and continue that pattern.

2. Set the control's **OnTimerEnd** property to this formula:

   Set(CurrentTime, Now())

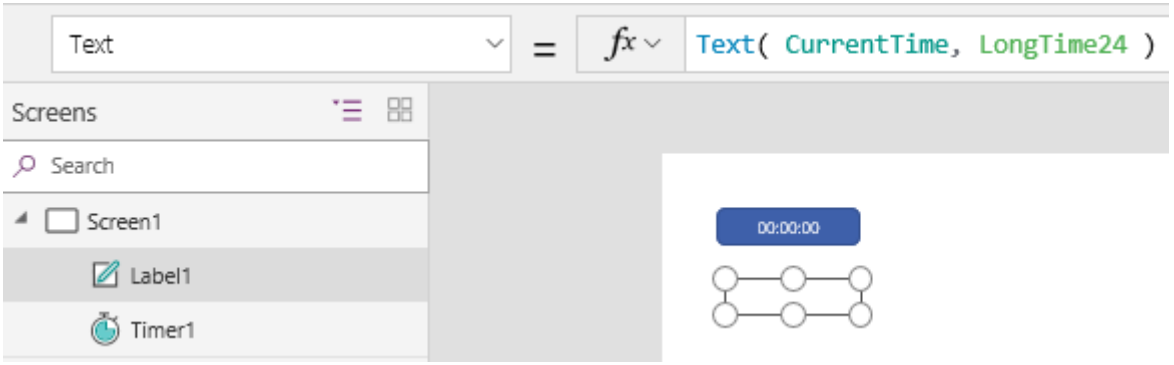
   Whenever the timer starts over (after each second), this formula sets the **CurrentTime** global variable to the current value of the **Now** function.

3. Add a Label control, and set its **Text** property to this formula:

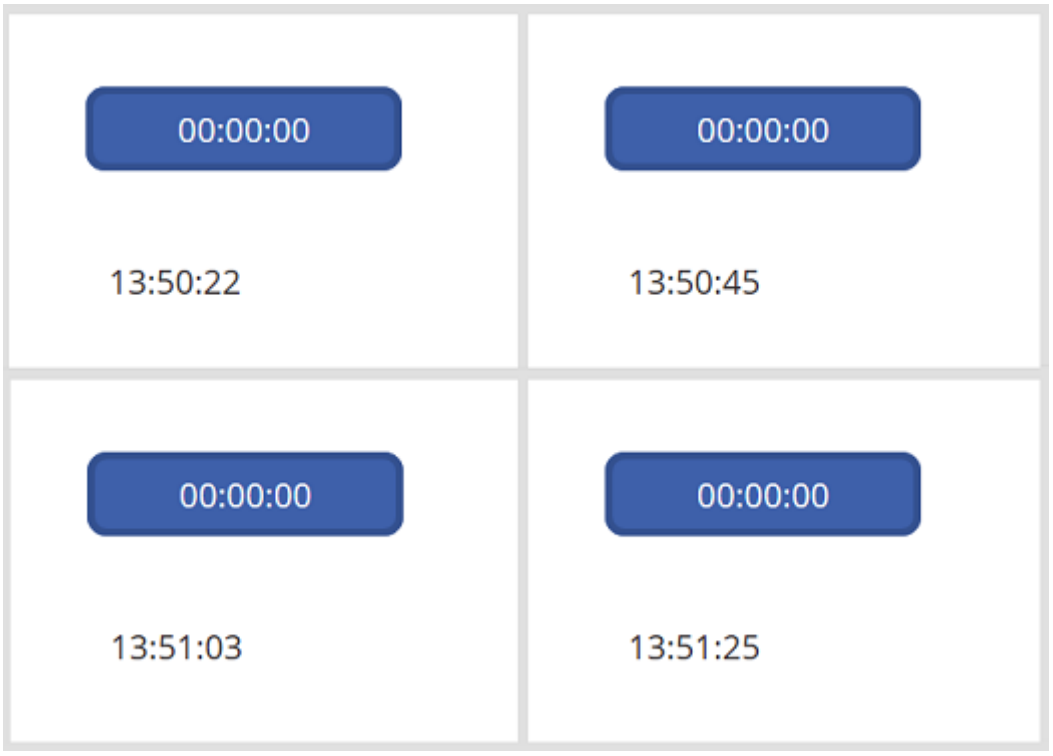
   Text(CurrentTime, LongTime24)

   Use the Text function to format the date and time however you want, or set this property to just **CurrentTime** to show hours and minutes but not seconds.



4. Preview the app by pressing F5, and then start the timer by clicking or tapping it.

   The label continually shows the current time, down to the second.



5. Set the timer's **AutoStart** property to **true** and its **Visible** property to **false**.

   The timer is invisible and starts automatically.

6. Set the screen's OnStart property so that the **CurrentTime** variable has a valid value, as in this example:

   Set(CurrentTime, Now())

   The label appears as soon as the app starts (before the timer runs for a full second).

JSON function

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Generates a JSON text string for a table, a record, or a value.

Description

The **JSON** function returns the JavaScript Object Notation (JSON) representation of a data structure as text so that it's suitable for storing or transmitting across a network. [ECMA-404](https://www.ecma-international.org/publications/files/ECMA-ST/ECMA-404.pdf) and IETF RFC 8259 describe the format, which is widely used by JavaScript and other programming languages.

Canvas apps support the data types that this table lists with details about their text representation:

Expand table

Data type	Description	Result example
Boolean	*true* or *false*.	`true`
Color	String that contains the 8-digit hexadecimal representation for the color. This representation takes the format *#rrggbbaa*, where *rr* is the red component, *gg* is green, *bb* is blue, and *aa* is the alpha channel. For the alpha channel, **00** is fully transparent, and **ff** is fully opaque. You can pass the string to the **ColorValue** function.	`"#102030ff"`
Currency	Number that uses the appropriate decimal separator for the user's language. Scientific notation is used if needed.	`1.345`
Date	String that contains the date in ISO 8601 **yyyy-mm-dd** format.	`"2019-03-31"`
DateTime	String that contains an ISO 8601 date/time. Date/time values are in UTC, as the ending "Z" indicates.	`"2019-03-31T22:32:06.822Z"`

Data type	Description	Result example
GUID	String that contains the GUID value. Letters are lowercase.	`"751b58ac-380e-4a04-a925-9f375995cc40"`
Image, Media	If **JSONFormat.IncludeBinaryData** is specified, media files are encoded in a string. Web references that use the http: or https: URL scheme aren't modified. References to in-memory binary data are encoded with the "data:*mimetype*; base64,..." format. In-memory data includes images that users capture by using the **Camera** control and any other references with the appres: and blob: URL schemes.	`"..."`
Number	Number that uses the appropriate decimal separator for the user's language. Scientific notation is used if needed.	`1.345`
Option set	Numeric value of the choice, not the label that's used for display. The numeric value is used because it's language independent.	`1001`
Time	String that contains an ISO 8601 *hh:mm:ss.fff* format.	`"23:12:49.000"`
Record	Comma-delimited list, between **{** and **}**, of fields and their values. This notation resembles that for records in canvas apps, but the name is always between double quotation marks. This format doesn't support records that are based on many-to-one relationships.	`{ "First Name": "Fred", "Age": 21 }`
Table	Comma-delimited list, between **[** and **]**, of records. This format doesn't support tables that are based on one-to-many relationships. Use the **JSONFormat.FlattenValueTables** option to remove the record for single column tables with the column named **Value**.	`[ { "First Name": "Fred", "Age": 21 }, { "First Name": "Jean", "Age": 20 } ]`
Two option	Boolean value of the two option, *true* or *false*, not the label that's used for display. The Boolean value is used because it's language independent.	`false`

Data type	Description	Result example
Hyperlink, Text	String between double quotation marks. The function escapes embedded double-quotation marks with a backslash, replaces newlines with "\n", and makes other standard JavaScript replacements.	`"This is a string."`

Specify the optional *Format* argument to control how readable the result is and how unsupported and binary data types are handled. By default, the output is as compact as possible with no unnecessary spaces or newlines, and unsupported data types and binary data aren't allowed. You can combine multiple formats if you specify the **&** operator.

Expand table

JSONFormat enum	Description
JSONFormat.Compact	Default. The output is as compact as possible with no added spaces or newlines.
JSONFormat.FlattenValueTables	As a Value table, `[1,2,3]` notation results in a table containing records where each record has a single **Value** column. In JSON, that same notation represents an array of three numbers. To make interoperability between the two easier, this option flattens a Power Fx Value table to a JSON friendly array instead of an array of records.
JSONFormat.IndentFour	To improve readability, the output contains a newline for each column and nesting level and uses four spaces for each indentation level.
JSONFormat.IncludeBinaryData	The result includes image, video, and audio-clip columns. This format can dramatically increase the result's size and degrade your app's performance.
JSONFormat.IgnoreBinaryData	The result doesn't include image, video, or audio-clip columns. If you specify neither **JSONFormat.IncludeBinaryData** nor **JSONFormat.IgnoreBinaryData**, the function produces an error if it encounters binary data.
JSONFormat.IgnoreUnsupportedTypes	Unsupported data types are allowed, but the result won't include them. By default, unsupported data types produce an error.

Use the **ShowColumns** and **DropColumns** functions to control which data the result includes and to remove unsupported data types.

Because **JSON** can be both memory and compute intensive, you can use this function only in behavior functions. You can capture the result from **JSON** into a variable, which you can then use in data flow.

If a column has both a display name and a logical name, the result contains the logical name. Display names reflect the language of the app user and are, therefore, inappropriate for data transfer to a common service.

Syntax

JSON(*DataStructure* [, *Format*])

- *DataStructure* – Required. The data structure to convert to JSON. Tables, records, and primitive values are supported, arbitrarily nested.
- *Format* - Optional. **JSONFormat** enum value. The default value is **JSONFormat.Compact**, which doesn't add newlines or spaces and blocks binary data and unsupported columns.

Examples

Hierarchical data

1. Insert a **Button** control, and set its **OnSelect** property to this formula.

```
Power Apps
```

```
ClearCollect( CityPopulations,
    { City: "London",    Country: "United Kingdom", Population: 8615000
},
    { City: "Berlin",    Country: "Germany",        Population: 3562000
},
    { City: "Madrid",    Country: "Spain",          Population: 3165000
},
    { City: "Hamburg",   Country: "Germany",        Population: 1760000
},
    { City: "Barcelona", Country: "Spain",          Population: 1602000
},
    { City: "Munich",    Country: "Germany",        Population: 1494000
}
);
```

```
ClearCollect( CitiesByCountry, GroupBy( CityPopulations, "Country",
"Cities" ) )
```

2. Select the button while holding down the Alt key.

   The **CitiesByCountry** collection is created with this data structure, which you can show by selecting **Collections** on the **File** menu and then selecting the name of the collection.

Cities	Country
City: "London", Population: 8,615,000	"United Kingdom"
City: "Berlin", Population: 3,562,000 City: "Hamburg", Population: 1,760,000 City: "Munich", Population: 1,494,000	"Germany"
City: "Madrid", Population: 3,165,000 City: "Barcelona", Population: 1,602,000	"Spain"

   You can also show this collection by selecting **Settings** > **Upcoming features** > **Enable formula bar result view**, selecting the name of the collection in the formula bar, and then selecting the down arrow next to the name of the collection under the formula bar.

```
ClearCollect( CityPopulations,
    { City: "London",    Country: "United Kingdom", Population: 8615000 },
    { City: "Berlin",    Country: "Germany",        Population: 3562000 },
    { City: "Madrid",    Country: "Spain",          Population: 3165000 },
    { City: "Hamburg",   Country: "Germany",        Population: 1760000 },
    { City: "Barcelona", Country: "Spain",          Population: 1602000 },
    { City: "Munich",    Country: "Germany",        Population: 1494000 }
);
ClearCollect( CitiesByCountry, GroupBy( CityPopulations, "Country", "Cities" ) )
```

CitiesByCountry | Data type: **Table**

Cities	Country
[Table]	United Kingdom
[Table]	Germany
[Table]	Spain

3. Insert another button, and set its **OnSelect** property to this formula:

```
Power Apps

Set( CitiesByCountryJSON, JSON( CitiesByCountry ) )
```

   This formula sets the global variable **CitiesByCountryJSON** to the JSON representation for **CitiesByCountry**.

4. Select the button while holding down the Alt key.

5. Insert a **Label** control, and set its **Text** property to this variable.

```
Power Apps

CitiesByCountryJSON
```

   The label shows this result, all on a single line with no spaces, suitable for transmission across a network:

```
JSON

[
  {
    "Cities": [{ "City": "London", "Population": 8615000 }],
    "Country": "United Kingdom"
  },
  {
    "Cities": [
      { "City": "Berlin", "Population": 3562000 },
      { "City": "Hamburg", "Population": 1760000 },
      { "City": "Munich", "Population": 1494000 }
    ],
    "Country": "Germany"
  },
  {
    "Cities": [
      { "City": "Madrid", "Population": 3165000 },
      { "City": "Barcelona", "Population": 1602000 }
    ],
    "Country": "Spain"
  }
]
```

6. Change the second button's formula to make the output more readable.

```
Power Apps
```

```
Set( CitiesByCountryJSON, JSON(CitiesByCountry, JSONFormat.IndentFour
))
```

7. Select the second button while holding down the Alt key.

   The label shows the more readable result.

JSON

```
[
  {
    "Cities": [
      {
        "City": "London",
        "Population": 8615000
      }
    ],
    "Country": "United Kingdom"
  },
  {
    "Cities": [
      {
        "City": "Berlin",
        "Population": 3562000
      },
      {
        "City": "Hamburg",
        "Population": 1760000
      },
      {
        "City": "Munich",
        "Population": 1494000
      }
    ],
    "Country": "Germany"
  },
  {
    "Cities": [
      {
        "City": "Madrid",
        "Population": 3165000
      },
      {
        "City": "Barcelona",
        "Population": 1602000
      }
    ],
    "Country": "Spain"
  }
]
```

Images and media in base64

1. Add an **Image** control.

   This control brings **SampleImage** with it.

2. Add a **Button** control, and set its **OnSelect** property to this formula.

   Power Apps

   ```
   Set( ImageJSON, JSON( SampleImage, JSONFormat.IncludeBinaryData ) )
   ```

3. Select the button while holding down the Alt key.

4. Add a label, and set its **Text** property to this variable.

   Power Apps

   ```
   ImageJSON
   ```

5. Resize the control and reduce the font size as needed to show most of the result.

   The label shows the text string that the **JSON** function captured.

   JSON

   ```
   "

   ```

Value tables

This formula:

Power Apps

```
JSON( [1,2,3] )
```

produces the text string **[{"Value":1},{"Value":2},{"Value":3}]**.

The same formula with the JSONFormat.FlattenValueTables option:

```
Power Apps
JSON( [1,2,3], JSONFormat.FlattenValueTables )
```

produces the text string **[1,2,3]**.

Note that the FlattenValueTables option has no impact when using JSON with the **CityPopulations** or **CitiesByCountry** collections as these tables are not Value tables. A Value table has a single column and it must be named "Value".

Language function

10/10/2025

Applies to: Canvas apps Copilot Studio Desktop flows Power Platform CLI Dataverse functions Power Pages

Returns the language tag of the current user.

Description

The **Language** function returns the language, script, and region of the current user as a language tag.

Use the language information to tailor your app across locales. For example, if you're creating an app that is used in Italy and France, you can use **Language** to automatically display Italian and French strings to your users in those different locations.

Language tags

A *language tag* can be in one of three formats:

Expand table

Return value	Description
"***lg-RE***"	*lg* is the two character abbreviation for the language and *RE* is the two character abbreviation for the region. It's the most common return type. For example, "en-GB" is returned for United Kingdom.
"***lg***"	*lg* is the two character abbreviation for the language. It's the format used when Power Apps has information about the language, but doesn't have information for the specific region.
"***lg-scrp-RE***"	*lg* is the two character abbreviation for the language, *scrp* is the four character abbreviation for the script, and *RE* is the two character abbreviation for the region.

Power Apps uses the IETF BCP-47 language tag format.

To see the list of supported language tags, type **Value("1",)** in the formula bar or advanced view and scroll through the list of locales suggested for the second argument.

The **Text** and **Value** functions also use language tags. Use these functions for translating to and from text strings in a globally aware manner. When passing a language tag to these functions

and the region wouldn't make a difference, you can use just the language portion of the tag.

Syntax

Language()

Examples

User's locale

It's assumed that the host operating system and/or browser are using the default locale for the location.

Expand table

Formula	Location	Return Value
Language()	Lisbon, Portugal	"pt-PT"
Language()	Rio de Janeiro, Brazil	"pt-BR"
Language()	Atlanta, USA	"en-US"
Language()	Manchester, United Kingdom	"en-GB"
Language()	Paris, France	"fr-FR"
Language()	Roseau, Dominica	"en"
Language()	Belgrade, Serbia	"sr-cyrl-RS" or "sr-latn-RS," depending on the user's system settings

Localization table

A simple approach to localization is to create an Excel spreadsheet mapping an author defined **TextID** to a translated text for the user's language. Although you could use a collection or any other data source for this table, we chose Excel because it's easy to edit and manage outside of the app by translators.

1. Create the following table in Excel:

TextID	LanguageTag	LocalizedText
"Hello"	"it"	"Ciao"
"Hello"	"fr"	"Salut"
"Hello"	*blank*	"Hello"
"Goodbye"	"it"	"Arrivederci"
"Goodbye"	"fr"	"Au revoir"
"Goodbye"	*blank*	"Goodbye"

The entry with *blank* for the **Language** column is used as the default if there's no specific text string found for a given language. This entry must appear after all other entries for a given **TextID**.

For our purposes, we only need to look at the language of the locale and not the region. If regional considerations were important, we could included the full language tag value in the table above.

2. Use the **Insert** ribbon, **Table** command, to make this into a proper Excel table. By default, it's named **Table1** but you can name it whatever you like with the **Table Tools/Design** ribbon and the **Table Name:** text box on the far left hand side.

3. Save the Excel file to your local file system.

4. In Power Apps, in the right-hand pane, click, or tap the **Data Sources** tab, and then click or tap **Add data source**.

5. Click or tap **Add static data to your app**, click, or tap the Excel file that you saved, and then click or tap **Open**.

6. Select the table that you created, and then click, or tap **Connect**.

In your app, wherever you used the text **"Hello"** before, use this formula instead:

- **LookUp(Table1, TextID = "Hello" && (LanguageTag = Left(Language(), 2) || IsBlank(LanguageTag))).LocalizedText**

This formula will lookup the appropriate **LocalizedText** value for the language of the user, and if that isn't found, will fall back on the default *blank* version.

Translated strings in other languages could be longer than they're in your language. In many cases, the labels and other elements that display the strings in your user interface are needed to be wider to accommodate.

Translation service

You can translate text on demand using a translation service, such as the Microsoft Translator service:

1. In Power Apps, in the right-hand pane, click or tap the **Data Sources** tab, and then click or tap **Add data source**.
2. Click or tap **Microsoft Translator**.

In your app, wherever you would have used the text **"Hello"** before, use this formula instead:

- **MicrosoftTranslator.Translate("Hello", Language())**

The Microsoft Translator service uses the same language tags that the **Language** function returns.

This approach comes with some drawbacks when compared to the previous example which utilized a pretranslated table of text strings:

- The translation takes time to complete, requiring a call to a service across the network. It results in a lag to see the translated text in your app.
- The translation is mechanical and may not be what you anticipate or be the best choice for the situation within your app.

First, FirstN, Index, Last, and LastN functions

04/20/2025

Applies to: ✅ Canvas apps ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Returns the first, last, or a specific record, or a set of first or last records, from a table.

Description

The **First** function returns the first record of a table.

The **FirstN** function returns the first set of records of a table; the second argument specifies the number of records to return.

The **Last** function returns the last record of a table.

The **LastN** function returns the last set of records of a table; the second argument specifies the number of records to return.

The **Index** function returns a record of a table based on its ordered position in the table. Record numbering begins with 1 so `First( table )` returning the same record as `Index( table, 1 )`. **Index** returns an error if the requested record index is less than 1, greater than the number of records in the table, or the table is empty.

First, **Index**, and **Last** return a single record. **FirstN** and **LastN** return a table, even if you specify only a single record.

Delegation

When used with a data source, these functions can't be delegated. Only the first portion of the data source will be retrieved and then the function applied. The result may not represent the complete story. A warning may appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

For example, when used with a data source containing a large table with 1 million records, **Last** will be subject to the non-delegation limit and will not return the last record of the entire data source. Likewise, using **Index** to request a record in the middle of 1 million records will result in an error because the index is out of range based on the non-delegation limit.

Syntax

First(*Table*)
Last(*Table*)

- *Table* - Required. Table to operate on.

FirstN(*Table* [, *NumberOfRecords*])
LastN(*Table* [, *NumberOfRecords*])

- *Table* - Required. Table to operate on.
- *NumberOfRecords* - Optional. Number of records to return. If you don't specify this argument, the function returns one record.

Index(*Table*, *RecordIndex*)

- *Table* - Required. Table to operate on.
- *RecordIndex* - Required. The index of the record to return. Record numbering begins with 1.

Examples

For the following examples, we'll use the **IceCream** data source, which contains the data in this table:

Flavor	Quantity
"Chocolate"	100
"Vanilla"	200
"Strawberry"	300
"Mint Chocolate"	60
"Pistachio"	200

This table can be placed in a collection with this formula (put in the OnStart formula for a Button control and press the button):

Power Fx

```
Collect( IceCream, Table( { Flavor: "Chocolate", Quantity: 100 },
                          { Flavor: "Vanilla", Quantity: 200 },
                          { Flavor: "Strawberry", Quantity: 300 },
                          { Flavor: "Mint Chocolate", Quantity: 60 },
                          { Flavor: "Pistachio", Quantity: 200 } ) )
```

Expand table

Formula	Description	Result
First(IceCream)	Returns the first record of **IceCream**.	{ Flavor: "Chocolate", Quantity: 100 }
Last(IceCream)	Returns the last record of **IceCream**.	{ Flavor: "Pistachio", Quantity: 200 }
Index(IceCream, 3)	Returns the third record of **IceCream**.	{ Flavor: "Strawberry", Quantity: 300 }
FirstN(IceCream, 2)	Returns a table containing the first two records of **IceCream**.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Chocolate"</td><td>100</td></tr><tr><td>"Vanilla"</td><td>200</td></tr></table>
LastN(IceCream, 2)	Returns a table containing the last two records of **IceCream**.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Mint Chocolate"</td><td>60</td></tr><tr><td>"Pistachio"</td><td>200</td></tr></table>
Index(IceCream, 4).Quantity	Returns the fourth record of the table, and extracts the Quantity column.	60
Index(IceCream, 10)	Returns an error since the record requested is beyond the bounds of the table.	*Error*

First, FirstN, Index, Last, and LastN functions

04/20/2025

Applies to: ✅ Canvas apps ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Returns the first, last, or a specific record, or a set of first or last records, from a table.

Description

The **First** function returns the first record of a table.

The **FirstN** function returns the first set of records of a table; the second argument specifies the number of records to return.

The **Last** function returns the last record of a table.

The **LastN** function returns the last set of records of a table; the second argument specifies the number of records to return.

The **Index** function returns a record of a table based on its ordered position in the table. Record numbering begins with 1 so `First( table )` returning the same record as `Index( table, 1 )`. **Index** returns an error if the requested record index is less than 1, greater than the number of records in the table, or the table is empty.

First, **Index**, and **Last** return a single record. **FirstN** and **LastN** return a table, even if you specify only a single record.

Delegation

When used with a data source, these functions can't be delegated. Only the first portion of the data source will be retrieved and then the function applied. The result may not represent the complete story. A warning may appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

For example, when used with a data source containing a large table with 1 million records, **Last** will be subject to the non-delegation limit and will not return the last record of the entire data source. Likewise, using **Index** to request a record in the middle of 1 million records will result in an error because the index is out of range based on the non-delegation limit.

Syntax

First(*Table*)
Last(*Table*)

- *Table* - Required. Table to operate on.

FirstN(*Table* [, *NumberOfRecords*])
LastN(*Table* [, *NumberOfRecords*])

- *Table* - Required. Table to operate on.
- *NumberOfRecords* - Optional. Number of records to return. If you don't specify this argument, the function returns one record.

Index(*Table*, *RecordIndex*)

- *Table* - Required. Table to operate on.
- *RecordIndex* - Required. The index of the record to return. Record numbering begins with 1.

Examples

For the following examples, we'll use the **IceCream** data source, which contains the data in this table:

Flavor	Quantity
"Chocolate"	100
"Vanilla"	200
"Strawberry"	300
"Mint Chocolate"	60
"Pistachio"	200

This table can be placed in a collection with this formula (put in the OnStart formula for a Button control and press the button):

Power Fx

```
Collect( IceCream, Table( { Flavor: "Chocolate", Quantity: 100 },
                          { Flavor: "Vanilla", Quantity: 200 },
                          { Flavor: "Strawberry", Quantity: 300 },
                          { Flavor: "Mint Chocolate", Quantity: 60 },
                          { Flavor: "Pistachio", Quantity: 200 } ) )
```

Expand table

Formula	Description	Result
First(IceCream)	Returns the first record of **IceCream**.	{ Flavor: "Chocolate", Quantity: 100 }
Last(IceCream)	Returns the last record of **IceCream**.	{ Flavor: "Pistachio", Quantity: 200 }
Index(IceCream, 3)	Returns the third record of **IceCream**.	{ Flavor: "Strawberry", Quantity: 300 }
FirstN(IceCream, 2)	Returns a table containing the first two records of **IceCream**.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Chocolate"</td><td>100</td></tr><tr><td>"Vanilla"</td><td>200</td></tr></table>
LastN(IceCream, 2)	Returns a table containing the last two records of **IceCream**.	<table><tr><th>Flavor</th><th>Quantity</th></tr><tr><td>"Mint Chocolate"</td><td>60</td></tr><tr><td>"Pistachio"</td><td>200</td></tr></table>
Index(IceCream, 4).Quantity	Returns the fourth record of the table, and extracts the Quantity column.	60
Index(IceCream, 10)	Returns an error since the record requested is beyond the bounds of the table.	*Error*

Launch and Param functions

Article • 03/04/2025

Applies to: Canvas apps

Launches a webpage or a canvas app and provides access to launch parameters.

Launch

Launches a webpage or a canvas app. The function supports:

- **Address** (required), the URL of the webpage of the canvas app.
- **Parameters** (optional), named values to pass to the webpage or canvas app. In a canvas app, parameters can be read with the **Param** function.
- **Target** (optional), the browser tab in which to launch the webpage or canvas app.

Launch can only be used in behavior formulas.

> **Note**
>
> - If the Launch formula is used to open Power Apps and the app isn't visible to the end user, it's recommended to check if the app is blocked by a browser pop-up blocker or if the browser is wait for the user's response to a dialog box that asks whether they want to navigate to a new screen.
> - Only **https**: URIs are supported when using Launch in the Power Apps Visual in PowerBI.

Address

Webpages are launched via a URL address. For example:

Power Fx

```
Launch( "https://bing.com" )
```

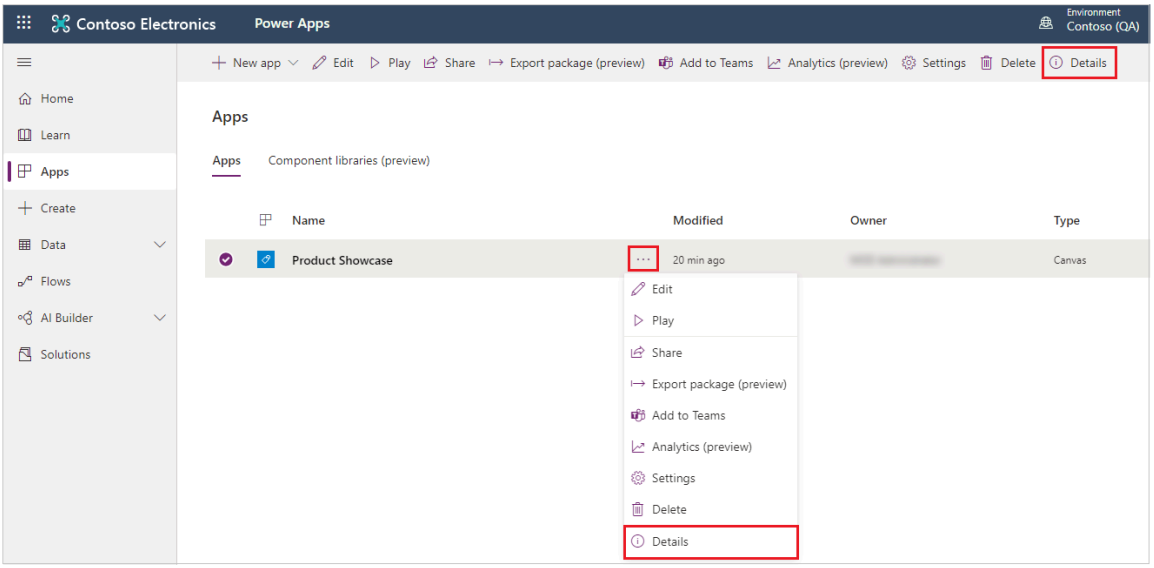
You can launch canvas apps with **Web link** or **App URI** (app id prefixed with `/providers/Microsoft.PowerApps/apps/`). To find these values for an app:

1. Go to Power Apps.

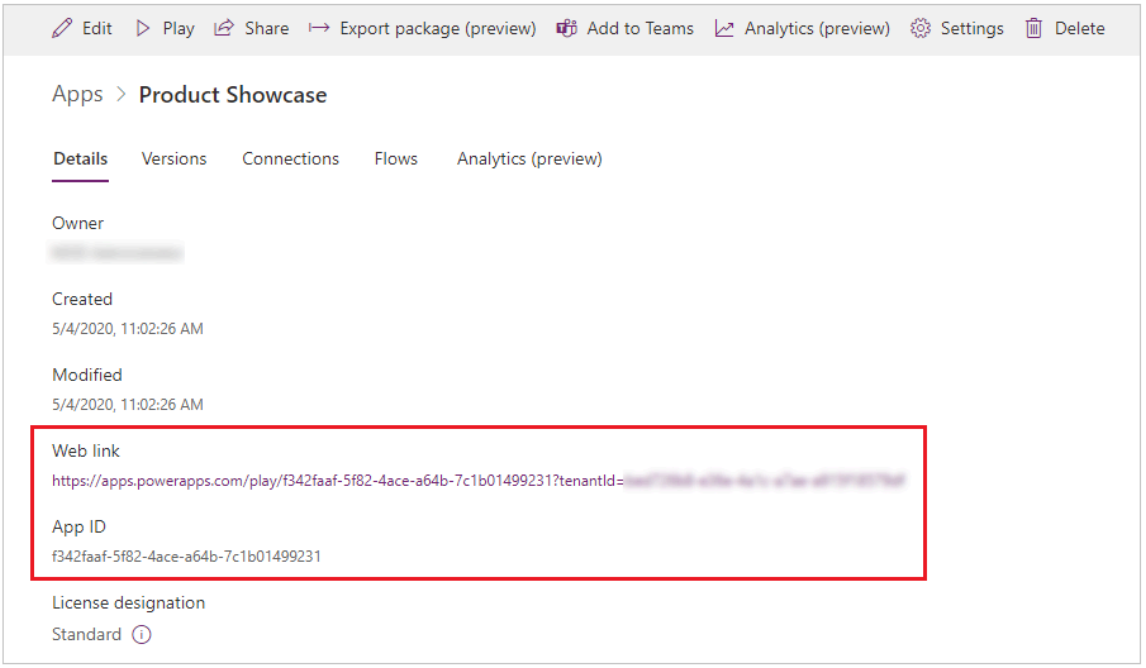
2. Select **Apps** from left navigation pane.

3. Select your app.

4. Select **Details** from top menu.
   You can also select **...** (**More Commands**) and then select **Details** from the drop-down menu.



5. Copy **Web link**.



The **Web link** can be used in any web page and will launch the canvas app. It can also be used with the **Launch** function. For example:

```
Power Fx
```

```
Launch( "https://apps.powerapps.com/e/{environment id}/a/{app id}?tenantId=
{tenantId}" )
```

Native apps on a device can't be launched directly. There may be indirect options available on some platforms, such as a native app installing a custom URL scheme or registering with the web browser to offer an option for specific web sites.

Parameters

Launch can pass parameters to the webpage or canvas app. Parameters can be provided in two ways:

- An argument list of name value pairs. For example:

  Power Fx

  ```
  Launch( "https://bing.com/search", "q", "Power Apps", "count", 1 )
  ```

- A record of field values. For example:

  Power Fx

  ```
  Launch( "https://bing.com/search", { q: "Power Apps", count: 1 } )
  ```

  This form can be easier to work with as it makes the association between name and value clearer. It's the only form that supports the optional *LaunchTarget* argument.

The address and parameters are URL encoded before being passed to replace certain non-alphanumeric characters with `%` and a hexadecimal number as if the **EncodeUrl** function has been used on each.

When launching a webpage, a query string of parameters can be included at the end of the URL address. Any additional parameters provided to **Launch** will be added to the end of the query string. Query strings don't work when launching a canvas app.

When launching an app on a mobile device where that app is already running, parameters will not be refreshed in the running app. An app reload is required for parameters to be refreshed.

Target

Use the *LaunchTarget* argument to specify the target browser window in which to open the webpage or app. Use one of the following **LaunchTarget** enum values or provide a custom window *name*.

Expand table

LaunchTarget enum	Description
New	The webpage or app is opened in a new window or tab.
Replace	The webpage or app replaces the current window or tab.
name	Instead of an enum value, use your own text string to *name* the window or tab. *Self* is an internal only name that is only used by the **Launch** function. It has no impact on nor will it match the title of the window that your users see. If a window or tab with the given *name* already exists, its contents will be replaced. Otherwise, a new window or tab will be created. *name* can't begin with the underscore character "_".

New is the default enum when running in a web browser with **Replace** and *name* as available options. In a mobile player, **New** is the default for webpages with *name* as an available option; while the current canvas app will always be replaced by another canvas app.

> **Note**
>
> - Using a *LaunchTarget* with any value other than **New** in embedded scenarios (for example, Power BI or SharePoint) is not supported and may result in unexpected behavior. In the future, this behavior may change, or may cause an error.

Param

The **Param** function retrieves a parameter passed to the app when it was launched. If the named parameter wasn't passed, **Param** returns *blank*.

- When launching a canvas app from another canvas app, use the *Parameter* arguments to the **Launch** function. Parameter names and values will be automatically URL encoded.
- When launching a canvas app from a web page, add parameters to the query string of the canvas app web link. This involves adding `&parametername=parametervalue` assuming the query string has already been

started for the `tenantId`. For example, adding `&First%20Name=Vicki&category=3` would pass two parameters: `First Name` with a value of `"Vicki"` and `category` with a value of `"3"` (value type is *text*). The parameter name and value must be URL encoded if they contain spaces or special characters, similar to using the **EncodeURL** function.

- Param names are case-sensitive.
- Param names and values will be automatically URL decoded for use in your app.
- Parameter values do not change unless the app is reloaded. Using **Launch** on a mobile device where the app is already running does not refresh the parameters.
- Even if the parameter contains a number, the type returned by **Param** will always be a text string. Conversion to other types will automatically occur or use explicit conversions such as the **Value** function to convert explicitly to a number.

> ⓘ **Note**
>
> For custom pages, the only parameters accepted by the page are: recordId and entityName.

Syntax

Launch(*Address* [, *ParameterName1*, *ParameterValue1*, ...])

- *Address* – Required. The address of a webpage or the ID of an app to launch.
- *ParameterName(s)* – Optional. Parameter name.
- *ParameterValue(s)* – Optional. Corresponding parameter values to pass to the app or the webpage.

Launch(*Address*, { [*ParameterName1*: *ParameterValue1*, ...] } [, *LaunchTarget*])

- *Address* – Required. The address of a webpage or the ID of an app to launch.
- *ParameterName(s)* – Optional. Parameter name.
- *ParameterValue(s)* – Optional. Corresponding parameter values to pass to the app or the webpage.
- *LaunchTarget* – Optional. A **LaunchTarget** enum value or a custom *name*.

Param(*ParameterName*)

- *ParameterName* - Required. The name of the parameter passed to the app.

Reserved parameters

The following keywords are reserved (regardless of case) for internal use, and shouldn't be used as a custom parameter in the **Param()** function:

- amp%3Bauthmode
- amp%3Benableonbehalfof
- amp%3Bhidenavbar
- amp%3Blocale
- appmetadataversion
- authmode
- channeltype
- cordovapath
- correlationid
- debug
- delegatelaunchurl
- delegatelaunchurl
- disablepreviewredirect
- embedderorigin
- enableonbehalfof
- groupid
- hideappsplash
- hidenavbar
- hint
- hostclienttype
- hostmode
- iframecontainerid
- isfullscreen
- ispreviewmode
- loader
- loaderType
- locale
- location
- packagekind
- packageproperties
- playerresourcespath
- playersessionid
- powerappslanguage
- screencolor
- sdkversion
- site
- skipappmetadata
- skipiframecreation

- skiplaunchappcache
- source
- sourcetime
- standaloneconsent
- teamid
- teamtype
- tenantId
- theme
- uselocalpackagehostresources
- userteamrole

Examples

Simple Launch

From a canvas app to a web page:

Expand table

Formula	Description
Launch("http://bing.com/search", "q", "Power Apps", "count", 1)	Opens the webpage **https://bing.com/search?q=Power%20Apps&count=1**. A new window or tab is opened.
Launch("http://bing.com/search", { q: "Power Apps", count: 1 })	The same as the previous examples using the equivalent record notation. A new window or tab is opened.
Launch("http://bing.com/search", { q: "Power Apps", count: 1 }, LaunchTarget.Replace)	The same as the previous examples, replacing the current window or tab with the result if running in a web browser.
Launch("http://bing.com/search", { q: "Power Apps", count: 1 }, "Search Results")	The same as the previous example, creating or replacing the contents of the window or tab named **Search Results**.

From a canvas app to a canvas app

Update the app ID, screen name, and record number as appropriate.

```
Power Fx
```

```
Launch( "/providers/Microsoft.PowerApps/apps/YOUR-APP-ID",
        { Navigate: "Second Screen", Record: 34 }
)
```

From a web page to a canvas app

Update the app ID, tenant ID, screen name, and record number as appropriate.

HTML

```
<html>
  <body>
    <a
      href="https://apps.powerapps.com/play/e/YOUR-APP-ENVIRONMENT-
ID/a/YOUR-APP-ID?tenantId=YOUR-TENANT-ID&Navigate=Second%20Screen&Record=34"
    >
      Launch canvas app
    </a>
  </body>
</html>
```

Simple Param

Simple launch examples above to launch canvas app from web page or from another canvas app show simple examples for Param function:

Expand table

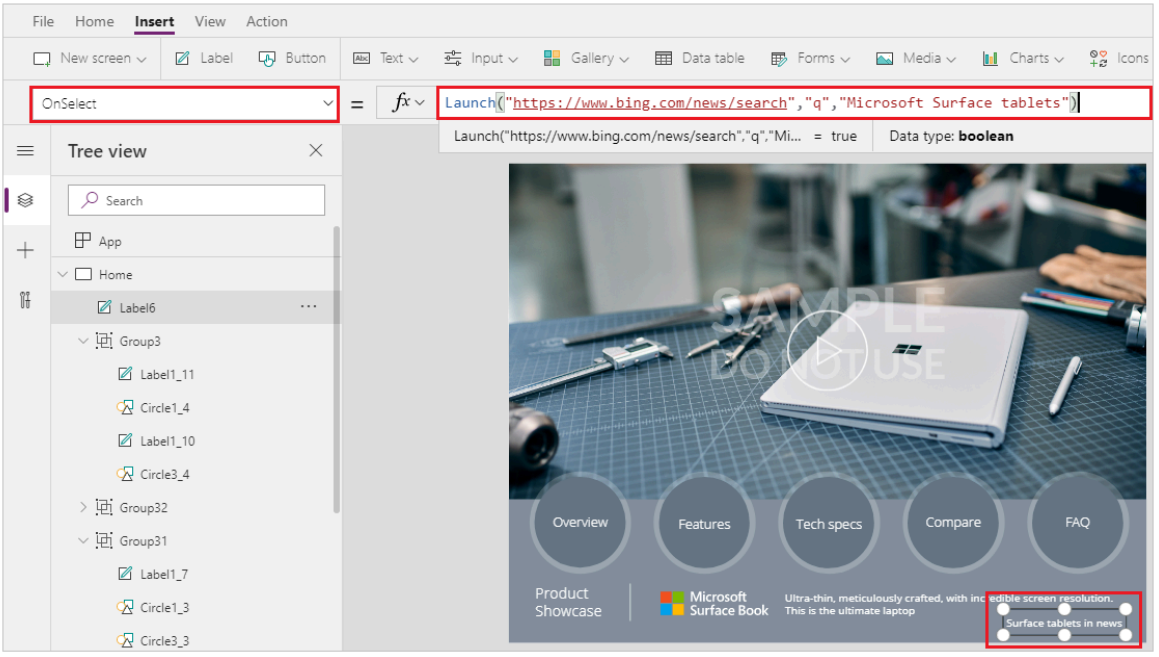
Formula	Description	Result
Param("Navigate")	The **Navigate** parameter was provided when the app was launched and is returned.	"Second Screen"
Param("Record")	The **Record** parameter was provided when the app was launched. Even though it was passed in as a number to the **Launch** function, the result from **Param** will be a text string that can be implicitly or explicitly converted to other types.	"34"
Param("User")	The **User** parameter wasn't provided. A *blank* value is returned that can be tested with the **IsBlank** function.	*blank*

Step by Step examples for Launch and Param

The **Product Showcase** tablet layout template was used for the following examples. To create an app with this template, follow the steps from create an app article and select the **Product Showcase** template. You can also use your own app.

Example - Launch

1. Go to Power Apps.
2. Select **Apps** from left navigation pane.
3. Select your app and then select **Edit**.
4. Select **Insert** from the menu and then select **Label**.
5. Move the label to the bottom right of the screen.
6. From the properties pane on the right-side, select **Color** as *white* and set **Border thickness** at *1*.
7. Select the **Text** property from right-side and enter text as *Surface tablets in news*.
8. From property list on top left, select **OnSelect**.
9. Enter formula as `Launch("https://www.bing.com/news/search","q","Microsoft Surface tablets")`. You can also use any other URL, parameter, and keywords of your choice.



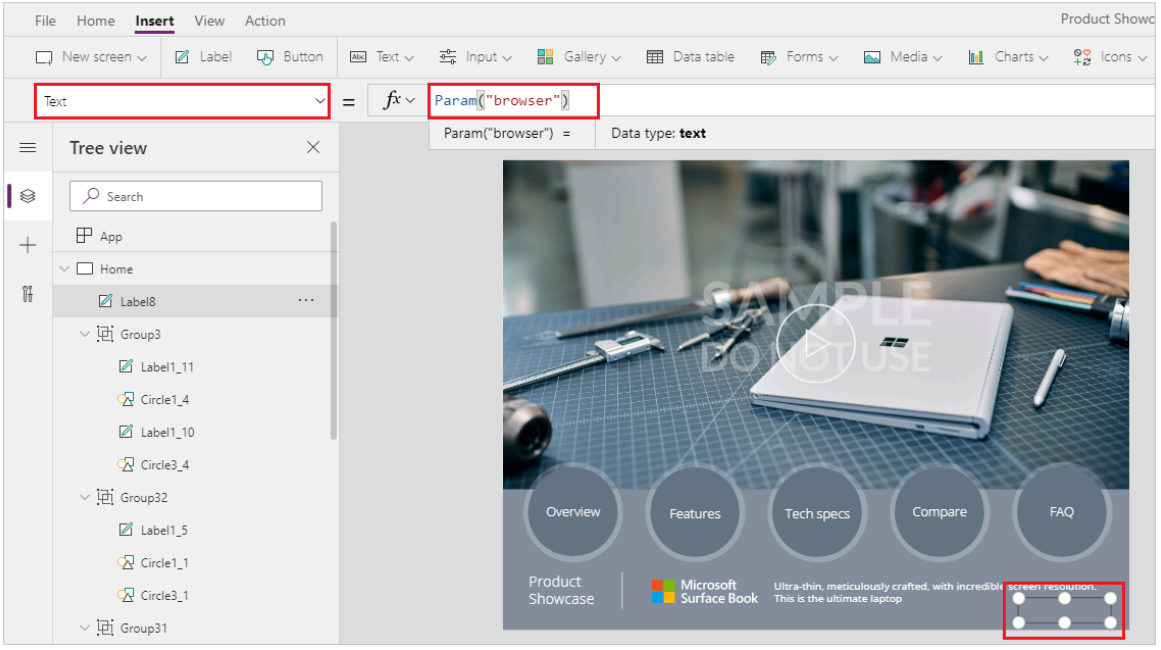
10. Save and publish the app.
11. Play the app.

12. Select label **Surface tablets in news** to launch news search with keywords *Microsoft Surface tablets*.

> **Tip**
>
> For scalability, you can replace the manually entered keywords in Launch function with variables.

Example - Param

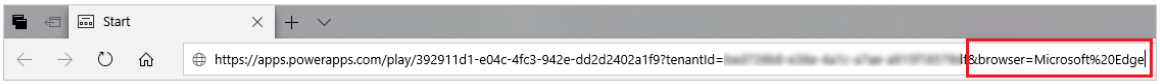
1. Go to Power Apps.
2. Select **Apps** from left navigation pane.
3. Select your app and then select **Edit**.
4. Select **Insert** from the menu and then select **Label**.
5. Move the label to the bottom right of the screen.
6. Select **Text** property for the label from top left.
7. Enter formula as `Param("browser")`. You can also use a different parameter of your choice.



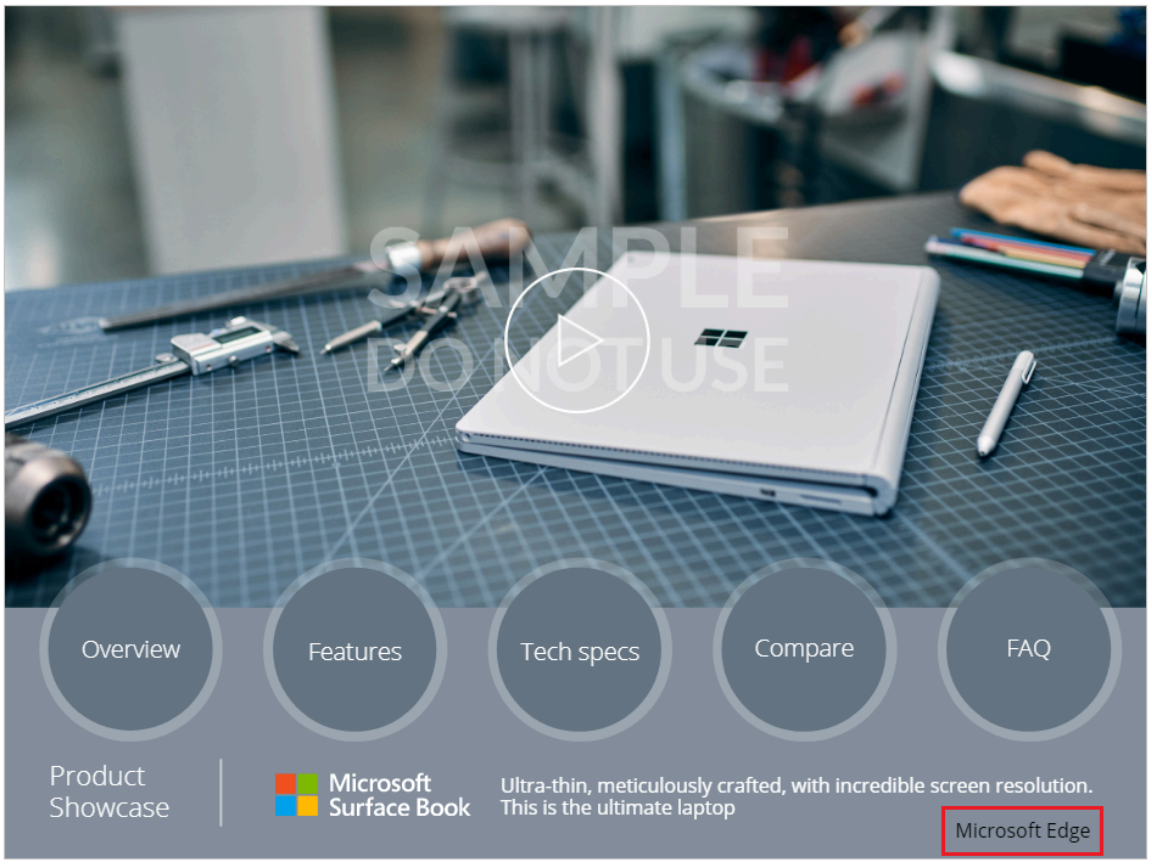
8. Save and publish the app.
9. Copy web link for your app from Power Apps.

10. Open a new browser.

11. Paste the app web link in the browser and append `&browser=Microsoft%20Edge` at the end.



12. When your app launches, the label shows the parameter value passed.

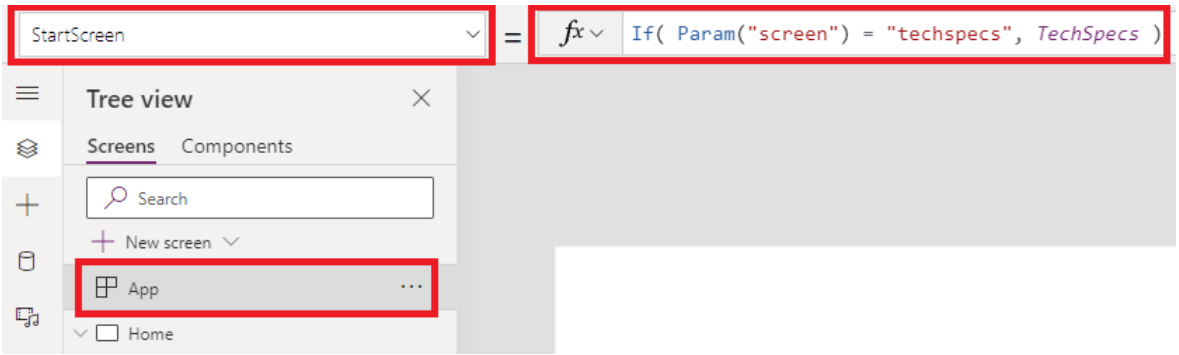


13. Close the app player and edit the app.

14. Select **App** from the Tree view on left navigation.

15. Select **StartScreen** property on top left.

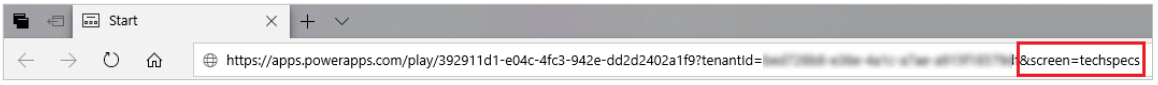
16. Enter the formula as `If( Param("screen") = "techspecs", TechSpecs )`.



If function in StartScreen property checks if parameter equals a certain value, in this case the value *techspecs*. And if it matches, returns the *TechSpecs* screen control to the **StartScreen** property.

> **Note**
>
> Replace the **TechSpecs** control name in the **If** function with the name of a screen control in your own app if you're not using the **Product Showcase** app template.

17. Save and publish the app.
18. Open a new browser.
19. Paste the app web link in the browser and append `&screen=techspecs` at the end.



20. The app directly launches with **TechSpecs** as the startscreen.

Left, Mid, and Right functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Dataverse formula columns ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Extracts the left, middle, or right portion of a string of text.

Description

The **Left**, **Mid**, and **Right** functions return a portion of a string.

- **Left** returns the beginning characters of a string.
- **Mid** returns the middle characters of a string.
- **Right** returns the ending characters of a string.

If you specify a single string as an argument, the function returns the portion that you requested of the string. If you specify a single-column table that contains strings, the function returns a single-column table with a **Value** column containing the portions that you requested of those strings. If you specify a multi-column table, you can shape it into a single-column table, as working with tables describes.

If the starting position is negative or beyond the end of the string, **Mid** returns *blank*. You can check the length of a string by using the **Len** function. If you request more characters than the string contains, the function returns as many characters as possible.

Syntax

Left(*String*, *NumberOfCharacters*)
Mid(*String*, *StartingPosition* [, *NumberOfCharacters*])
Right(*String*, *NumberOfCharacters*)

- *String* - Required. The string to from which to extract the result.
- *StartingPosition* - Required (**Mid** only). The starting position. The first character of the string is position 1.
- *NumberOfCharacters* - Required (**Left** and **Right** only). The number of characters to return. If omitted for the **Mid** function, the function returns the portion from the starting position until the end of the string.

Left(*SingleColumnTable*, *NumberOfCharacters*)
Mid(*SingleColumnTable*, *StartingPosition* [, *NumberOfCharacters*])

Right(*SingleColumnTable*, *NumberOfCharacters*)

- *SingleColumnTable* - Required. A single-column table of strings from which to extract the results.
- *StartingPosition* - Required (**Mid** only). The starting position. The first character of the string is position 1.
- *NumberOfCharacters* - Required (**Left** and **Right** only). The number of characters to return. If omitted for the **Mid** function, the function returns the portion from the starting position until the end of the string.

Examples

Single string

The examples in this section use a text-input control as their data source. The control is named **Author** and contains the string "E. E. Cummings".

Expand table

Formula	Description	Result
Left(Author.Text, 5)	Extracts up to five characters from the start of the string.	"E. E."
Mid(Author.Text, 7, 4)	Extracts up to four characters, starting with the seventh character, from the string.	"Cumm"
Mid(Author.Text, 7)	Extracts all characters, starting with the seventh character, from the string.	"Cummings"
Right(Author.Text, 5)	Extracts up to five characters from the end of the string.	"mings"

Single-column table

Each example in this section extracts strings from the **Address** column of this data source, named **People**, and returns a single-column table that contains the results:

Expand table

Name	Address
"Jean"	"123 Main St NE"

Name	Address
"Fred"	"789 SW 39th #3B"

Expand table

Formula	Description	Result
Left(ShowColumns(People, "Address"), 8)	Extracts the first eight characters of each string.	A single-column table with a `Value` column containing the following values: "123 Main", "789 SW 3"
Mid(ShowColumns(People, "Address"), 5, 7)	Extracts the middle seven characters of each string, starting with the fifth character.	A single-column table with a `Value` column containing the following values: "Main St", "SW 39th"
Right(ShowColumns(People, "Address"), 7)	Extracts the last seven characters of each string.	A single-column table with a `Value` column containing the following values: "n St NE", "9th #3B"

Step-by-step example

1. Import or create a collection named **Inventory**, and show it in a gallery, as the first procedure in Show images and text in a gallery describes.
2. Set the **Text** property of the lower label in the gallery to this function:

   Right(ThisItem.ProductName, 3)

   The label shows the last three characters of each product name.

Len function

Article • 04/20/2025

Applies to: Canvas apps Cards Copilot Studio Desktop flows Dataverse formula columns Model-driven apps Power Platform CLI Dataverse functions Power Pages

Returns the length of a string of text.

Description

If you specify a single string as the argument, the return value is the length as a number. If you specify a single-column table that contains strings, the return value is a single-column table with a **Value** column that contains the length of each string. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If you specify a blank string, **Len** returns 0.

Syntax

Len(*String*)

- *String* - Required. The string to measure.

Len(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of strings to measure.

Examples

Single string

For the examples in this section, the data source is a text-input control that's named **Author** and that contains the string "E. E. Cummings".

Expand table

Formula	Description	Result
Len(Author.Text)	Measures the length of the string in the **Author** control.	14
Len("")	Measures the length of an empty string.	0

Single-column table

For the first example in this section, the data source is named **People** and contains this data:

Expand table

Name	Address
"Jean"	"123 Main St NE"
"Fred"	"789 SW 39th #3B"

Expand table

Formula	Description	Result
Len(ShowColumns(People, "Address"))	In the **Address** column of the **People** table: • Measures the length of each string. • Returns a single-column table that contains the length of each string.	A single-column table with a `Value` column containing the following values: 14, 15
Len(["Hello", "to the", "World", ""])	In the **Value** column of the inline table: • Measures the length of each string. • Returns a single-column table that contains the length of each string.	A single-column table with a `Value` column containing the following values: 5, 6, 5, 0

Abs, Exp, Ln, Power, Log, and Sqrt functions

Article • 04/20/2025

Expand table

Functions	Applies to
Abs **Exp** **Ln** **Power** **Sqrt**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Log	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Calculates absolute values, logarithms, square roots, and the results of raising *e* or any number to specified powers.

Description

The **Abs** function returns the non-negative value of its argument. If a number is negative, **Abs** returns the positive equivalent.

The **Exp** function returns *e* raised to the power of its argument. The transcendental number *e* begins 2.7182818...

The **Ln** function returns the natural logarithm (base *e*) of its argument.

The **Power** function returns a number raised to a power. It's equivalent to using the ^ operator.

The **Log** function returns the logarithm of its first argument in the base specified by its second argument (or 10 if not specified).

The **Sqrt** function returns the number that, when multiplied by itself, equals its argument.

If you pass a single number, the return value is a single result based on the function called. If you pass a single-column table that contains numbers, the return value is a single-column table of results in a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined valued, the result is *blank*. Which can happen with square roots and logarithms of negative numbers.

Syntax

Abs(*Number*)
Exp(*Number*)
Ln(*Number*)
Sqrt(*Number*)

- *Number* - Required. Number to operate on.

Power(*Base*, *Exponent*)

- *Base* - Required. Base number to raise.
- *Exponent* - Required. The exponent to which the base number is raised.

Log(*Number*, *Base*)

- *Number* - Required. Number to calculate the logarithm.
- *Base* - Optional. The base of the logarithm to calculate. By default, 10 (when not specified).

Abs(*SingleColumnTable*)
Exp(*SingleColumnTable*)
Ln(*SingleColumnTable*)
Sqrt(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Examples

Single number

Expand table

Formula	Description	Result
Abs(-55)	Returns the number without the negative sign.	55
Exp(2)	Returns *e* raised to the power of 2, or *e* * *e*.	7.389056...
Ln(100)	Returns the natural logarithm (base *e*) of the number 100.	4.605170...
Log(100)	Returns the logarithm in base 10 of the number 100.	2
Log(64, 2)	Returns the logarithm in base 2 of the number 64.	6

Formula	Description	Result
Power(5, 3)	Returns 5 raised to the power of 3, or 5 * 5 * 5.	125
Sqrt(9)	Returns the number that, when multiplied by itself, results in 9.	3

Single-column table

The examples in this section use a data source that's named **ValueTable** and that contains this data:

Expand table

Value
9
-4
2

Expand table

Formula	Description	Result
Abs(ValueTable)	Returns the absolute value of each number in the table.	A single-column table with a `Value` column containing the following values: 9, 4, 2
Exp(ValueTable)	Returns *e* raised to the power of each number in the table.	A single-column table with a `Value` column containing the following values: 8103.083927..., 0.018315..., 7.389056...
Ln(ValueTable)	Returns the natural logarithm of each number in the table.	A single-column table with a `Value` column containing the following values: 2.197224..., Blank(), 0.693147...
Sqrt(ValueTable)	Returns the square root of each number in the table	A single-column table with a `Value` column containing the following values: 3, Blank(), 1.414213...

Step-by-step example

1. Add a **Text input** control, and name it **Source**.
2. Add a **Label** control, and set its **Text** property to this formula:
   Sqrt(Value(Source.Text))

3. Type a number into **Source**, and confirm that the **Label** control shows the square root of the number that you typed.

SaveData, LoadData, and ClearData functions

06/18/2025

Applies to: Canvas apps

Saves and reloads a collection from the app host's storage.

Description

The **SaveData** function stores a collection for later use under a name.

The **LoadData** function reloads a collection by name that was previously saved with **SaveData**. You can't use this function to load a collection from another source.

The **ClearData** function clears the storage under a specific name or clears all storage associated with the app if no name is provided.

> **Note**
>
> - The name shared between **SaveData**, **LoadData**, and **ClearData** is a key, not a file name. It need not be complex as names are unique to each app and there is no danger of name conflict. The name must not contain any of these characters: `*".?:\<>|/`.
> - SaveData is limited to 1 MB of data for Power Apps running in Teams and in a web browser. There is no fixed limit for Power Apps running in a mobile player but there are practical limits discussed below.
> - Don't use **SaveData** to store sensitive data in the web since it'll be stored in plain text.

Use these functions to improve app-startup performance by:

- Caching data in the **App.OnStart** formula on a first run.
- Reloading the local cache on next runs.

You can also use these functions to add simple offline capabilities to your app.

You can't use these functions inside a browser when:

- Authoring the app in Power Apps Studio.

To test your app, run it in Power Apps Mobile on an iPhone or Android device.

These functions are limited by the amount of available app memory as they operate on an in-memory collection. Available memory can vary depending on factors such as:

- The device and operating system.
- The memory that the Power Apps player uses.
- Complexity of the app with screens and controls.

Test your app with expected scenarios on the type of devices you expect the app to run when storing large data. Expect to have between 30 MB and 70 MB of available memory generally.

These functions depend on the collection being implicitly defined with **Collect** or **ClearCollect**. You don't need to call **Collect** or **ClearCollect** to load data into the collection for defining it. It's a common case when using **LoadData** after a previous **SaveData**. All that is needed is the presence of these functions in a formula to implicitly define the structure of the collection. For more information, see creating and removing variables.

The loaded data will be appended to the collection. Use the **Clear** function before calling **LoadData** if you want to start with an empty collection.

Data security

Consider carefully the isolation and encryption of data stored with **SaveData** and decide if it's appropriate for your needs, especially if devices are shared by multiple users.

Data stored with **SaveData** is isolated from other Power Apps by the Power Apps players. Data is stored based on the app's App ID, automatically isolating the **SaveData** name space between Power Apps.

The operating system and browser is responsible for isolating data between Power Apps and other apps on a device and with websites. For example, the operating system is responsible for isolating data stored in Microsoft Outlook from data stored in Power Apps, and also isolating that data from websites such as Bing.com or PowerApps.com. The operating system's built in app sandbox facilities are used for **SaveData** storage which is usually not accessible to or hidden from the user.

When using the same app, the operating system and browser is also responsible for isolating the data between different operating system level users. For example, if two different users share a computer and use two different Windows login credentials, the operating system is responsible for isolating data between the two Windows users.

Data may or may not be isolated between different Power Apps users if the operating system user is the same. Not every Power Apps player treats this the same way. For example, while

logged in as the same Windows user, in the Power Apps player, the user signs out of Power Apps and signs in as a different Power Apps user. Data stored in an app before the change of Power Apps user, may be accessible to the second Power Apps user within the same app. The data may also be removed and the first Power Apps user may no longer be able to access it. The behavior varies between Power Apps players.

The operating system may also encrypt the data or you can use a mobile device management tool such as Microsoft Intune. Data stored when playing an app in a web browser is not encrypted.

Syntax

SaveData(*Collection*, *Name*)
LoadData(*Collection*, *Name* [, *IgnoreNonexistentFile*])

- *Collection* - Required. Collection to be stored or loaded.
- *Name* - Required. Name of the storage. The name must be same to save and load same set of data. The name space isn't shared with other apps. Names must not contain any of these characters: `*".?:\<>|/`.
- *IgnoreNonexistentFile* - Optional. A Boolean value indicating what to do if the file doesn't already exist. Use *false* (default) to return an error and *true* to suppress the error.

ClearData([*Name*])

- *Name* - Optional. Name of the storage previously saved with **SaveData**. If *Name* is not provided, all storage associated with the app is cleared.

Examples

Expand table

Formula	Description	Result
SaveData(LocalCache, "MyCache")	Save the **LocalCache** collection to the user's device under the name "MyCache", suitable for **LoadData** to retrieve later.	Data is saved to the app host under the name "MyCache".
LoadData(LocalCache, "MyCache")	Loads the **LocalCache** collection from the user's device under the name "MyCache", previously stored with a call to **SaveData**.	Data is loaded from the app host under the name "MyCache".
ClearData("MyCache")	Clears the storage under the name "MyCache". Any data stored under this name will no longer be available through **LoadData**.	Data is removed from the app host under the name "MyCache".

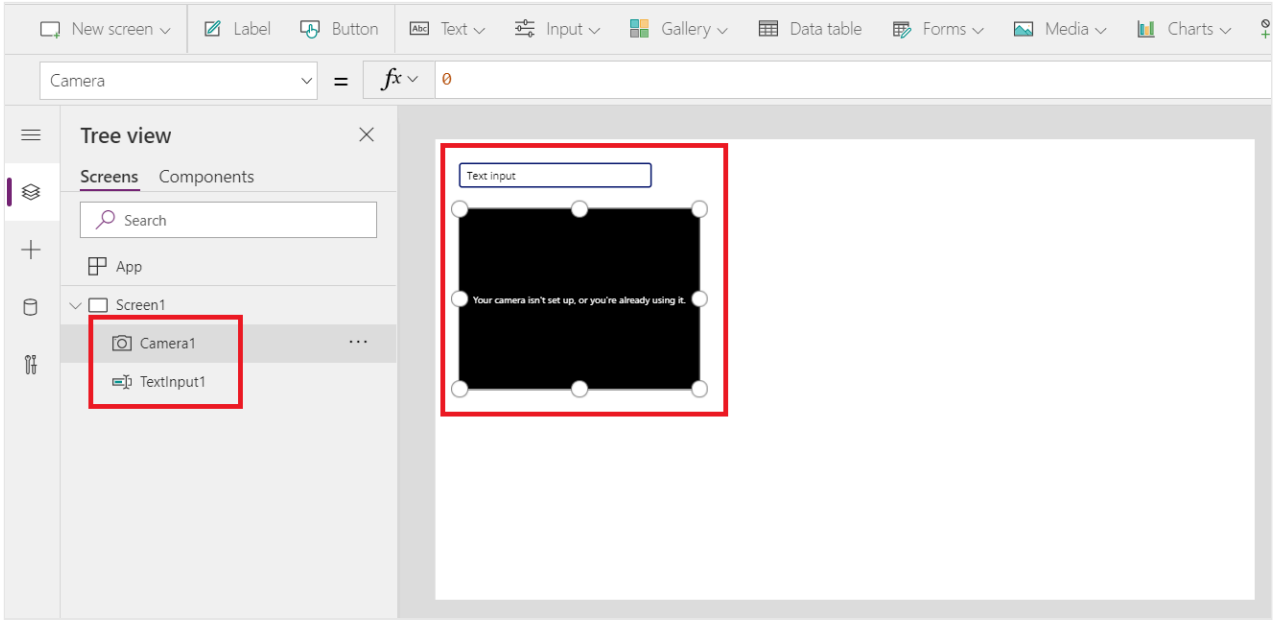
Formula	Description	Result
ClearData()	Clear all storage associated with this app. Data stored by other apps is not affected.	All data is removed from the app host.

Simple offline example

Following simple example captures and stores the names and pictures of everyday items while offline. It stores the information in the device's local storage for later use. This allows the app to be closed or the device to restart without losing data.

> **Note**
>
> This example uses a camera control to capture images. Since **SaveData** is limited to 1 MB of data when running in Teams or a web browser, this example will not work with more than a few images. Also, depending on the camera, it may not work with even one image. Use a device to work through this full example, or remove the camera control and picture part of this example to run in Teams or in a web browser.

1. Create a blank canvas app with a tablet layout. For more details, read creating an app from a template and select **Tablet layout** under **Blank app**.
2. Add a **Text input** control and a **Camera** control and arrange them roughly as shown:

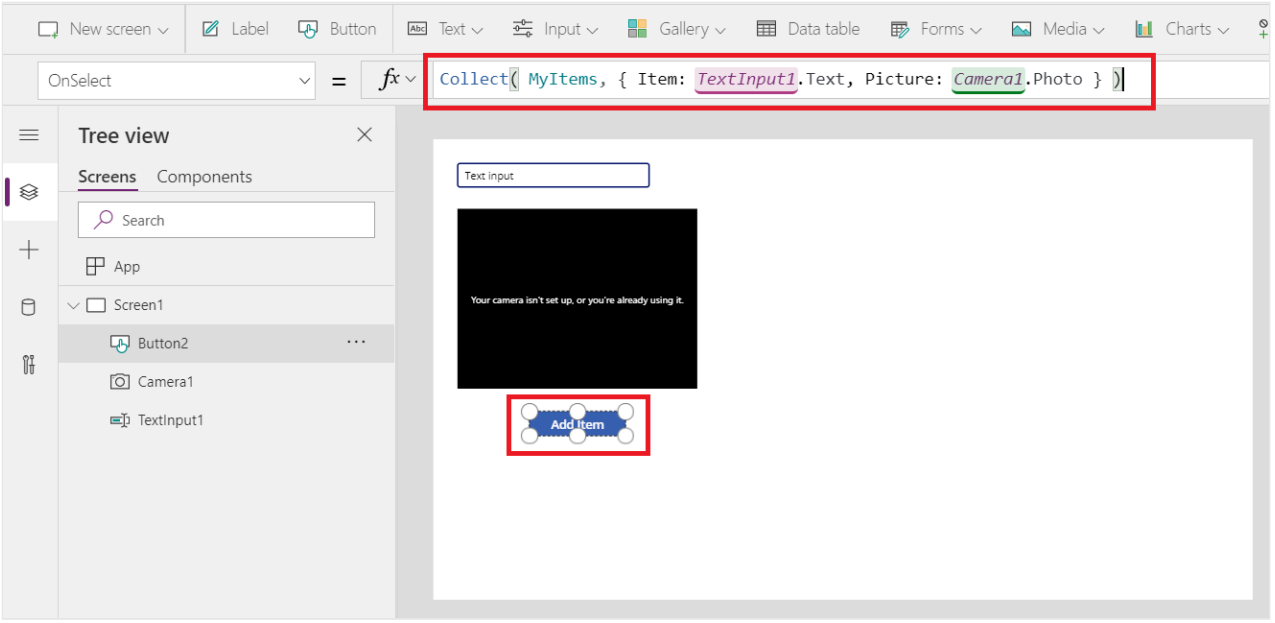


3. Add a **Button** control.
4. Double-click the button control to change the button text to **Add Item** (or modify the **Text** property).

5. Set the **OnSelect** property of the button control to this formula that will add an item to our collection:

```
Power Fx

Collect( MyItems, { Item: TextInput1.Text, Picture: Camera1.Photo } )
```



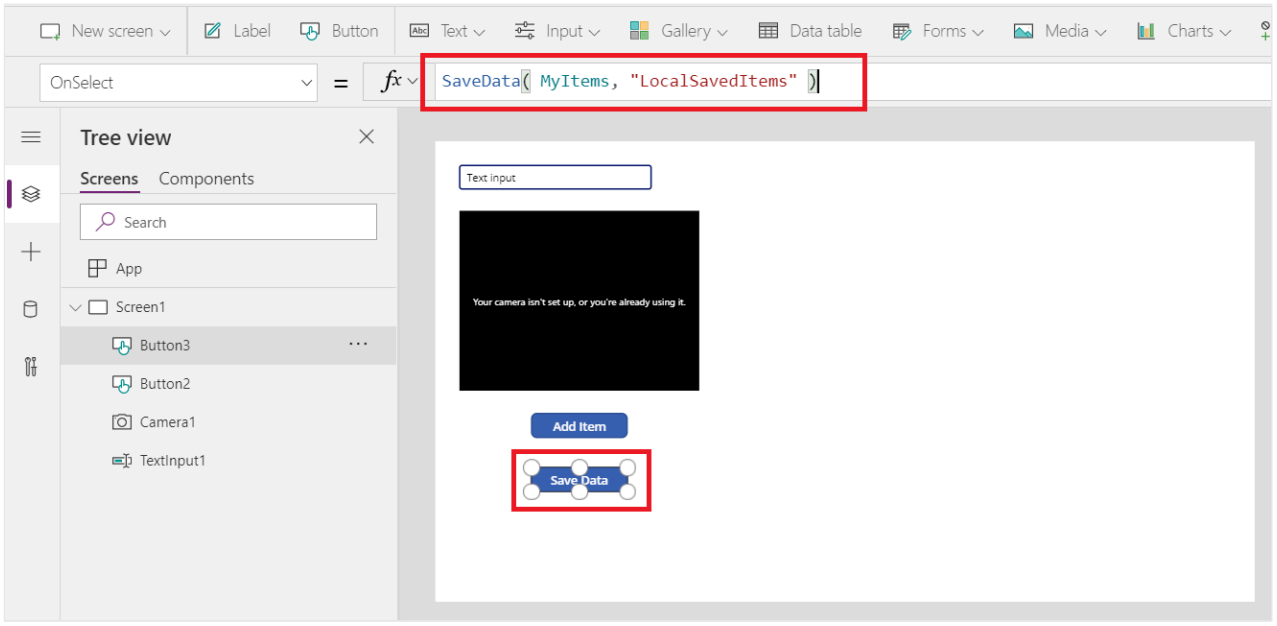
6. Add another **Button** control.

7. Double-click the button control to change the button text to **Save Data** (or modify the **Text** property).

8. Set the **OnSelect** property of the button control to this formula in order to save our collection to the local device:

```
Power Fx

SaveData( MyItems, "LocalSavedItems" )
```



It's tempting to test the button as it doesn't affect anything. But you'll only see an error as you're authoring in a web browser. Save the app first and open on a device before you follow the next steps to test this formula:

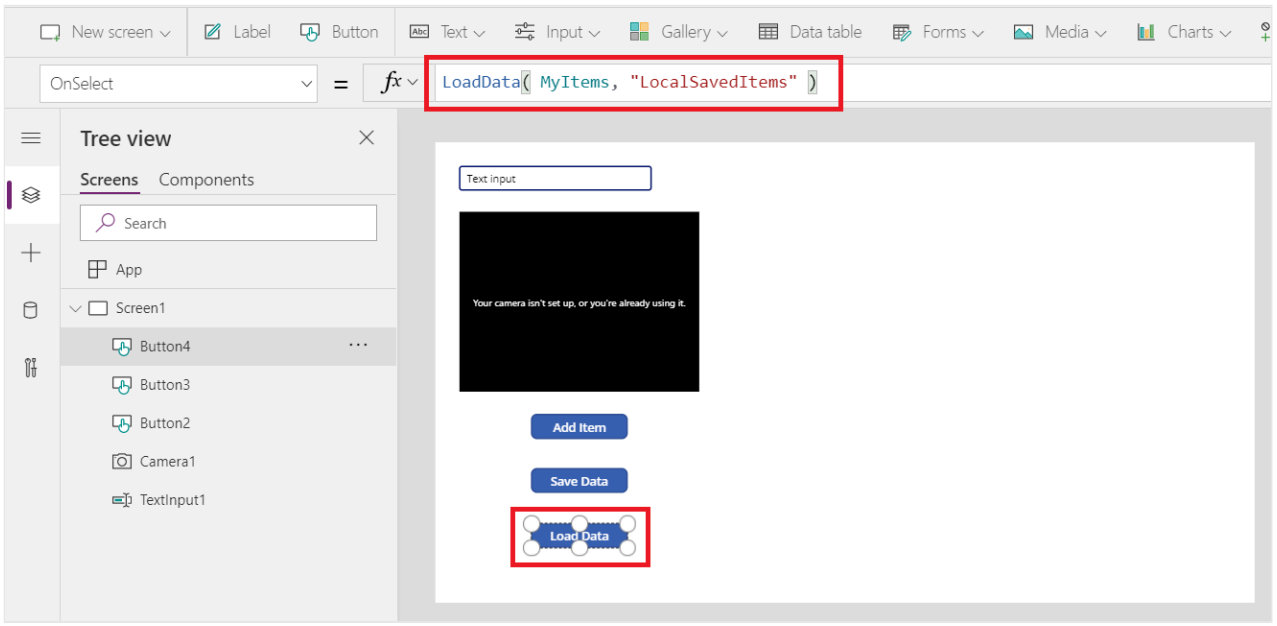
9. Add a third **Button** control.

10. Double-click the button control to change the button text to **Load Data** (or modify the **Text** property).

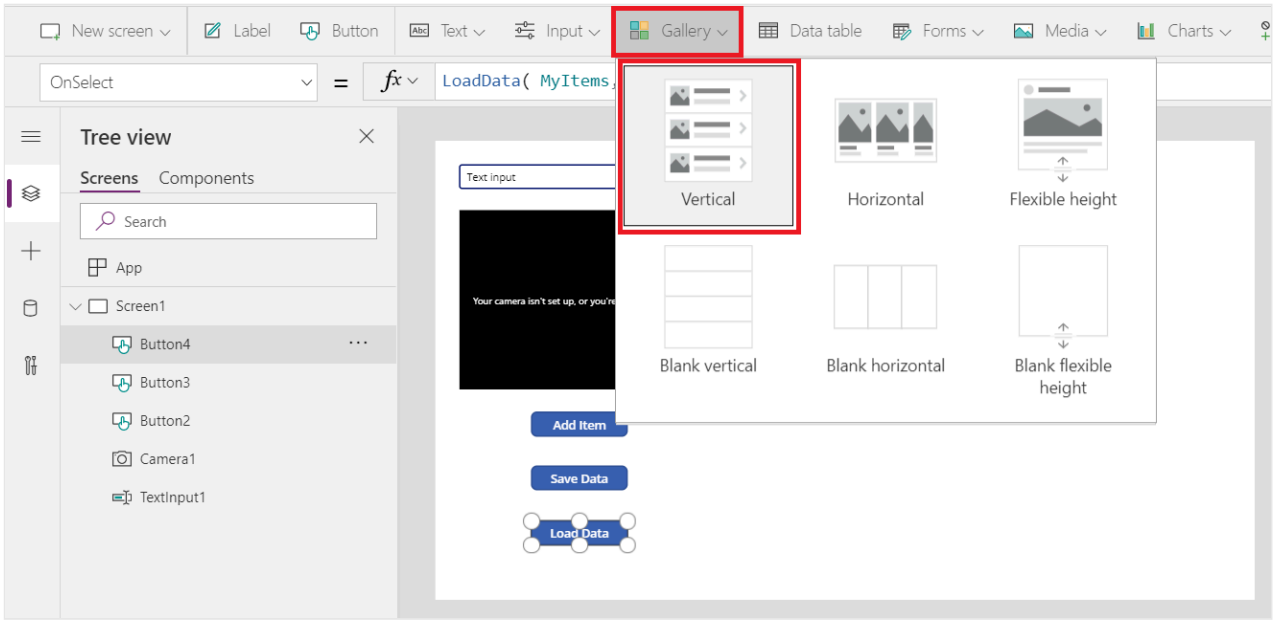
11. Set the **OnSelect** property of the button control to this formula in order to load our collection from the local device:

```
Power Fx

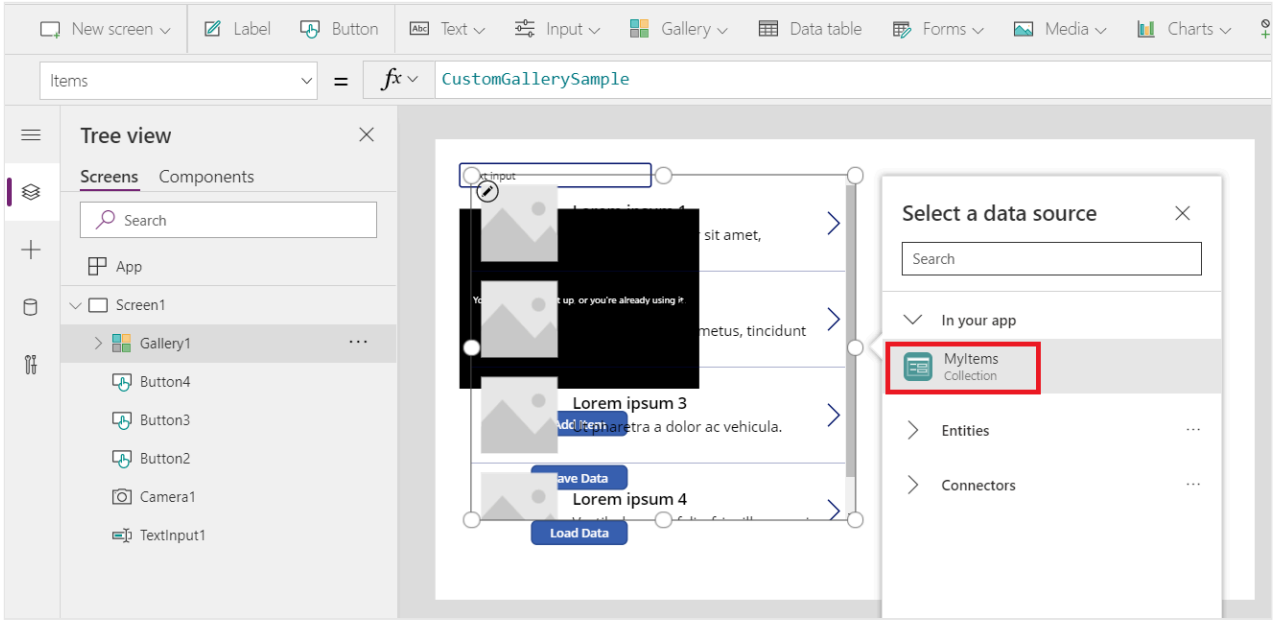
LoadData( MyItems, "LocalSavedItems" )
```



12. Add a Gallery control with a Vertical layout that includes a picture and text areas:

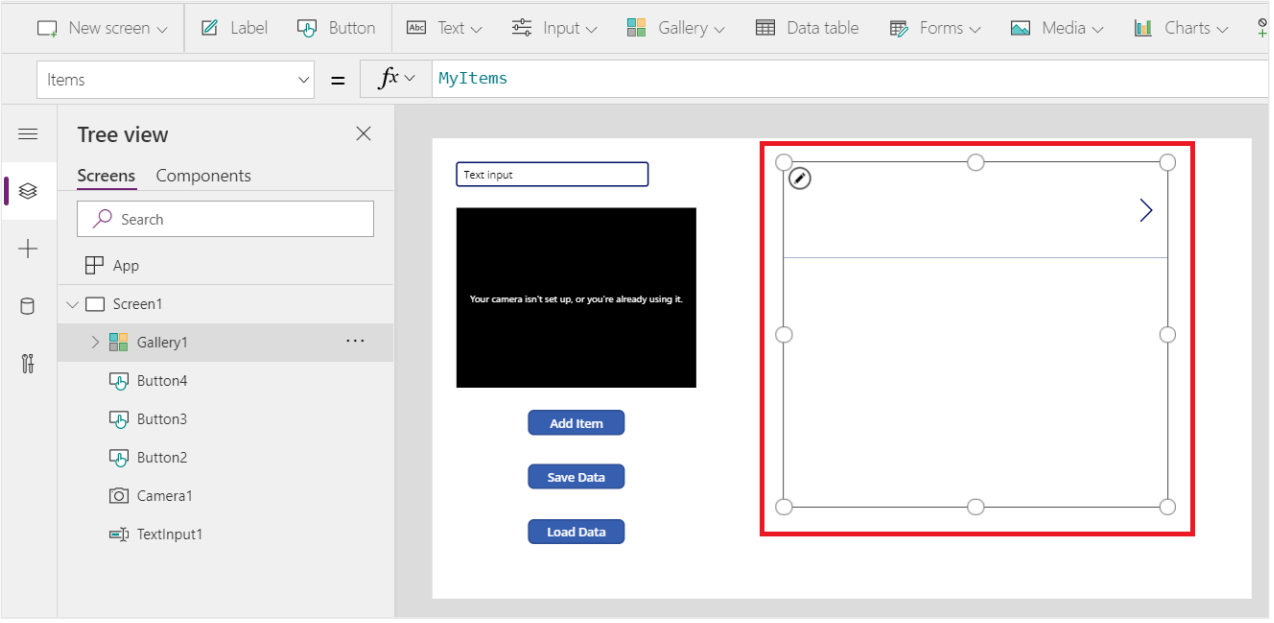


13. When prompted, select the **MyItems** collection as the data source for this gallery. This will set the **Items** property of the **Gallery** control:



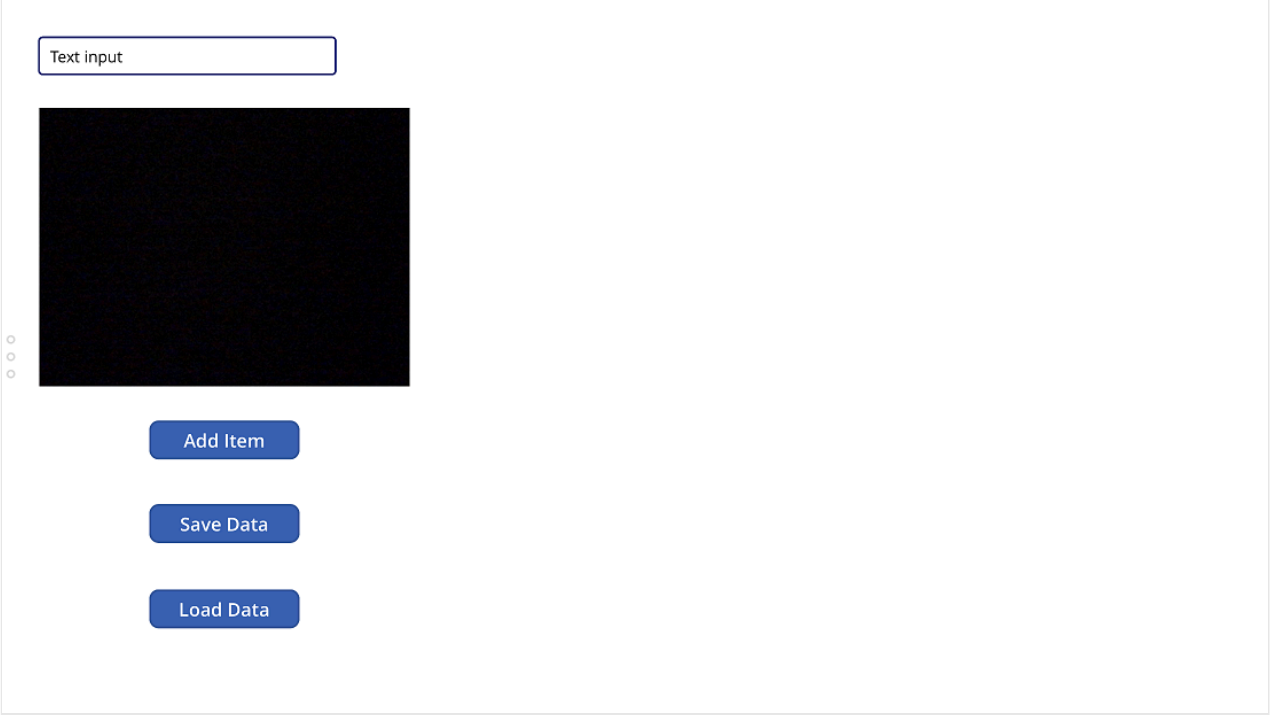
The image control in the gallery template should default its **Image** property to **ThisItem.Picture** and the label controls should both default their **Text** properties to **ThisItem.Item**. Check these formulas if after adding items in the following steps you don't see anything in the gallery.

14. Position the control to the right of the other controls:



15. Save your app. If it's the first time it has been saved, there's no need to publish it. If it's not the first time, publish the app after you save.

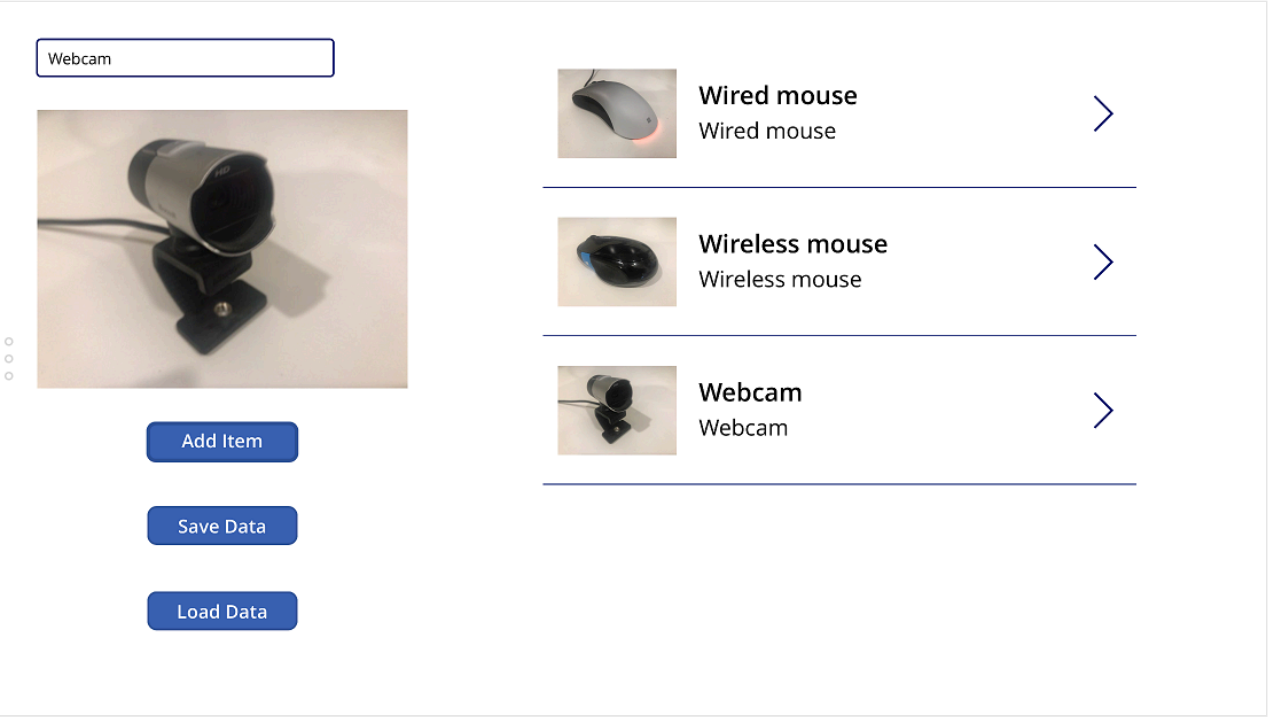
16. Open your app on a device such as a phone or tablet. **SaveData** and **LoadData** can't be used in Studio or in a web browser. Refresh your app list if you don't see your app immediately, it can take a few seconds for the app to appear on your device. Signing out and back in to your account can help too.



Once your app has been downloaded, you can disconnect from the network and run the app offline.

17. Enter the name and take a picture of an item.

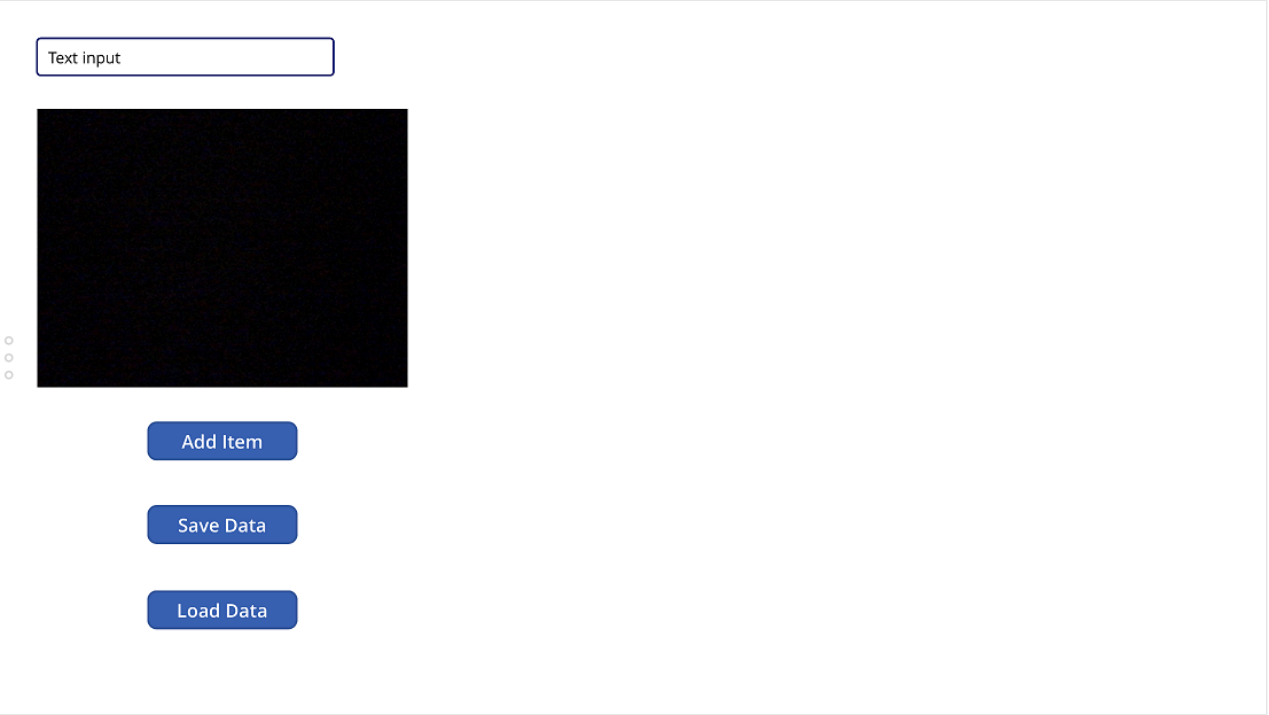
18. Select the **Add Item** button. Repeat adding items a couple of times to load up your collection.



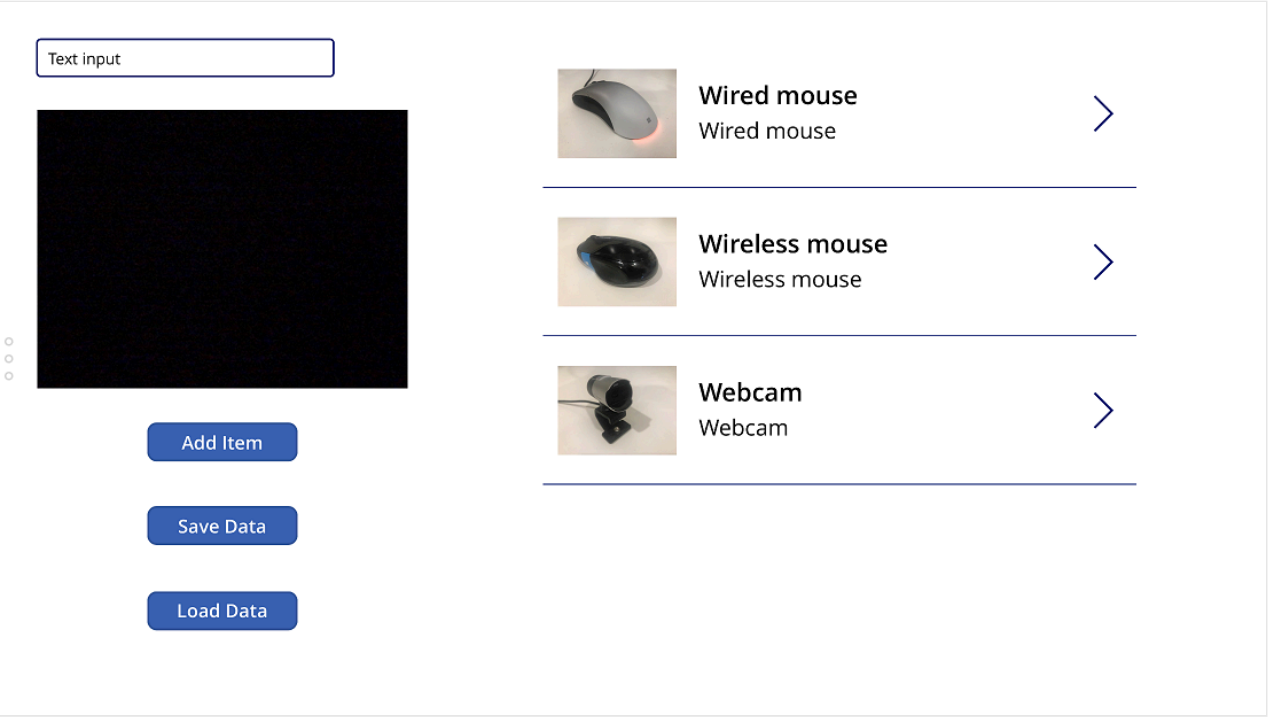
19. Select the **Save Data** button. This will save the data in your collection to your local device.

20. Close the app. Your collection in memory will be lost including all item names and pictures, but they'll still be there in the device's storage.

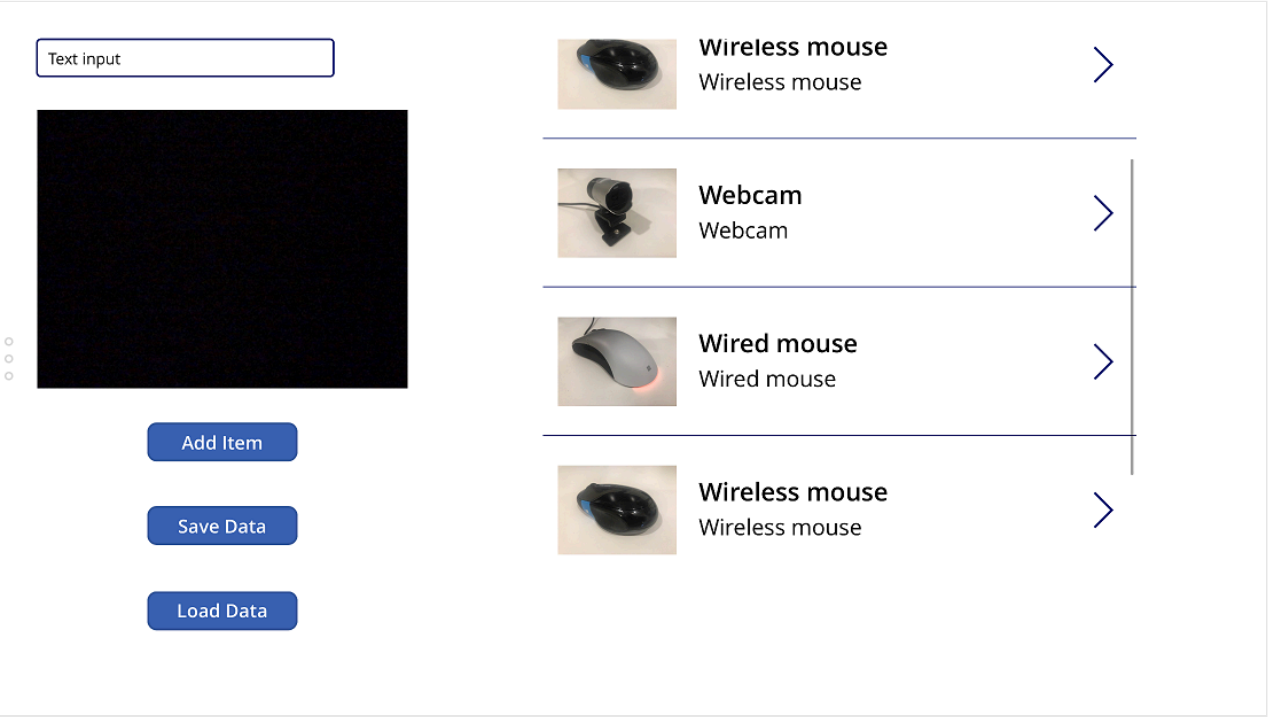
21. Launch the app again. The collection in memory will again show as empty in the gallery.



22. Select the **Load Data** button. The collection will be repopulated from the stored data on your device and your items will be back in the gallery. The collection was empty before this button calls the **LoadData** function; there was no need to call **Collect** or **ClearCollect** before loading the data from storage.



23. Select the **Load Data** button again. The stored data will be appended to the end of the collection and a scroll bar will appear on the gallery. If you would like to replace rather than append, use the **Clear** function first to clear out the collection before calling the **LoadData** function.



More advanced offline example

For a detailed example, see the article on simple offline capabilities.

Acceleration, App, Compass, Connection, and Location signals in Power Apps

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

Returns information about the app's environment, such as where the user is located in the world and which screen is displayed.

Description and syntax

Signals are values that can change at any time, independent of how the user may be interacting with the app. Formulas that are based on signals automatically recalculate as these values change.

Signals typically return a record of information. You can use and store this information as a record, or you can extract individual properties by using the . operator.

> **Note**
>
> The **Acceleration** and **Compass** functions return accurate values in a native player such as on iOS or Android, but those functions return zero values as you create or modify an app in the browser.

Acceleration

The **Acceleration** signal returns the device's acceleration in three dimensions relative to the device's screen. Acceleration is measured in *g* units of 9.81 m/second^2 or 32.2 ft/second^2 (the acceleration that the Earth imparts to objects at its surface due to gravity).

Expand table

Property	Description
Acceleration.X	Right and left. Right is a positive number.
Acceleration.Y	Forward and back. Forward is a positive number.

Property	Description
Acceleration.Z	Up and down. Up is a positive number.

App

Among other properties, the **App** object includes a signal that indicates which screen is showing.

Expand table

Property	Description
App.ActiveScreen	Screen that's showing. Returns a screen object, which you can use to reference properties of the screen or compare to another screen to determine which screen is showing. You can use the **Back** or **Navigate** function to change the screen that's showing.

More information: **App** object documentation.

Compass

The **Compass** signal returns the compass heading of the top of the screen. The heading is based on magnetic north.

Expand table

Property	Description
Compass.Heading	Heading in degrees. Returns a number 0 to 360, and 0 is north.

Connection

The **Connection** signal returns the information about the network connection. When on a metered connection, you may want to limit how much data you send or receive over the network. Or, if your app is enabled for offline, you may want to display different information depending on the current sync state.

Expand table

Property	Description
Connection.Connected	Returns a Boolean **true** or **false** value that indicates whether the device is connected to a network.
Connection.Metered	Returns a Boolean **true** or **false** value that indicates whether the connection is metered.
Connection.Sync	Returns an enum named **ConnectionSync** which holds the current synchronization state for an app that is enabled for offline.

Below are the enums values available for Connection.Sync.

Expand table

Enum value	Description
Connected	Your device is connected to the network and your app is ready to work offline
ConnectedWithWarning	Your device is connected with a warning.
ConnectedPendingUpsync	Some data on your device must be synchronized with the service.
ConnectedError	There was an error on the last synchronization attempt.
ConnectedRefresh	Your app is currently synchronizing data with the service.
NotConnected	Your device isn't connected to the service.
NotConnectedWithWarning	The last synchronization warning.
NotConnectedPendingUpsync	There are updates on your device waiting to be synchronized.
NotConnectedSyncError	The last synchronization error.

Location

The **Location** signal returns the location of the device based on the Global Positioning System (GPS) and other device information, such as cell-tower communications and IP address.

When a user accesses the location information for the first time, the device may prompt that user to allow access to this information.

As the location changes, dependencies on the location will continuously recalculate, which will consume power from the device's battery. To conserve battery life, you can

use the **Enable** and **Disable** functions to turn location updates on and off. Location is automatically turned off if the displayed screen doesn't depend on location information.

Expand table

Property	Description
Location.Altitude	Returns a number that indicates the altitude, measured in meters, above sea level.
Location.Latitude	Returns a number, from –90 to 90, that indicates the latitude, as measured in degrees from the equator. A positive number indicates a location that's north of the equator.
Location.Longitude	Returns a number, from –180 to 180, that indicates the longitude, as measured in degrees from Greenwich, England. A positive number indicates a location that's east of Greenwich.

Examples

In a baseball field, a pitcher throws a phone from the pitcher's mound to a catcher at home plate. The phone is lying flat with respect to the ground, the top of the screen is pointed at the catcher, and the pitcher adds no spin. At this location, the phone has cellular network service that's metered but no WiFi. The **PlayBall** screen is displayed. The app is enabled for offline and is connected to the service.

Expand table

Formula	Description	Result
Location.Latitude	Returns the latitude of the current location. The field is located at map coordinates 47.591 N, 122.333 W.	47.591 The latitude will change continuously as the ball moves between the pitcher and the catcher.
Location.Longitude	Returns the longitude of the current location.	122.333 The longitude will change continuously as the ball moves between the pitcher and the catcher.
Location	Returns the latitude and longitude of the current location, as a record.	{ Latitude: 47.591, Longitude: 122.333 }

Formula	Description	Result
Compass.Heading	Returns the compass heading of the top of the screen. At this field, home plate is roughly southwest from the pitcher's mound.	230.25
Acceleration.X	Returns the acceleration of the device side to side. The pitcher is throwing the phone straight ahead with respect to the screen's top, so the device isn't accelerating side to side.	0
Acceleration.Y	Returns the acceleration of the device front to back. The pitcher initially gives the device a large acceleration when throwing the device, going from 0 to 90 miles per hour (132 feet per second) in half a second. After the device is in the air, ignoring air friction, the device doesn't accelerate further. The device decelerates when the catcher catches it, bringing it to a stop.	8.2, while the pitcher throws the device. 0, while the device is in the air. -8.2, as the catcher catches the device.
Acceleration.Z	Returns the acceleration of the device top to bottom. While in the air, the device experiences the effects of gravity.	0, before the pitcher throws the device. 1, while the device is in the air. 0, after the catcher catches the device.
Acceleration	Returns the acceleration as a record.	{ X: 0, Y: 264, Z: 0 } as the pitcher throws the device.
Connection.Connected	Returns a Boolean value that indicates whether the device is connected to a network	**true**
Connection.Metered	Returns a Boolean value that indicates whether the connection is metered	**true**
Connection.Sync	Returns an enum value that indicates current sync state.	**ConnectionSync.Connected**
App.ActiveScreen = PlayBall	Returns a Boolean value that indicates whether **PlayBall** is	**true**

Formula	Description	Result
	displayed.	
App.ActiveScreen.Fill	Returns the background color for the displayed screen.	**Color.Green**

Filter, Search, and LookUp functions

Applies to: ✅ Canvas apps ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Finds one or more records in a table.

Watch this video to learn how to use **Filter**, **Search**, and **LookUp** functions:

https://learn-video.azurefd.net/vod/player?id=55b2c144-b5ac-4d66-b398-fea03eb21f17&locale=en-us&embedUrl=%2Fpower-platform%2Fpower-fx%2Freference%2Ffunction-filter-lookup

> **Note**
>
> PAC CLI pac power-fx commands do not support the **Search** function.

Description

The **Filter** function finds records in a table that satisfy a formula. Use **Filter** to find a set of records that match one or more criteria and discard those records that don't.

The **LookUp** function finds the first record in a table that satisfies a formula. Use **LookUp** to find a single record that matches one or more criteria.

For both, the formula is evaluated for each record of the table. Records that result in *true* are included in the result. Besides the normal formula operators, you can use the **in** and **exactin** operators for substring matches.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

The **Search** function finds records in a table that contain a string in one of their columns. The string might occur anywhere within the column; for example, searching for "rob" or "bert" would find a match in a column that contains "Robert". Searching is case-insensitive. Unlike **Filter** and **LookUp**, the **Search** function uses a single string to match instead of a formula.

Filter and **Search** return a table that contains the same columns as the original table and the records that match the criteria. **LookUp** returns only the first record found, after applying a

formula to reduce the record to a single value. If no records are found, **Filter** and **Search** return an empty table, and **LookUp** returns *blank*.

Tables are a value in Power Apps, just like a string or number. They can be passed to and returned from functions. **Filter**, **Search**, and **LookUp** don't modify a table. Instead, they take a table as an argument and return a table, a record, or a single value from it. See working with tables for more details.

Delegation

When possible, Power Apps will delegate filter and sort operations to the data source and page through the results on demand. For example, when you start an app that shows a **Gallery** control filled with data, only the first set of records will be initially brought to the device. As the user scrolls, additional data is brought down from the data source. The result is a faster start time for the app and access to very large data sets.

However, delegation may not always be possible. Data sources vary on what functions and operators they support with delegation. If complete delegation of a formula isn't possible, the authoring environment will flag the portion that can't be delegated with a warning. When possible, consider changing the formula to avoid functions and operators that can't be delegated. The delegation list details which data sources and operations can be delegated.

If delegation is not possible, Power Apps will pull down only a small set of records to work on locally. Filter and sort functions will operate on a reduced set of records. What is available in the **Gallery** may not be the complete story, which could be confusing to users.

See the delegation overview for more information.

Syntax

Filter(Table*, *Formula1* [, *Formula2*, ...])

- *Table* - Required. Table to search.
- *Formula(s)* - Required. The formula by which each record of the table is evaluated. The function returns all records that result in **true**. You can reference columns within the table. If you supply more than one formula, the results of all formulas are combined with the **And** function.

Search(Table*, *SearchString*, *Column1* [, *Column2*, ...])

- *Table* - Required. Table to search.

- *SearchString* - Required. The string to search for. If *blank* or an empty string, all records are returned.
- *Column(s)* - Required. The names of columns within *Table* to search. If *SearchString* is found within the data of any of these columns as a partial match, the full record will be returned.

> **Note**
>
> In Power Apps prior to version 3.24042, column names for the **Search** function were specified with a text string using double quotes, and if connected to a data source they also needed to be logical names. For example, the logical name **"cr43e_name"** with double quotes was used instead of the display name **Name** without quotes. For SharePoint and Excel data sources that contain column names with spaces, each space was specified with **"_x0020_"**, for example **"Column Name"** as **"Column_x0020_Name"**. After this version, all apps were automatically updated to the new syntax described in this article.

LookUp(Table*, *Formula* [, *ReductionFormula*])

- *Table* - Required. Table to search. In the UI, the syntax is shown as *source* above the function box.
- *Formula* - Required. The formula by which each record of the table is evaluated. The function returns the first record that results in **true**. You can reference columns within the table. In the UI, the syntax is shown as *condition* above the function box.
- *ReductionFormula* - Optional. This formula is evaluated over the record that was found, and then reduces the record to a single value. You can reference columns within the table. If you don't use this parameter, the function returns the full record from the table. In the UI, the syntax is shown as *result* above the function box.

Examples

The following examples use the **IceCream** data source:

Flavor	Quantity	OnOrder
"Chocolate"	100	75
"Vanilla"	200	50
"Strawberry"	300	0
"Mint Chocolate"	60	100

Expand table

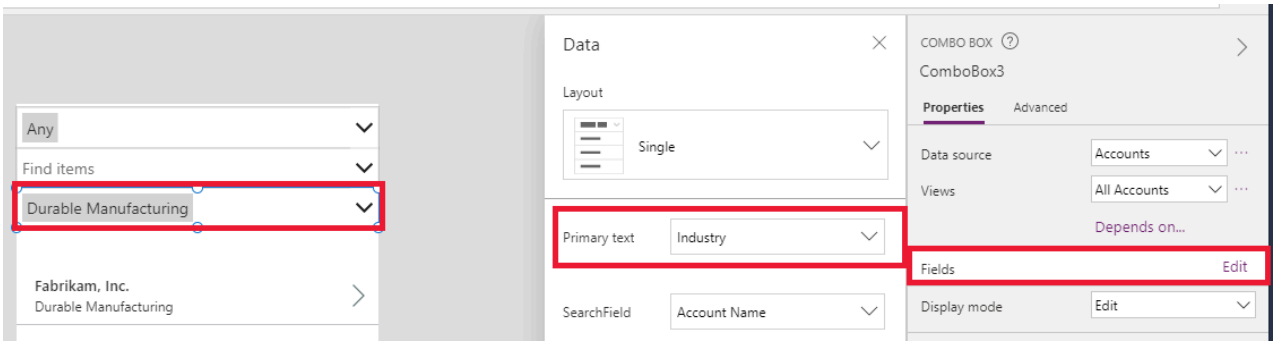
Formula	Description	Result
Filter(IceCream, OnOrder > 0)	Returns records where **OnOrder** is greater than zero.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Chocolate"</td><td>100</td><td>75</td></tr><tr><td>"Vanilla"</td><td>200</td><td>50</td></tr><tr><td>"Mint Chocolate"</td><td>60</td><td>100</td></tr></table>
Filter(IceCream, Quantity + OnOrder > 225)	Returns records where the sum of **Quantity** and **OnOrder** columns is greater than 225.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Vanilla"</td><td>200</td><td>50</td></tr><tr><td>"Strawberry"</td><td>300</td><td>0</td></tr></table>
Filter(IceCream, "chocolate" in Lower(Flavor))	Returns records where the word "chocolate" appears in the **Flavor** name, independent of uppercase or lowercase letters.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Chocolate"</td><td>100</td><td>75</td></tr><tr><td>"Mint Chocolate"</td><td>60</td><td>100</td></tr></table>
Filter(IceCream, Quantity < 10 && OnOrder < 20)	Returns records where the **Quantity** is less than 10 and **OnOrder** is less than 20. No records match these criteria, so an empty table is returned.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr></table>
Search(IceCream, "choc", Flavor)	Returns records where the string "choc" appears in the **Flavor** name, independent of uppercase or lowercase letters.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Chocolate"</td><td>100</td><td>75</td></tr><tr><td>"Mint Chocolate"</td><td>60</td><td>100</td></tr></table>
Search(IceCream, "", Flavor)	Because the search term is empty, all records are returned.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Chocolate"</td><td>100</td><td>75</td></tr><tr><td>"Vanilla"</td><td>200</td><td>50</td></tr><tr><td>"Strawberry"</td><td>300</td><td>0</td></tr><tr><td>"Mint Chocolate"</td><td>60</td><td>100</td></tr></table>
LookUp(IceCream, Flavor = "Chocolate", Quantity)	Searches for a record with **Flavor** equal to "Chocolate", of which there's one. For the first record that's found, returns the **Quantity** of that record.	100
LookUp(IceCream, Quantity > 150, Quantity + OnOrder)	Searches for a record with **Quantity** greater than 150, of which there are multiple. For the first record that's found, which is "Vanilla" **Flavor**, returns the sum of **Quantity** and **OnOrder** columns.	250
LookUp(IceCream, Flavor = "Pistachio", OnOrder)	Searches for a record with **Flavor** equal to "Pistachio", of which there are none. Because none is found, **Lookup** returns *blank*.	*blank*
LookUp(IceCream, Flavor = "Vanilla")	Searches for a record with **Flavor** equal to "Vanilla", of which there's one. Since no reduction formula was supplied, the entire record is returned.	{ Flavor: "Vanilla", Quantity: 200, OnOrder: 75 }

Filtering with choice columns

The following example uses the **Account** table in Microsoft Dataverse as data source. This example shows how to **Filter** list of accounts based on selected Combo box control values:

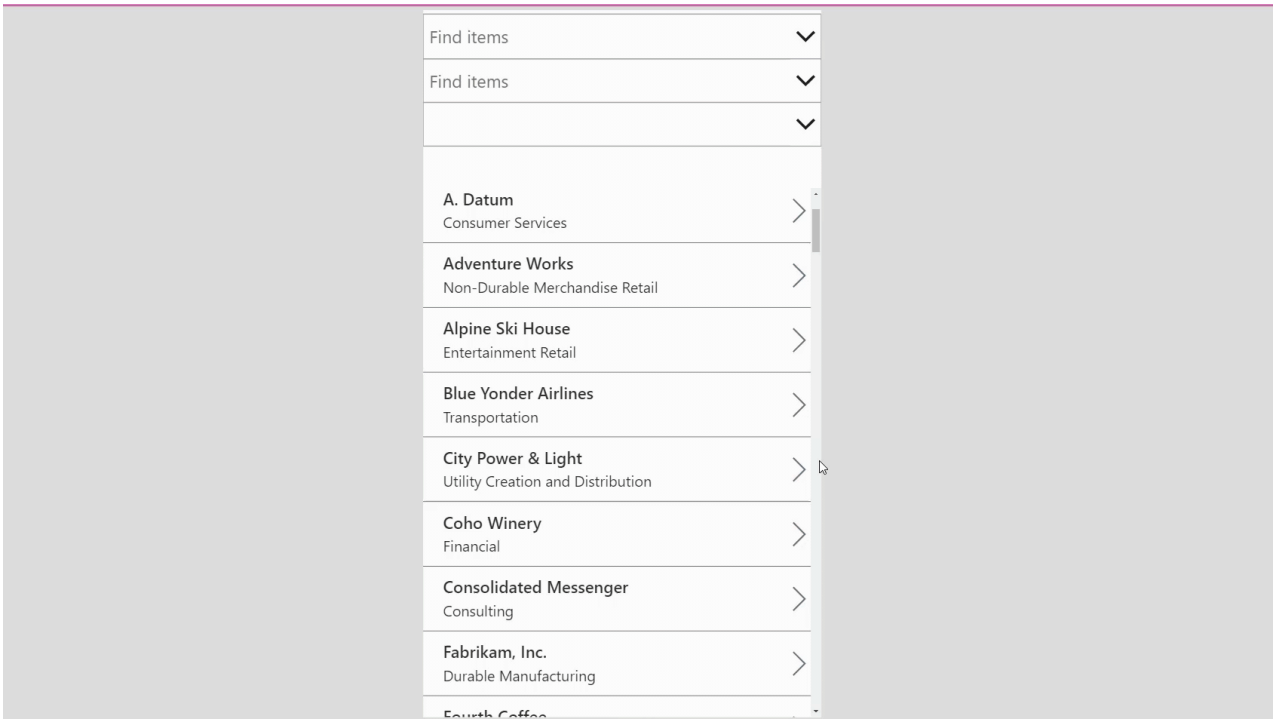
Step by step

1. Open a blank app.
2. Add a new screen by selecting the **New Screen** option.
3. On the **Insert** tab, select **Gallery** and then select **Vertical**.
4. On the **Properties** tab of the right-hand pane, open **Data Source** and then select **Accounts**.
5. (Optional) In the **Layout** list, select different options.
6. On the **Insert** tab, select **Input** and then select **Combo box**. Repeat the step to add two more combo box controls.
7. For each combo box control, on the **Properties** tab of the right-hand pane, open **Data Source** and then select **Accounts**. Select **Edit** next to **Fields** option and then select the **Primary text** and **SearchField** values. The **Primary text** should be the choices column you want to add to the combo box. Repeat the step for other two combo box controls.



8. Now select **Gallery** control and set the **Items** property to the following formula:

```
Filter(Accounts,
 'Industry' = ComboBox3.Selected.Industry Or
IsBlank(ComboBox3.Selected.Industry),
 'Relationship Type' = ComboBox2.Selected.'Relationship Type' Or
   IsBlank(ComboBox2.Selected.'Relationship Type'),
 'Preferred Method of Contact' = ComboBox1.Selected.'Preferred Method of
Contact' Or
   IsBlank(ComboBox1.Selected.'Preferred Method of Contact'))
```



Search user experience

The following examples use the **IceCream** data source:

In many apps, you can type one or more characters into a search box to filter a list of records in a large data set. As you type, the list shows only those records that match the search criteria.

The examples in the rest of this article show the results of searching a list, named **Customers**, that contain this data:

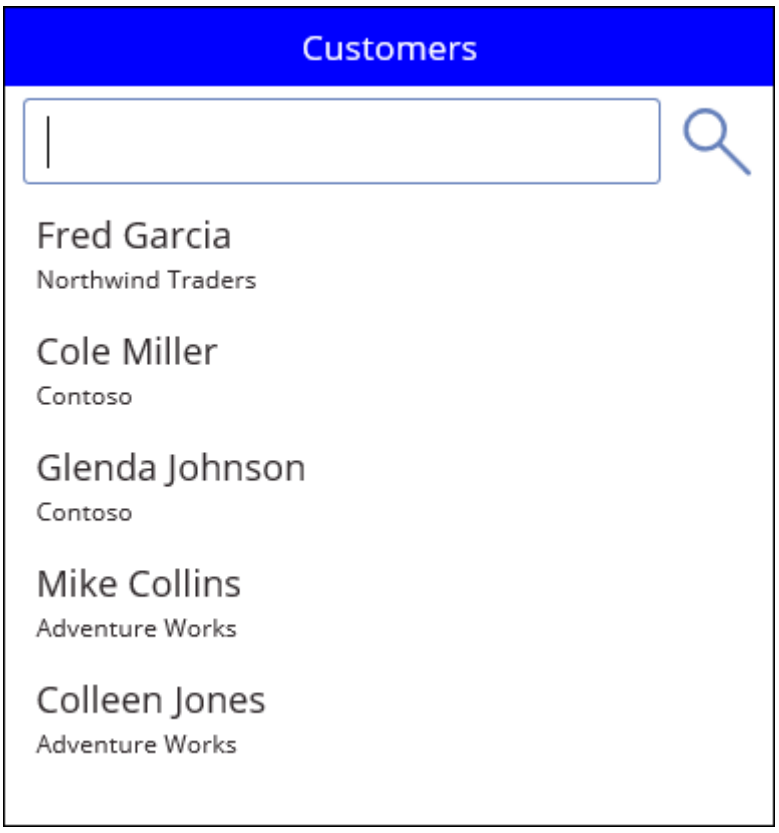
Name	Company
"Fred Garcia"	"Northwind Traders"
"Cole Miller"	"Contoso"
"Glenda Johnson"	"Contoso"
"Mike Collins"	"Adventure Works"
"Colleen Jones"	"Adventure Works"

To create this data source as a collection, create a **Button** control and set its **OnSelect** property to this formula:

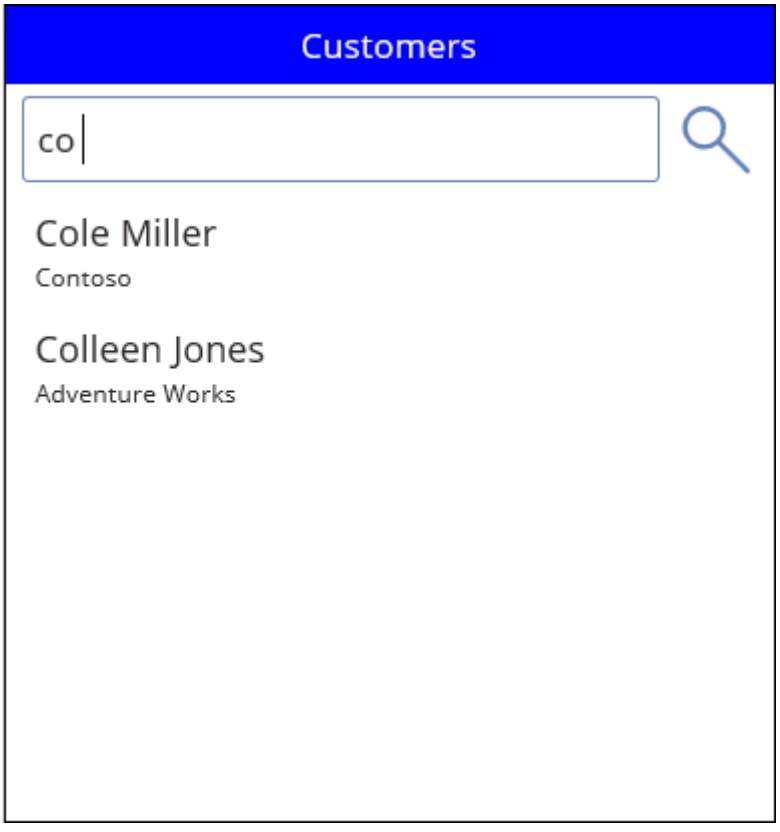
ClearCollect(Customers, Table({ Name: "Fred Garcia", Company: "Northwind Traders" }, { Name: "Cole Miller", Company: "Contoso" }, { Name: "Glenda Johnson", Company: "Contoso" }, { Name: "Mike Collins", Company: "Adventure Works" }, { Name: "Colleen Jones", Company: "Adventure Works" }))

As in this example, you can show a list of records in a **Gallery control** at the bottom of a screen. Near the top of the screen, you can add a **Text input** control, named **SearchInput**, so

that users can specify which records interest them.



As the user types characters in **SearchInput**, the results in the gallery are automatically filtered. In this case, the gallery is configured to show records for which the name of the customer (not the name of the company) starts with the sequence of characters in **SearchInput**. If the user types **co** in the search box, the gallery shows these results:



To filter based on the **Name** column, set the **Items** property of the gallery control to one of these formulas:

Expand table

Formula	Description	Result
Filter(Customers, StartsWith(Name, SearchInput.Text))	Filters the **Customers** data source for records in which the search string appears at the start of the **Name** column. The test is case insensitive. If the user types **co** in the search box, the gallery shows **Colleen Jones** and **Cole Miller**. The gallery doesn't show **Mike Collins** because the **Name** column for that record doesn't start with the search string.	
Filter(Customers, SearchInput.Text in Name)	Filters the **Customers** data source for records in which the search string appears anywhere in the **Name** column. The test is case insensitive. If the user types **co** in the search box, the gallery shows **Colleen Jones, Cole Miller,** and **Mike Collins** because the search string appears somewhere in the **Name** column of all of those records.	Search(Customers, SearchInput.Text, Name)	Similar to using the **in** operator, the **Search** function searches for a match anywhere within the **Name** column of each record. You must enclose the column name in double quotation marks.	

You can expand your search to include the **Company** column and the **Name** column:

Expand table

Formula	Description	Result
`Filter(Customers, StartsWith(Name, SearchInput.Text) || StartsWith(Company, SearchInput.Text) )`	Filters the **Customers** data source for records in which either the **Name** column or the **Company** column starts with the search string (for example, **co**). The || operator is *true* if either **StartsWith** function is *true*.	
`Filter(Customers, SearchInput.Text in Name || SearchInput. Text in Company)`	Filters the **Customers** data source for records in which either the **Name** column or the **Company** column contains the search string (for example, **co**) anywhere within it.	
`Search(Customers, SearchInput.Text, Name, Company)`	Similar to using the **in** operator, the **Search** function searches the **Customers** data source for records in which either the **Name** column or the **Company** column contains the search string (for example, **co**) anywhere within it. The **Search** function is easier to read and write	

Formula	Description	Result
	than **Filter** if you want to specify multiple columns and multiple **in** operators.

Lower, Upper, and Proper functions

Article • 04/20/2025

Expand table

Functions	Applies to
Lower **Upper**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Proper	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Converts letters in a string of text to all lowercase, all uppercase, or proper case.

Description

The **Lower**, **Upper**, and **Proper** functions convert the case of letters in strings.

- **Lower** converts any uppercase letters to lowercase.
- **Upper** converts any lowercase letters to uppercase.
- **Proper** converts the first letter in each word to uppercase if it's lowercase and converts any other uppercase letters to lowercase.

All three functions ignore characters that aren't letters.

If you pass a single string, the return value is the converted version of that string. If you pass a single-column table that contains strings, the return value is a single-column table of converted strings. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

Syntax

Lower(*String*)
Upper(*String*)
Proper(*String*)

- *String* - Required. The string to convert.

Lower(*SingleColumnTable*)
Upper(*SingleColumnTable*)
Proper(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of strings to convert.

Examples

Single string

The examples in this section use a text-input control, named **Author**, as their data source. The control contains the string "E. E. CummINGS".

Expand table

Formula	Description	Result
Lower(Author.Text)	Converts any uppercase letters in the string to lowercase.	"e. e. cummings"
Upper(Author.Text)	Converts any lowercase letters in the string to uppercase.	"E. E. CUMMINGS"
Proper(Author.Text)	Converts the first letter of each word to uppercase if it's lowercase, and converts any other uppercase letters to lowercase.	"E. E. Cummings"

Single-column table

The examples in this section convert strings from the **Address** column of the **People** data source, which contains this data:

Expand table

Name	Address
"Jean"	"123 Main St NE"
"Fred"	"789 SW 39th #3B"

Each formula returns a single-column table that contains the converted strings.

Expand table

Formula	Description	Result
Lower(ShowColumns(People, "Address"))	Converts any letter that's lowercase to uppercase.	A single-column table with a `Value` column containing the

Formula	Description	Result
		following values: "123 main st ne", "789 sw 39th #3b"
Upper(ShowColumns(People, "Address"))	Converts any letter that's lowercase to uppercase.	A single-column table with a `Value` column containing the following values: "123 MAIN ST NE", "789 SW 39TH #3B"
Proper(ShowColumns(People, "Address"))	Converts any first letter of a word that's lowercase to uppercase, and converts any other letter that's uppercase to lowercase.	A single-column table with a `Value` column containing the following values: "123 Main St Ne", "789 Sw 39th #3b"

Step-by-step example

1. Add a **Text input** control, and name it **Source**.
2. Add a label, and set its **Text** property to this function:
   Proper(Source.Text)
3. Press F5, and then type **WE ARE THE BEST!** into the **Source** box.
   The label shows **We Are The Best!**

IsMatch, Match, and MatchAll functions

06/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Tests for a match or extracts parts of a text string based on a pattern.

Description

The **IsMatch** function tests whether a text string matches a pattern that can comprise ordinary characters, predefined patterns, or a regular expression. The **Match** and **MatchAll** functions return what was matched, including submatches.

Use **IsMatch** to validate what a user typed in a **Text input** control. For example, confirm whether the user entered a valid email address before the result is saved to your data source. If the entry doesn't match your criteria, add other controls that prompt the user to fix the entry.

Use **Match** to extract the first text string that matches a pattern and **MatchAll** to extract all text strings that match. Extract submatches to parse complex strings.

Match returns a record of information for the first match found, and **MatchAll** returns a table of records for every match found. The record or records contain:

Expand table

Column	Type	Description
named sub-match or sub-matches	Text	Each named submatch has its own column. Create a named submatch by using **(?<*name*>...)** in the regular expression. If a named submatch has the same name as one of the predefined columns, the submatch takes precedence, and a warning is generated. Rename the submatch to avoid this warning.
FullMatch	Text	All of the text string that was matched.
StartMatch	Number	The starting position of the match within the input text string. The first character of the string returns 1.
SubMatches, only if **MatchOptions.NumberedSubMatches** is used.	Single-column table of	The table of numbered submatches in the order in which they appear in the regular expression. Generally, named submatches are

Column	Type	Description
	Text (column **Value**)	easier to work with and are encouraged. Use the ForAll function or Index function to work with an individual sub-match. If no submatches are defined in the regular expression, this table will be present but empty.

These functions support MatchOptions. By default:

- These functions perform a case-sensitive match. Use **MatchOptions.IgnoreCase** to perform case-insensitive matches.
- **IsMatch** matches the entire text string (**Complete** MatchOption), while **Match** and **MatchAll** search for a match anywhere in the text string (**Contains** MatchOption). Use **Complete**, **Contains**, **BeginsWith**, or **EndsWith** as appropriate for your scenario.

IsMatch returns *true* if the text string matches the pattern or *false* if it doesn't. **Match** returns *blank* if no match is found that can be tested with the IsBlank function. **MatchAll** returns an empty table if no match is found that can be tested with the IsEmpty function.

If you use **MatchAll** to split a text string, consider using the Split function, which is simpler and faster.

Patterns

The key to using these functions is in describing the pattern to match. You describe the pattern in a text string as a combination of:

- Ordinary characters, such as "**abc**" or "**123**".
- Predefined patterns, such as **Letter**, **MultipleDigits**, or **Email**. (The **Match** enum defines these patterns.)
- Regular-expression codes, such as "**\d+\s+\d+**" or "**[a-z]+**".

Combine these elements using the string-concatenation operator &. For example, "**abc**" & **Digit** & "**\s+**" is a valid pattern that matches the characters "a", "b", and "c", followed by a digit from 0 to 9, followed by at least one whitespace character.

Ordinary characters

The simplest pattern is a sequence of ordinary characters that match exactly.

For example, when used with the **IsMatch** function, the string "Hello" matches the pattern "**Hello**" exactly. No more and no less. The string `"hello!"` doesn't match the pattern because

of the exclamation point on the end and because the case is wrong for the letter "h". (See Match options for ways to modify this behavior.)

In the pattern language, the characters `. ? * + ( ) [ ] ^ $ | \` are reserved for special purposes. To use these characters, either prefix the character with a **** (backslash) to indicate that the character should be taken literally, or use one of the predefined patterns. For example, you can match the string `"Hello?"` by using the pattern `"Hello\\?"` with a backslash before the question mark.

Predefined patterns

Predefined patterns provide a simple way to match either one of a set of characters or a sequence of multiple characters. Use the string-concatenation operator **&** to combine your own text strings with members of the **Match** enum:

Expand table

Match enum	Description	Regular expression
Any	Matches any character.	`.`
Comma	Matches a comma `,`.	`,`
Digit	Matches a single digit ("0" through "9").	`\d`
Email	Matches an email address that contains an "at" symbol ("@") and a domain name that contains a dot (".")	*See note*
Hyphen	Matches a hyphen.	`-` *See note*
LeftParen	Matches a left parenthesis `(`.	`\(`
Letter	Matches a letter.	`\p{L}`
MultipleDigits	Matches one or more digits.	`\d+`
MultipleLetters	Matches one or more letters.	`\p{L}+`
MultipleNonSpaces	Matches one or more characters that don't add whitespace (not space, tab, or newline).	`\S+`
MultipleSpaces	Matches one or more characters that add whitespace (space, tab, or newline).	`\s+`
NonSpace	Matches a single character that doesn't add whitespace.	`\S`
OptionalDigits	Matches zero, one, or more digits.	`\d*`

Match enum	Description	Regular expression
OptionalLetters	Matches zero, one, or more letters.	`\p{L}*`
OptionalNonSpaces	Matches zero, one, or more characters that don't add whitespace.	`\S*`
OptionalSpaces	Matches zero, one, or more characters that add whitespace.	`\s*`
Period	Matches a period or dot `.`.	`\.`
RightParen	Matches a right parenthesis `)`.	`\)`
Space	Matches a character that adds whitespace.	`\s`
Tab	Matches a tab character.	`\t`

For example, the pattern **"A" & MultipleDigits** matches the letter "A" followed by one or more digits.

Power Apps uses a different definition for **Match.EMail** and **Match.Hyphen**. Evaluate `Text( Match.Email )` to see the regular expression used by your host.

Regular expressions

The pattern they these functions use is called a regular expression. Power Fx's specific dialect of regular expressions is detailed in Regular expressions in Power Fx.

Regular expressions are powerful and serve a wide variety of purposes. They can also look like a random sequence of punctuation marks. This article doesn't describe all aspects of regular expressions, but a wealth of information, tutorials, and tools are available online.

Regular expressions have a long history and are available in many programming languages. Every programming language has its own dialect of regular expressions, and there are few standards. We strive to ensure the same regular expression gives the same result across all Power Fx implementations. Compatibility isn't easy to accomplish as Power Fx runs on top of JavaScript and .NET which have significant differences. To accommodate running on different platforms, Power Fx regular expressions are limited to a subset of features that are widely supported across the industry.

As a result, some regular expressions that may work in other environments may be blocked or require a tweak in Power Fx. Authoring time errors are reported as unsupported features are encountered. This is one of the reasons that the regular expression and options must be an authoring time constant and not dynamic (for example, provided in a variable).

> **Note**
>
> Power Apps uses an earlier version of Power Fx regular expressions that has fewer limitations but also fewer features. **MatchOptions.DotAll** and **MatchOptions.FreeSpacing** aren't available and the definitions of **Match.Email** and **Match.Hyphen** are different. Unicode surrogate pairs aren't treated as a single character. **MatchOptions.NumberedSubMatches** is the default. The version of regular expressions described here will be available in Power Apps soon, under a "Power Fx V1.0 compatibility" switch.

Here are some basic elements of regular expressions that build up complexity in parsing a number.

Expand table

Feature	Example	Description
Predfined character class	`\d`	This regular expression matches a single number, such as `1`. A character class matches a set of characters and `\d` matches the standard digits `0` to `9` and also digits defined in the Unicode character category "Nd". There are character classes for letters and numbers with `\w` and spaces including newlines with `\s`. There are also inverse character classes that are capitalized: `\D` matches everything that `\d` does not.
One or More	`\d+`	This regular expression matches one or more numbers, such as `123`. A `+` after an element says "one or more" of the last element.
Zero or One	`\+?\d`	This regular expression matches an optional `+` sign followed by one ore more numbers, such as `+123` as well as just `123`. A `?` after an element says "this is optional, it can occur zero or one time". The `+` has a backslash before it to distinguish it as a literal character rather than the "one or more" usage.
Grouping and alternation	`(-|\+)?\d+`	This regular expression matches either an `+` sign or a `-`, optionally, and then a series of numbers, such as `-123`, `+123`, and `123`. We are introducing two concepts here that are often used together. First, we have the parenthesis that group as set of elements together, for the `?` to act upon. Second, we have `|` which says "either this or that".
Custom character class	`(-|\+)?\d+[eE][\-\+]?\d+`	This regular expression adds an exponent to the mix with two character classes, matching `+123e-12`. A character class is like `|` alternation providing a "match one of these things" in a more

Feature	Example	Description
		compact form. As with the `+`, `-` has special meaning in regular expression character classes so we need to escape it.
Zero or More	`(-|\+)?\d+\.?\d*[eE][\-\+]?\d+`	This regular expression adds the decimal after the integer portion of the number, such as `-123.456e-89` or `-123.E+32`. The `\d` after the decimal point has a `*` quantifier that says "zero or more times" for decimal digits after the `.`
Capture groups	`(?<number>(-|\+)?\d+\.?\d*)[eE](?<exponent>[\-\+]?\d+)`	Finally, we add capture groups for `number` and `exponent`. Not only can a regular expression match the entire string, it can also extract portions for use in your formulas, in this case the part before the `e` (or `E`) and the part after.

These examples only give a small taste of what regular expressions can do. They are commonly used to validate ID numbers, email addresses, phone numbers, dates and times, and to extract information from all kinds of text files. Continue your journey by reading Regular expressions in Power Fx, experiment, and use the web to learn more.

Match options

Modify the behavior of these functions by specifying one or more options, which you combine using the string- concatenation operator (**&**).

Expand table

MatchOptions enum	Description	Impact on a regular expression
MatchOptions.BeginsWith	The pattern must match from the beginning of the text.	Adds a ^ to the start of the regular expression.
MatchOptions.Complete	Default for **IsMatch** on Power Apps. The pattern matches the entire string of text, from beginning to end.	Adds a ^ to the start and a $ to the end of the regular expression.
MatchOptions.Contains	Default for **Match** and **MatchAll**, and **IsMatch** outside of Power Apps. The pattern must appear somewhere in the text but doesn't need to begin or end it.	Doesn't modify the regular expression.
MatchOptions.DotAll	Changes the behavior of the `.` (dot) operator to match all characters,	Doesn't modify the regular expression.

MatchOptions enum	Description	Impact on a regular expression
	including newline characters. Not available in Power Apps.	This option is the equivalent of the standard "s" modifier for regular expressions.
MatchOptions.EndsWith	The pattern must match the end of the string of text.	Adds a **$** to the end of the regular expression.
MatchOptions.FreeSpacing	Whitespace characters, including newlines, are ignored in the regular expression. End-of-line comments beginning with a `#` are ignored. Not available in Power Apps.	Only changes how the regular expression syntax. This option is the equivalent of the standard "x" modifier for regular expressions.
MatchOptions.IgnoreCase	Treats uppercase and lowercase letters as identical. By default, matching is case sensitive.	Doesn't modify the regular expression. This option is the equivalent of the standard "i" modifier for regular expressions.
MatchOptions.Multiline	Changes the behavior of `^` and `$` to match at the end of aline.	Doesn't modify the regular expression. This option is the equivalent of the standard "m" modifier for regular expressions.
MatchOptions.NumberedSubMatches	Named captures are preferred because they are easier to understand and maintain. Performance also improves as unneeded captures aren't retained. But for older regular expressions, treats each set of parenthesis as a numbered capture that is included with the **SubMatches** table in the result. Default in Power Apps.	Doesn't modify the regular expression. Named captures are disabled and `\1` style back references are enabled.

Using **MatchAll** is the same as using the standard "g" modifier for regular expressions.

Syntax

IsMatch(*Text*, *Pattern* [, *Options*])

- *Text* – Required. The text string to test.
- *Pattern* – Required. The pattern to test as a text string. Concatenate predefined patterns that the **Match** enum defines or provide a regular expression. *Pattern* must be a constant formula without variables, data sources, or other dynamic references that change as the app runs. Note, that the formula must be expressed as "Match.PredefinedPattern" e.g. Match.Email
- *Options* – Optional. A text-string combination of **MatchOptions** enum values. By default, **MatchOptions.Complete** is used. *Options* must be a constant formula without variables, data sources, or other dynamic references that change as the app runs.

Match(*Text*, *Pattern* [, *Options*])

- *Text* – Required. The text string to match.
- *Pattern* – Required. The pattern to match as a text string. Concatenate predefined patterns that the **Match** enum defines, or provide a regular expression. *Pattern* must be a constant formula without any variables, data sources, or other dynamic references that change as the app runs.
- *Options* – Optional. A text-string combination of **MatchOptions** enum values. By default, **MatchOptions.Contains** is used. *Options* must be a constant formula without any variables, data sources, or other dynamic references that change as the app runs.

MatchAll(*Text*, *Pattern* [, *Options*])

- *Text* – Required. The text string to match.
- *Pattern* – Required. The pattern to match as a text string. Concatenate predefined patterns that the **Match** enum defines or provide a regular expression. *Pattern* must be a constant formula without variables, data sources, or other dynamic references that change as the app runs.
- *Options* – Optional. A text-string combination of **MatchOptions** enum values. By default, **MatchOptions.Contains** is used. *Options* must be a constant formula without variables, data sources, or other dynamic references that change as the app runs.

IsMatch examples

Ordinary characters

Imagine your app has a **Text input** control named **TextInput1**. Users enter values into this control to store them in a database.

Users type **Hello world** into **TextInput1**.

Expand table

Formula	Description	Result
`IsMatch( TextInput1.Text, "Hello world" )`	Tests whether the user's input matches, exactly, the string "Hello world".	**true**
`IsMatch( TextInput1.Text, "Good bye" )`	Tests whether the user's input matches, exactly, the string "Good bye".	**false**
`IsMatch( TextInput1.Text, "hello", Contains )`	Tests whether the user's input contains the word "hello" (case sensitive).	**false**
`IsMatch( TextInput1.Text, "hello", Contains & IgnoreCase )`	Tests whether the user's input contains the word "hello" (case insensitive).	**true**

Predefined patterns

Expand table

Formula	Description	Result
`IsMatch( "123-45-7890", Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit )`	Matches a United States Social Security Number	**true**
`IsMatch( "joan@contoso.com", Match.Email )`	Matches an email address	**true**
`IsMatch( "123.456", Match.MultipleDigits & Match.Period & Match.OptionalDigits )`	Matches a sequence of digits, a period, and then zero or more digits.	**true**
`IsMatch( "123", Match.MultipleDigits & Match.Period & Match.OptionalDigits )`	Matches a sequence of digits, a period, and then zero or more digits. A period doesn't appear in the text to match, so this pattern isn't matched.	**false**

Regular expressions

Expand table

Formula	Description	Result
`IsMatch( "986", "\d+" )`	Matches an integer greater than zero.	**true**

Formula	Description	Result
`IsMatch( "1.02", "\d+(\.\d\d)?" )`	Matches a positive currency amount. If the input contains a decimal point, the input must also contain two numeric characters after the decimal point. For example, 3.00 is valid, but 3.1 isn't.	**true**
`IsMatch( "-4.95", "(-)?\d+(\.\d\d)?" )`	Matches a positive or negative currency amount. If the input contains a decimal point, the input must also contain two numeric characters after the decimal point.	**true**
`IsMatch( "111-11-1111", "\d{3}-\d{2}-\d{4}" )`	Matches a United States Social Security number. Validates the format, type, and length of the supplied input field. The string to match must consist of three numeric characters followed by a dash, then two numeric characters followed by a dash, and then four numeric characters.	**true**
`IsMatch( "111-111-111", "\d{3}-\d{2}-\d{4}" )`	Same as the previous example, but one of the hyphens is out of place in the input.	**false**
`IsMatch( "AStrongPasswordNot", "(?!^[0-9]\*$)(?!^[a-zA-Z]\*$)([a-zA-Z0-9]{8,10})" )`	Validates a strong password that must contain eight, nine, or 10 characters, at least one digit, and at least one alphabetic character. The string can't contain special characters.	**false**

Match and MatchAll examples

Expand table

Formula	Description	Result

`Match( "Bob Jones <bob.jones@contoso.com>", "<(?<email>" & Match.Email & ")>")`	Extracts only the email portion of the contact information.	{
		email: "bob.jones@contoso.com",
		FullMatch: "<bob.jones@contoso.com>",
		StartMatch: 11
		}

`Match( "Bob Jones <InvalidEmailAddress>", "<(?<email>" & Match.Email & ")>"`	Extracts only the email portion of the contact information. No legal address is found (there is no @ sign), so the function returns *blank*.	*blank*
`Match( Language(), "(<language>\w{2})(?:-(?<script>\w{4}))?(?:-(?<region>\w{2}))?" )`	Extracts the language, script, and region portions of the language tag that the Language function returns. These results reflect the	{ language: "en", script: *blank*, region: "US",

Formula	Description	Result
	United States; see the Language function documentation for more examples. The **(?:** operator groups characters without creating another sub-match.	FullMatch: "en-US", StartMatch: 1 }

`Match( "PT2H1M39S", "PT(?:(?<hours>\d+)H)?(?:(?<minutes>\d+)M)?(?:(?<seconds>\d+)S)?" )`	Extracts the hours, minutes, and seconds from an ISO 8601 duration value. The extracted numbers are still in a text string; use the Value function to convert it to a number before mathematical operations are performed on it.	{
		hours: "2",
		minutes: "1",
		seconds: "39",
		FullMatch: "PT2H1M39S",
		StartMatch: 1
		}

Let's drill into that last example. If you wanted to convert this string to a date/time value using the Time function, you must pass in the named submatches individually. To do this, use the With function operating on the record that **Match** returns:

Power Fx

```
With(
    Match( "PT2H1M39S", "PT(?:(?<hours>\d+)H)?(?:(?<minutes>\d+)M)?(?:(?<seconds>\d+)S)?" ),
   Time( Value( hours ), Value( minutes ), Value( seconds ) )
)
```

For these examples, add a Button control, set its **OnSelect** property to this formula, and then select the button:

Power Fx

```
Set( pangram, "The quick brown fox jumps over the lazy dog." )
```

Expand table

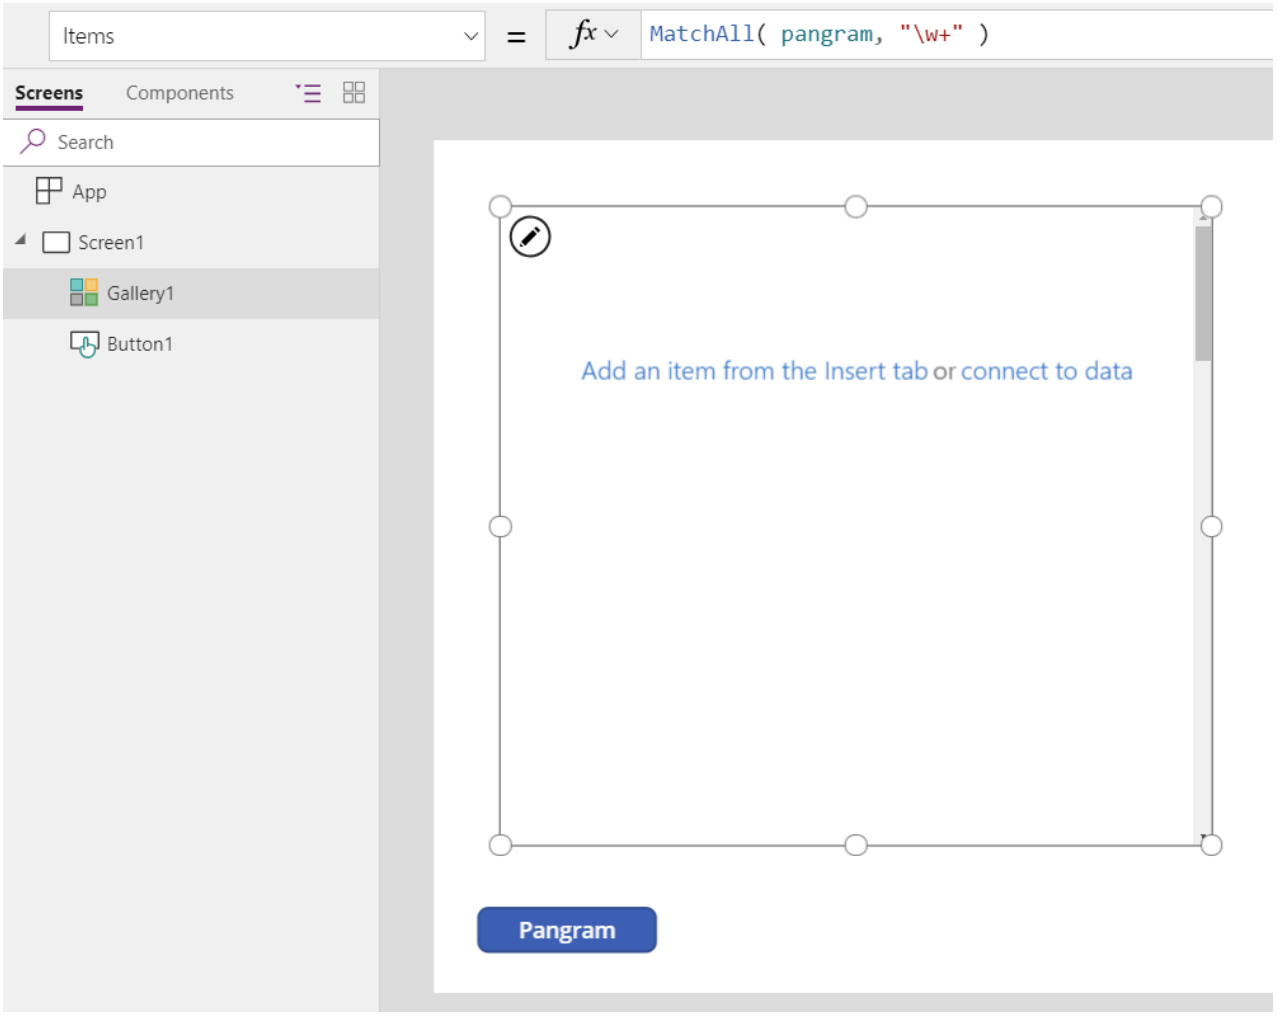
Formula	Description	Result

`Match( pangram, "THE", IgnoreCase )`	Find all matches of "THE" in the text string that the **pangram** variable contains. The string contains two matches, but only the first is returned because	{
		FullMatch: "The",
		StartMatch: 32
		}

<table>
<tr><th>Formula</th><th>Description</th><th>Result</th></tr>
<tr><td></td><td>you're using Match and not MatchAll.</td><td></td></tr>
<tr><td><code>MatchAll(pangram, "the")</code></td><td>Find all matches of "the" in the text string that the pangram variable contains. The test is case sensitive, so only the second instance of "the" is found.</td><td><table><tr><th>FullMatch</th><th>SubMatches</th><th>StartMatch</th></tr><tr><td>"the"</td><td>[ ]</td><td>32</td></tr></table></td></tr>
<tr><td><code>MatchAll(pangram, "the", IgnoreCase)</code></td><td>Find all matches of "the" in the text string that the pangram variable contains. In this case, the test is case insensitive, so both instances of the word are found.</td><td><table><tr><th>FullMatch</th><th>SubMatches</th><th>StartMatch</th></tr><tr><td>"The"</td><td>[ ]</td><td>1</td></tr><tr><td>"the"</td><td>[ ]</td><td>32</td></tr></table></td></tr>
<tr><td><code>MatchAll(pangram, "\b\wo\w\b")</code></td><td>Finds all three-letter words with an "o" in the middle. "brown" is excluded because it's not a three-letter word and, therefore, fails to match "\b" (word boundary).</td><td><table><tr><th>FullMatch</th><th>SubMatches</th><th>StartMatch</th></tr><tr><td>"fox"</td><td>[ ]</td><td>17</td></tr><tr><td>"dog"</td><td>[ ]</td><td>41</td></tr></table></td></tr>
<tr><td><code>Match(pangram, "\b\wo\w\b\s*(?<between>\w.+\w)\s*\b\wo\w\b")</code></td><td>Matches all the characters between "fox" and "dog".</td><td>{
between: "jumps over the lazy",
FullMatch: "fox jumps over the lazy dog",
StartMatch: 17
}</td></tr>
</table>

To see the results of **MatchAll** in a gallery:

1. In an empty screen, insert a blank vertical gallery control.
2. Set the gallery's **Items** property to **MatchAll(pangram, "\w+")** or **MatchAll(pangram, MultipleLetters)**.



3. Select "Add an item from the Insert tab" in the middle of the gallery control to select the template of the gallery.

4. Add a Label control to the gallery's template.

5. Set the label's **Text** property to **ThisItem.FullMatch**.

   The gallery is filled with each word in our example text. To see all the words on one screen, resize the gallery's template and the label control.

IsMatch, Match, and MatchAll functions

06/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Tests for a match or extracts parts of a text string based on a pattern.

Description

The **IsMatch** function tests whether a text string matches a pattern that can comprise ordinary characters, predefined patterns, or a regular expression. The **Match** and **MatchAll** functions return what was matched, including submatches.

Use **IsMatch** to validate what a user typed in a **Text input** control. For example, confirm whether the user entered a valid email address before the result is saved to your data source. If the entry doesn't match your criteria, add other controls that prompt the user to fix the entry.

Use **Match** to extract the first text string that matches a pattern and **MatchAll** to extract all text strings that match. Extract submatches to parse complex strings.

Match returns a record of information for the first match found, and **MatchAll** returns a table of records for every match found. The record or records contain:

Expand table

Column	Type	Description
named sub-match or sub-matches	Text	Each named submatch has its own column. Create a named submatch by using **(?<*name*>...)** in the regular expression. If a named submatch has the same name as one of the predefined columns, the submatch takes precedence, and a warning is generated. Rename the submatch to avoid this warning.
FullMatch	Text	All of the text string that was matched.
StartMatch	Number	The starting position of the match within the input text string. The first character of the string returns 1.
SubMatches, only if **MatchOptions.NumberedSubMatches** is used.	Single-column table of	The table of numbered submatches in the order in which they appear in the regular expression. Generally, named submatches are

Column	Type	Description
	Text (column **Value**)	easier to work with and are encouraged. Use the ForAll function or Index function to work with an individual sub-match. If no submatches are defined in the regular expression, this table will be present but empty.

These functions support MatchOptions. By default:

- These functions perform a case-sensitive match. Use **MatchOptions.IgnoreCase** to perform case-insensitive matches.
- **IsMatch** matches the entire text string (**Complete** MatchOption), while **Match** and **MatchAll** search for a match anywhere in the text string (**Contains** MatchOption). Use **Complete**, **Contains**, **BeginsWith**, or **EndsWith** as appropriate for your scenario.

IsMatch returns *true* if the text string matches the pattern or *false* if it doesn't. **Match** returns *blank* if no match is found that can be tested with the IsBlank function. **MatchAll** returns an empty table if no match is found that can be tested with the IsEmpty function.

If you use **MatchAll** to split a text string, consider using the Split function, which is simpler and faster.

Patterns

The key to using these functions is in describing the pattern to match. You describe the pattern in a text string as a combination of:

- Ordinary characters, such as "**abc**" or "**123**".
- Predefined patterns, such as **Letter**, **MultipleDigits**, or **Email**. (The **Match** enum defines these patterns.)
- Regular-expression codes, such as "**\d+\s+\d+**" or "**[a-z]+**".

Combine these elements using the string-concatenation operator &. For example, "**abc**" & **Digit** & "**\s+**" is a valid pattern that matches the characters "a", "b", and "c", followed by a digit from 0 to 9, followed by at least one whitespace character.

Ordinary characters

The simplest pattern is a sequence of ordinary characters that match exactly.

For example, when used with the **IsMatch** function, the string "Hello" matches the pattern "**Hello**" exactly. No more and no less. The string `"hello!"` doesn't match the pattern because

of the exclamation point on the end and because the case is wrong for the letter "h". (See Match options for ways to modify this behavior.)

In the pattern language, the characters `. ? * + ( ) [ ] ^ $ | \` are reserved for special purposes. To use these characters, either prefix the character with a **** (backslash) to indicate that the character should be taken literally, or use one of the predefined patterns. For example, you can match the string `"Hello?"` by using the pattern `"Hello\\?"` with a backslash before the question mark.

Predefined patterns

Predefined patterns provide a simple way to match either one of a set of characters or a sequence of multiple characters. Use the string-concatenation operator **&** to combine your own text strings with members of the **Match** enum:

Expand table

Match enum	Description	Regular expression
Any	Matches any character.	`.`
Comma	Matches a comma `,`.	`,`
Digit	Matches a single digit ("0" through "9").	`\d`
Email	Matches an email address that contains an "at" symbol ("@") and a domain name that contains a dot (".")	*See note*
Hyphen	Matches a hyphen.	`-` *See note*
LeftParen	Matches a left parenthesis `(`.	`\(`
Letter	Matches a letter.	`\p{L}`
MultipleDigits	Matches one or more digits.	`\d+`
MultipleLetters	Matches one or more letters.	`\p{L}+`
MultipleNonSpaces	Matches one or more characters that don't add whitespace (not space, tab, or newline).	`\S+`
MultipleSpaces	Matches one or more characters that add whitespace (space, tab, or newline).	`\s+`
NonSpace	Matches a single character that doesn't add whitespace.	`\S`
OptionalDigits	Matches zero, one, or more digits.	`\d*`

Match enum	Description	Regular expression
OptionalLetters	Matches zero, one, or more letters.	`\p{L}*`
OptionalNonSpaces	Matches zero, one, or more characters that don't add whitespace.	`\S*`
OptionalSpaces	Matches zero, one, or more characters that add whitespace.	`\s*`
Period	Matches a period or dot `.`.	`\.`
RightParen	Matches a right parenthesis `)`.	`\)`
Space	Matches a character that adds whitespace.	`\s`
Tab	Matches a tab character.	`\t`

For example, the pattern **"A" & MultipleDigits** matches the letter "A" followed by one or more digits.

Power Apps uses a different definition for **Match.EMail** and **Match.Hyphen**. Evaluate `Text( Match.Email )` to see the regular expression used by your host.

Regular expressions

The pattern they these functions use is called a regular expression. Power Fx's specific dialect of regular expressions is detailed in Regular expressions in Power Fx.

Regular expressions are powerful and serve a wide variety of purposes. They can also look like a random sequence of punctuation marks. This article doesn't describe all aspects of regular expressions, but a wealth of information, tutorials, and tools are available online.

Regular expressions have a long history and are available in many programming languages. Every programming language has its own dialect of regular expressions, and there are few standards. We strive to ensure the same regular expression gives the same result across all Power Fx implementations. Compatibility isn't easy to accomplish as Power Fx runs on top of JavaScript and .NET which have significant differences. To accommodate running on different platforms, Power Fx regular expressions are limited to a subset of features that are widely supported across the industry.

As a result, some regular expressions that may work in other environments may be blocked or require a tweak in Power Fx. Authoring time errors are reported as unsupported features are encountered. This is one of the reasons that the regular expression and options must be an authoring time constant and not dynamic (for example, provided in a variable).

> **Note**
>
> Power Apps uses an earlier version of Power Fx regular expressions that has fewer limitations but also fewer features. **MatchOptions.DotAll** and **MatchOptions.FreeSpacing** aren't available and the definitions of **Match.Email** and **Match.Hyphen** are different. Unicode surrogate pairs aren't treated as a single character. **MatchOptions.NumberedSubMatches** is the default. The version of regular expressions described here will be available in Power Apps soon, under a "Power Fx V1.0 compatibility" switch.

Here are some basic elements of regular expressions that build up complexity in parsing a number.

Expand table

Feature	Example	Description
Predfined character class	`\d`	This regular expression matches a single number, such as `1`. A character class matches a set of characters and `\d` matches the standard digits `0` to `9` and also digits defined in the Unicode character category "Nd". There are character classes for letters and numbers with `\w` and spaces including newlines with `\s`. There are also inverse character classes that are capitalized: `\D` matches everything that `\d` does not.
One or More	`\d+`	This regular expression matches one or more numbers, such as `123`. A `+` after an element says "one or more" of the last element.
Zero or One	`\+?\d`	This regular expression matches an optional `+` sign followed by one ore more numbers, such as `+123` as well as just `123`. A `?` after an element says "this is optional, it can occur zero or one time". The `+` has a backslash before it to distinguish it as a literal character rather than the "one or more" usage.
Grouping and alternation	`(-|\+)?\d+`	This regular expression matches either an `+` sign or a `-`, optionally, and then a series of numbers, such as `-123`, `+123`, and `123`. We are introducing two concepts here that are often used together. First, we have the parenthesis that group as set of elements together, for the `?` to act upon. Second, we have `|` which says "either this or that".
Custom character class	`(-|\+)?\d+[eE][\-\+]?\d+`	This regular expression adds an exponent to the mix with two character classes, matching `+123e-12`. A character class is like `|` alternation providing a "match one of these things" in a more

Feature	Example	Description
		compact form. As with the `+`, `-` has special meaning in regular expression character classes so we need to escape it.
Zero or More	`(-|\+)?\d+\.?\d*[eE][\-\+]?\d+`	This regular expression adds the decimal after the integer portion of the number, such as `-123.456e-89` or `-123.E+32`. The `\d` after the decimal point has a `*` quantifier that says "zero or more times" for decimal digits after the `.`
Capture groups	`(?<number>(-|\+)?\d+\.?\d*)[eE](?<exponent>[\-\+]?\d+)`	Finally, we add capture groups for `number` and `exponent`. Not only can a regular expression match the entire string, it can also extract portions for use in your formulas, in this case the part before the `e` (or `E`) and the part after.

These examples only give a small taste of what regular expressions can do. They are commonly used to validate ID numbers, email addresses, phone numbers, dates and times, and to extract information from all kinds of text files. Continue your journey by reading Regular expressions in Power Fx, experiment, and use the web to learn more.

Match options

Modify the behavior of these functions by specifying one or more options, which you combine using the string- concatenation operator (**&**).

Expand table

MatchOptions enum	Description	Impact on a regular expression
MatchOptions.BeginsWith	The pattern must match from the beginning of the text.	Adds a ^ to the start of the regular expression.
MatchOptions.Complete	Default for **IsMatch** on Power Apps. The pattern matches the entire string of text, from beginning to end.	Adds a ^ to the start and a $ to the end of the regular expression.
MatchOptions.Contains	Default for **Match** and **MatchAll**, and **IsMatch** outside of Power Apps. The pattern must appear somewhere in the text but doesn't need to begin or end it.	Doesn't modify the regular expression.
MatchOptions.DotAll	Changes the behavior of the `.` (dot) operator to match all characters,	Doesn't modify the regular expression.

MatchOptions enum	Description	Impact on a regular expression
	including newline characters. Not available in Power Apps.	This option is the equivalent of the standard "s" modifier for regular expressions.
MatchOptions.EndsWith	The pattern must match the end of the string of text.	Adds a **$** to the end of the regular expression.
MatchOptions.FreeSpacing	Whitespace characters, including newlines, are ignored in the regular expression. End-of-line comments beginning with a `#` are ignored. Not available in Power Apps.	Only changes how the regular expression syntax. This option is the equivalent of the standard "x" modifier for regular expressions.
MatchOptions.IgnoreCase	Treats uppercase and lowercase letters as identical. By default, matching is case sensitive.	Doesn't modify the regular expression. This option is the equivalent of the standard "i" modifier for regular expressions.
MatchOptions.Multiline	Changes the behavior of `^` and `$` to match at the end of aline.	Doesn't modify the regular expression. This option is the equivalent of the standard "m" modifier for regular expressions.
MatchOptions.NumberedSubMatches	Named captures are preferred because they are easier to understand and maintain. Performance also improves as unneeded captures aren't retained. But for older regular expressions, treats each set of parenthesis as a numbered capture that is included with the **SubMatches** table in the result. Default in Power Apps.	Doesn't modify the regular expression. Named captures are disabled and `\1` style back references are enabled.

Using **MatchAll** is the same as using the standard "g" modifier for regular expressions.

Syntax

IsMatch(*Text*, *Pattern* [, *Options*])

- *Text* – Required. The text string to test.
- *Pattern* – Required. The pattern to test as a text string. Concatenate predefined patterns that the **Match** enum defines or provide a regular expression. *Pattern* must be a constant formula without variables, data sources, or other dynamic references that change as the app runs. Note, that the formula must be expressed as "Match.PredefinedPattern" e.g. Match.Email
- *Options* – Optional. A text-string combination of **MatchOptions** enum values. By default, **MatchOptions.Complete** is used. *Options* must be a constant formula without variables, data sources, or other dynamic references that change as the app runs.

Match(*Text*, *Pattern* [, *Options*])

- *Text* – Required. The text string to match.
- *Pattern* – Required. The pattern to match as a text string. Concatenate predefined patterns that the **Match** enum defines, or provide a regular expression. *Pattern* must be a constant formula without any variables, data sources, or other dynamic references that change as the app runs.
- *Options* – Optional. A text-string combination of **MatchOptions** enum values. By default, **MatchOptions.Contains** is used. *Options* must be a constant formula without any variables, data sources, or other dynamic references that change as the app runs.

MatchAll(*Text*, *Pattern* [, *Options*])

- *Text* – Required. The text string to match.
- *Pattern* – Required. The pattern to match as a text string. Concatenate predefined patterns that the **Match** enum defines or provide a regular expression. *Pattern* must be a constant formula without variables, data sources, or other dynamic references that change as the app runs.
- *Options* – Optional. A text-string combination of **MatchOptions** enum values. By default, **MatchOptions.Contains** is used. *Options* must be a constant formula without variables, data sources, or other dynamic references that change as the app runs.

IsMatch examples

Ordinary characters

Imagine your app has a **Text input** control named **TextInput1**. Users enter values into this control to store them in a database.

Users type **Hello world** into **TextInput1**.

Expand table

Formula	Description	Result
`IsMatch( TextInput1.Text, "Hello world" )`	Tests whether the user's input matches, exactly, the string "Hello world".	**true**
`IsMatch( TextInput1.Text, "Good bye" )`	Tests whether the user's input matches, exactly, the string "Good bye".	**false**
`IsMatch( TextInput1.Text, "hello", Contains )`	Tests whether the user's input contains the word "hello" (case sensitive).	**false**
`IsMatch( TextInput1.Text, "hello", Contains & IgnoreCase )`	Tests whether the user's input contains the word "hello" (case insensitive).	**true**

Predefined patterns

Expand table

Formula	Description	Result
`IsMatch( "123-45-7890", Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit & Match.Digit )`	Matches a United States Social Security Number	**true**
`IsMatch( "joan@contoso.com", Match.Email )`	Matches an email address	**true**
`IsMatch( "123.456", Match.MultipleDigits & Match.Period & Match.OptionalDigits )`	Matches a sequence of digits, a period, and then zero or more digits.	**true**
`IsMatch( "123", Match.MultipleDigits & Match.Period & Match.OptionalDigits )`	Matches a sequence of digits, a period, and then zero or more digits. A period doesn't appear in the text to match, so this pattern isn't matched.	**false**

Regular expressions

Expand table

Formula	Description	Result
`IsMatch( "986", "\d+" )`	Matches an integer greater than zero.	**true**

Formula	Description	Result
`IsMatch( "1.02", "\d+(\.\d\d)?" )`	Matches a positive currency amount. If the input contains a decimal point, the input must also contain two numeric characters after the decimal point. For example, 3.00 is valid, but 3.1 isn't.	**true**
`IsMatch( "-4.95", "(-)?\d+(\.\d\d)?" )`	Matches a positive or negative currency amount. If the input contains a decimal point, the input must also contain two numeric characters after the decimal point.	**true**
`IsMatch( "111-11-1111", "\d{3}-\d{2}-\d{4}" )`	Matches a United States Social Security number. Validates the format, type, and length of the supplied input field. The string to match must consist of three numeric characters followed by a dash, then two numeric characters followed by a dash, and then four numeric characters.	**true**
`IsMatch( "111-111-111", "\d{3}-\d{2}-\d{4}" )`	Same as the previous example, but one of the hyphens is out of place in the input.	**false**
`IsMatch( "AStrongPasswordNot", "(?!^[0-9]\*$)(?!^[a-zA-Z]\*$)([a-zA-Z0-9]{8,10})" )`	Validates a strong password that must contain eight, nine, or 10 characters, at least one digit, and at least one alphabetic character. The string can't contain special characters.	**false**

Match and MatchAll examples

Expand table

Formula	Description	Result

`Match( "Bob Jones <bob.jones@contoso.com>", "<(?<email>" & Match.Email & ")>")`	Extracts only the email portion of the contact information.	{
		email: "bob.jones@contoso.com",
		FullMatch: "<bob.jones@contoso.com>",
		StartMatch: 11
		}

`Match( "Bob Jones <InvalidEmailAddress>", "<(?<email>" & Match.Email & ")>"`	Extracts only the email portion of the contact information. No legal address is found (there is no @ sign), so the function returns *blank*.	*blank*
`Match( Language(), "(<language>\w{2})(?:-(?<script>\w{4}))?(?:-(?<region>\w{2}))?" )`	Extracts the language, script, and region portions of the language tag that the Language function returns. These results reflect the	{ language: "en", script: *blank*, region: "US",

Formula	Description	Result
	United States; see the Language function documentation for more examples. The **(?:** operator groups characters without creating another sub-match.	FullMatch: "en-US", StartMatch: 1 }

`Match( "PT2H1M39S", "PT(?:(?<hours>\d+)H)?(?:(?<minutes>\d+)M)?(?:(?<seconds>\d+)S)?" )`	Extracts the hours, minutes, and seconds from an ISO 8601 duration value. The extracted numbers are still in a text string; use the Value function to convert it to a number before mathematical operations are performed on it.	{
		hours: "2",
		minutes: "1",
		seconds: "39",
		FullMatch: "PT2H1M39S",
		StartMatch: 1
		}

Let's drill into that last example. If you wanted to convert this string to a date/time value using the Time function, you must pass in the named submatches individually. To do this, use the With function operating on the record that **Match** returns:

Power Fx

```
With(
    Match( "PT2H1M39S", "PT(?:(?<hours>\d+)H)?(?:(?<minutes>\d+)M)?(?:(?<seconds>\d+)S)?" ),
   Time( Value( hours ), Value( minutes ), Value( seconds ) )
)
```

For these examples, add a Button control, set its **OnSelect** property to this formula, and then select the button:

Power Fx

```
Set( pangram, "The quick brown fox jumps over the lazy dog." )
```

Expand table

Formula	Description	Result

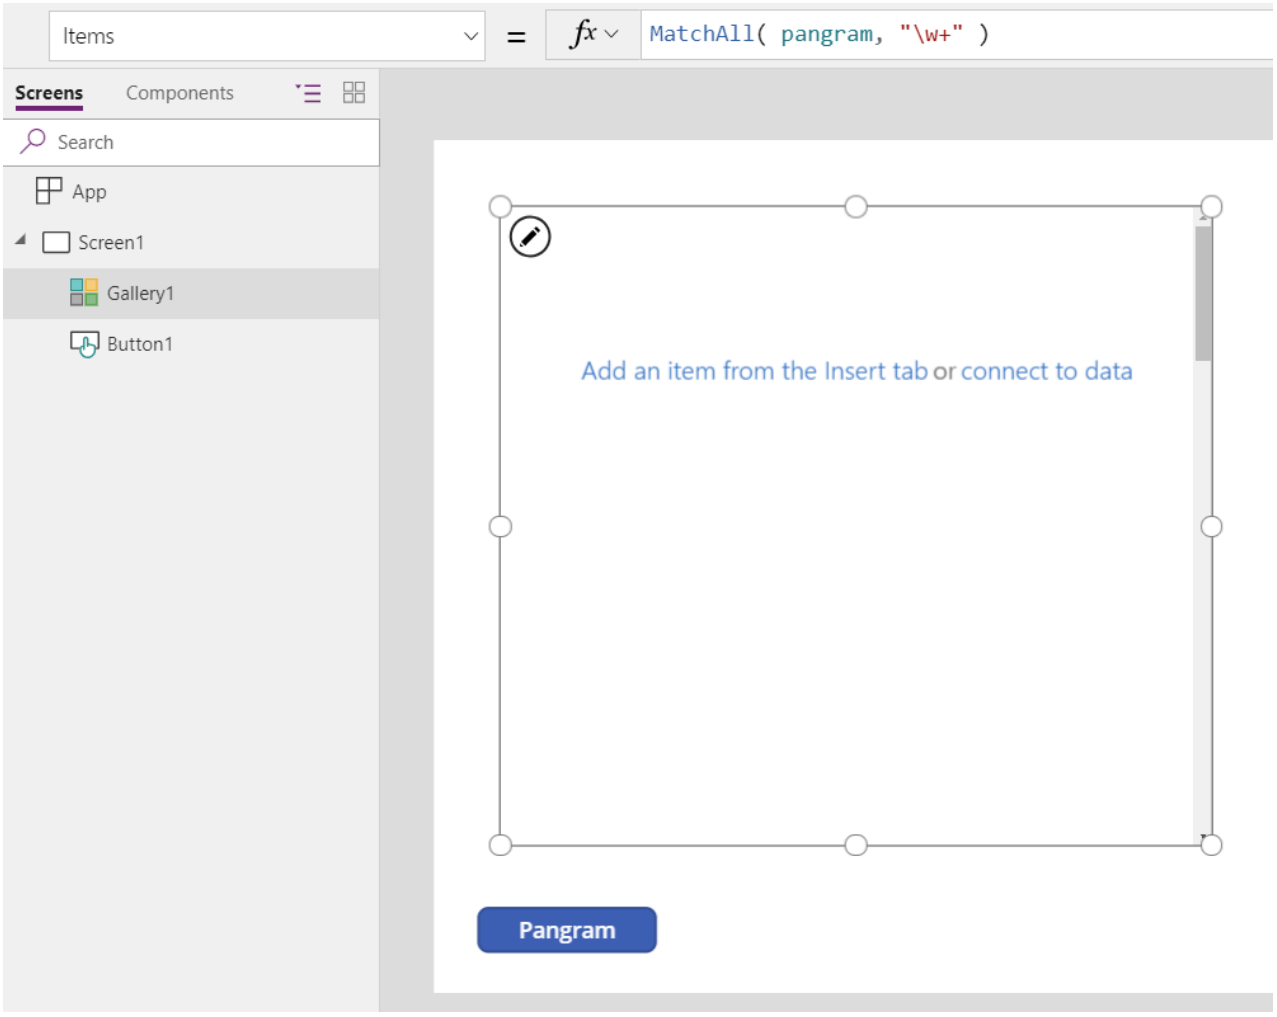
`Match( pangram, "THE", IgnoreCase )`	Find all matches of "THE" in the text string that the **pangram** variable contains. The string contains two matches, but only the first is returned because	{
		FullMatch: "The",
		StartMatch: 32
		}

<table>
<tr><th>Formula</th><th>Description</th><th>Result</th></tr>
<tr><td></td><td>you're using Match and not MatchAll.</td><td></td></tr>
<tr><td><code>MatchAll(pangram, "the")</code></td><td>Find all matches of "the" in the text string that the pangram variable contains. The test is case sensitive, so only the second instance of "the" is found.</td><td><table><tr><th>FullMatch</th><th>SubMatches</th><th>StartMatch</th></tr><tr><td>"the"</td><td>[ ]</td><td>32</td></tr></table></td></tr>
<tr><td><code>MatchAll(pangram, "the", IgnoreCase)</code></td><td>Find all matches of "the" in the text string that the pangram variable contains. In this case, the test is case insensitive, so both instances of the word are found.</td><td><table><tr><th>FullMatch</th><th>SubMatches</th><th>StartMatch</th></tr><tr><td>"The"</td><td>[ ]</td><td>1</td></tr><tr><td>"the"</td><td>[ ]</td><td>32</td></tr></table></td></tr>
<tr><td><code>MatchAll(pangram, "\b\wo\w\b")</code></td><td>Finds all three-letter words with an "o" in the middle. "brown" is excluded because it's not a three-letter word and, therefore, fails to match "\b" (word boundary).</td><td><table><tr><th>FullMatch</th><th>SubMatches</th><th>StartMatch</th></tr><tr><td>"fox"</td><td>[ ]</td><td>17</td></tr><tr><td>"dog"</td><td>[ ]</td><td>41</td></tr></table></td></tr>
<tr><td><code>Match(pangram, "\b\wo\w\b\s*(?<between>\w.+\w)\s*\b\wo\w\b")</code></td><td>Matches all the characters between "fox" and "dog".</td><td>{
between: "jumps over the lazy",
FullMatch: "fox jumps over the lazy dog",
StartMatch: 17
}</td></tr>
</table>

To see the results of **MatchAll** in a gallery:

1. In an empty screen, insert a blank vertical gallery control.
2. Set the gallery's **Items** property to **MatchAll(pangram, "\w+")** or **MatchAll(pangram, MultipleLetters)**.



3. Select "Add an item from the Insert tab" in the middle of the gallery control to select the template of the gallery.

4. Add a Label control to the gallery's template.

5. Set the label's **Text** property to **ThisItem.FullMatch**.

   The gallery is filled with each word in our example text. To see all the words on one screen, resize the gallery's template and the label control.

Average, Max, Min, StdevP, Sum, and VarP functions

Article • 04/20/2025

Expand table

Functions	Applies to
Average **Max** **Min** **Sum**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
StdevP **VarP**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Aggregate functions that summarize a set of numbers.

Description

The **Average** function calculates the average, or arithmetic mean, of its arguments.

The **Max** function finds the maximum value.

The **Min** function finds the minimum value.

The **Sum** function calculates the sum of its arguments.

The **StdevP** function calculates the standard deviation of its arguments.

The **VarP** function calculates the variance of its arguments.

You can supply the values for these functions as:

- Separate arguments. For example, **Sum(1, 2, 3)** returns 6.
- A table and a formula to operate over that table. The aggregate will be calculated on the values of the formula for each record.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

These functions operate on numeric values only. Other types of values, such as strings or records, are ignored. Use the **Value** function to convert a string into a number.

The **Average**, **Max**, **Min**, and **Sum** functions can be delegated when used with a data source that supports delegation for these functions. However, **StdevP** and **VarP** can't be delegated for any data sources. If delegation is not supported, only the first portion of the data will be retrieved and then the function applied locally. The result may not represent the complete story. A delegation warning will appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

Syntax

Average(*NumericalFormula1*, [*NumericalFormula2*, ...])
Max(*NumericalFormula1*, [*NumericalFormula2*, ...])
Min(*NumericalFormula1*, [*NumericalFormula2*, ...])
Sum(*NumericalFormula1*, [*NumericalFormula2*, ...])
StdevP(*NumericalFormula1*, [*NumericalFormula2*, ...])
VarP(*NumericalFormula1*, [*NumericalFormula2*, ...])

- *NumericalFormula(s)* - Required. Numeric values to operate on.

Average(*Table*, *NumericalFormula*)
Max(*Table*, *NumericalFormula*)
Min(*Table*, *NumericalFormula*)
Sum(*Table*, *NumericalFormula*)
StdevP(*Table*, *NumericalFormula*)
VarP(*Table*, *NumericalFormula*)

- *Table* - Required. Table to operate on.
- *NumericalFormula* - Required. Formula to evaluate for each record. The result of this formula is used for the aggregation. You can use columns of the table in the formula.

Examples

Step by step

Let's say that you had a data source named **Sales** that contained a **CostPerUnit** column and a **UnitsSold** column, and you set the **Text** property of a label to this function:
Sum(Sales, CostPerUnit * UnitsSold)

The label would show total sales by multiplying the values in those columns for each record and then adding the results from all records together:

Units sold	Cost per unit
30	$150
45	$125
20	$175

Total sales:

$13625

As a different example, let's say that you had sliders that were named **Slider1**, **Slider2**, and **Slider3** and a label with its **Text** property set to this formula:

Sum(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the sum of all values to which the sliders were set.

Average(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the average of all values to which the sliders were set.

Max(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the maximum of all values to which the sliders were set.

Min(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the minimum of all values to which the sliders were set.

StdevP(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the standard deviation of all values to which the sliders were set.

VarP(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the variance of all values to which the sliders were set.

Left, Mid, and Right functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Dataverse formula columns ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Extracts the left, middle, or right portion of a string of text.

Description

The **Left**, **Mid**, and **Right** functions return a portion of a string.

- **Left** returns the beginning characters of a string.
- **Mid** returns the middle characters of a string.
- **Right** returns the ending characters of a string.

If you specify a single string as an argument, the function returns the portion that you requested of the string. If you specify a single-column table that contains strings, the function returns a single-column table with a **Value** column containing the portions that you requested of those strings. If you specify a multi-column table, you can shape it into a single-column table, as working with tables describes.

If the starting position is negative or beyond the end of the string, **Mid** returns *blank*. You can check the length of a string by using the **Len** function. If you request more characters than the string contains, the function returns as many characters as possible.

Syntax

Left(*String*, *NumberOfCharacters*)
Mid(*String*, *StartingPosition* [, *NumberOfCharacters*])
Right(*String*, *NumberOfCharacters*)

- *String* - Required. The string to from which to extract the result.
- *StartingPosition* - Required (**Mid** only). The starting position. The first character of the string is position 1.
- *NumberOfCharacters* - Required (**Left** and **Right** only). The number of characters to return. If omitted for the **Mid** function, the function returns the portion from the starting position until the end of the string.

Left(*SingleColumnTable*, *NumberOfCharacters*)
Mid(*SingleColumnTable*, *StartingPosition* [, *NumberOfCharacters*])

Right(*SingleColumnTable*, *NumberOfCharacters*)

- *SingleColumnTable* - Required. A single-column table of strings from which to extract the results.
- *StartingPosition* - Required (**Mid** only). The starting position. The first character of the string is position 1.
- *NumberOfCharacters* - Required (**Left** and **Right** only). The number of characters to return. If omitted for the **Mid** function, the function returns the portion from the starting position until the end of the string.

Examples

Single string

The examples in this section use a text-input control as their data source. The control is named **Author** and contains the string "E. E. Cummings".

Expand table

Formula	Description	Result
Left(Author.Text, 5)	Extracts up to five characters from the start of the string.	"E. E."
Mid(Author.Text, 7, 4)	Extracts up to four characters, starting with the seventh character, from the string.	"Cumm"
Mid(Author.Text, 7)	Extracts all characters, starting with the seventh character, from the string.	"Cummings"
Right(Author.Text, 5)	Extracts up to five characters from the end of the string.	"mings"

Single-column table

Each example in this section extracts strings from the **Address** column of this data source, named **People**, and returns a single-column table that contains the results:

Expand table

Name	Address
"Jean"	"123 Main St NE"

Name	Address
"Fred"	"789 SW 39th #3B"

Expand table

Formula	Description	Result
Left(ShowColumns(People, "Address"), 8)	Extracts the first eight characters of each string.	A single-column table with a `Value` column containing the following values: "123 Main", "789 SW 3"
Mid(ShowColumns(People, "Address"), 5, 7)	Extracts the middle seven characters of each string, starting with the fifth character.	A single-column table with a `Value` column containing the following values: "Main St", "SW 39th"
Right(ShowColumns(People, "Address"), 7)	Extracts the last seven characters of each string.	A single-column table with a `Value` column containing the following values: "n St NE", "9th #3B"

Step-by-step example

1. Import or create a collection named **Inventory**, and show it in a gallery, as the first procedure in Show images and text in a gallery describes.
2. Set the **Text** property of the lower label in the gallery to this function:

   Right(ThisItem.ProductName, 3)

   The label shows the last three characters of each product name.

Average, Max, Min, StdevP, Sum, and VarP functions

Article • 04/20/2025

Expand table

Functions	Applies to
Average **Max** **Min** **Sum**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
StdevP **VarP**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Aggregate functions that summarize a set of numbers.

Description

The **Average** function calculates the average, or arithmetic mean, of its arguments.

The **Max** function finds the maximum value.

The **Min** function finds the minimum value.

The **Sum** function calculates the sum of its arguments.

The **StdevP** function calculates the standard deviation of its arguments.

The **VarP** function calculates the variance of its arguments.

You can supply the values for these functions as:

- Separate arguments. For example, **Sum(1, 2, 3)** returns 6.
- A table and a formula to operate over that table. The aggregate will be calculated on the values of the formula for each record.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

These functions operate on numeric values only. Other types of values, such as strings or records, are ignored. Use the **Value** function to convert a string into a number.

The **Average**, **Max**, **Min**, and **Sum** functions can be delegated when used with a data source that supports delegation for these functions. However, **StdevP** and **VarP** can't be delegated for any data sources. If delegation is not supported, only the first portion of the data will be retrieved and then the function applied locally. The result may not represent the complete story. A delegation warning will appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

Syntax

Average(*NumericalFormula1*, [*NumericalFormula2*, ...])
Max(*NumericalFormula1*, [*NumericalFormula2*, ...])
Min(*NumericalFormula1*, [*NumericalFormula2*, ...])
Sum(*NumericalFormula1*, [*NumericalFormula2*, ...])
StdevP(*NumericalFormula1*, [*NumericalFormula2*, ...])
VarP(*NumericalFormula1*, [*NumericalFormula2*, ...])

- *NumericalFormula(s)* - Required. Numeric values to operate on.

Average(*Table*, *NumericalFormula*)
Max(*Table*, *NumericalFormula*)
Min(*Table*, *NumericalFormula*)
Sum(*Table*, *NumericalFormula*)
StdevP(*Table*, *NumericalFormula*)
VarP(*Table*, *NumericalFormula*)

- *Table* - Required. Table to operate on.
- *NumericalFormula* - Required. Formula to evaluate for each record. The result of this formula is used for the aggregation. You can use columns of the table in the formula.

Examples

Step by step

Let's say that you had a data source named **Sales** that contained a **CostPerUnit** column and a **UnitsSold** column, and you set the **Text** property of a label to this function:
Sum(Sales, CostPerUnit * UnitsSold)

The label would show total sales by multiplying the values in those columns for each record and then adding the results from all records together:

Units sold	Cost per unit
30	$150
45	$125
20	$175

Total sales:

$13625

As a different example, let's say that you had sliders that were named **Slider1**, **Slider2**, and **Slider3** and a label with its **Text** property set to this formula:

Sum(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the sum of all values to which the sliders were set.

Average(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the average of all values to which the sliders were set.

Max(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the maximum of all values to which the sliders were set.

Min(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the minimum of all values to which the sliders were set.

StdevP(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the standard deviation of all values to which the sliders were set.

VarP(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the variance of all values to which the sliders were set.

Day, Month, Year, Hour, Minute, Second, and Weekday functions

Article • 06/10/2024

Applies to: Canvas apps Dataverse formula columns Desktop flows Model-driven apps Power Pages Power Platform CLI

Returns individual components of a Date/Time value.

Description

The **Day** function returns the day component of a Date/Time value, ranging from 1 to 31.

The **Month** function returns the month component of a Date/Time value, ranging from 1 to 12.

The **Year** function returns the year component of a Date/Time value, starting with 1900.

The **Hour** function returns the hour component of a Date/Time value, ranging from 0 (12:00 AM) to 23 (11:00 PM).

The **Minute** function returns the minute component of a Date/Time value, ranging from 0 to 59.

The **Second** function returns the second component of a Date/Time value, ranging from 0 to 59.

The **Weekday** function returns the weekday of a Date/Time value. By default, the result ranges from 1 (Sunday) to 7 (Saturday). You can specify a different range with a Microsoft Excel Weekday function code or a StartOfWeek enumeration value:

Expand table

Excel code	StartOfWeek enumeration	Description
1, 17	StartOfWeek.Sunday	Numbers 1 (Sunday) through 7 (Saturday). Default.
2, 11	StartOfWeek.Monday	Numbers 1 (Monday) through 7 (Sunday).
3	StartOfWeek.MondayZero	Numbers 0 (Monday) through 6 (Sunday).
12	StartOfWeek.Tuesday	Numbers 1 (Tuesday) through 7 (Monday).

Excel code	StartOfWeek enumeration	Description
13	**StartOfWeek.Wednesday**	Numbers 1 (Wednesday) through 7 (Tuesday).
14	**StartOfWeek.Thursday**	Numbers 1 (Thursday) through 7 (Wednesday).
15	**StartOfWeek.Friday**	Numbers 1 (Friday) through 7 (Thursday).
16	**StartOfWeek.Saturday**	Numbers 1 (Saturday) through 7 (Friday).

All functions return a number.

See working with dates and times for more information.

Syntax

Day(*DateTime*)
Month(*DateTime*)
Year(*DateTime*)
Hour(*DateTime*)
Minute(*DateTime*)
Second(*DateTime*)

- *DateTime* - Required. Date/Time value to operate on.

Weekday(*DateTime* [, *WeekdayFirst*])

- *DateTime* - Required. Date/Time value to operate on.
- *WeekdayFirst* - Optional. Excel code specifying which day starts the week. If not supplied, 1 (Sunday first) is used.

Examples

For the following example, the current time is **3:59:37 PM** on **Thursday, April 9, 2015**.

Expand table

Formula	Description	Result
Year(Now())	Returns the year component of the current time and date.	2015
Month(Now())	Returns the month component of the current time and date.	4

Formula	Description	Result
Day(Now())	Returns the day component of the current time and date.	9
Hour(Now())	Returns the hour component of the current time and date.	15
Minute(Now())	Returns the minute component of the current time and date.	59
Second(Now())	Returns the second component of the current time and date.	37
Weekday(Now())	Returns the weekday component of the current time and date, using the default start of the week as Sunday.	5
Weekday(Now(), 14)	Returns the weekday component of the current time and date, using an Excel code to specify the start of the week as Thursday.	1
Weekday(Now(), StartOfWeek.Wednesday)	Returns the weekday component of the current time and date, using a **StartOfWeek** enumeration to specify the start of the week as Wednesday.	2

Mod function

06/21/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Returns the remainder of a division.

Description

The **Mod** function returns the remainder after a number is divided by a divisor.

The result has the same sign as the divisor.

Syntax

Mod(*Number*, *Divisor*)

- *Number* - Required. Number to divide.
- *Divisor* - Required. Number to divide by.

Examples

Expand table

Formula	Description	Result
Mod(25, 4)	The number that remains after dividing 25 by 4	1
Mod(25, -4)	The number that remains after dividing 25 by -4	-3
Mod(-25, -4)	The number that remains after dividing -25 by -4	-1
Mod(-25, 4)	The number that remains after dividing -25 by 4	3

Day, Month, Year, Hour, Minute, Second, and Weekday functions

Article • 06/10/2024

Applies to: Canvas apps Dataverse formula columns Desktop flows Model-driven apps Power Pages Power Platform CLI

Returns individual components of a Date/Time value.

Description

The **Day** function returns the day component of a Date/Time value, ranging from 1 to 31.

The **Month** function returns the month component of a Date/Time value, ranging from 1 to 12.

The **Year** function returns the year component of a Date/Time value, starting with 1900.

Back and Navigate functions

Article • 03/22/2024

Changes which screen is displayed.

Overview

Most apps contain multiple screens. Use the **Back** and **Navigate** function to change which screen is displayed. For example, set the **OnSelect** property of a button to a formula that includes a **Navigate** function if you want to show a different screen when a user selects that button. In that formula, you can specify a visual transition, such as **Fade**, to control how one screen changes to another.

Back and **Navigate** change only which screen is displayed. Screens that aren't currently displayed continue to operate behind the scenes. You can build formulas that refer to properties of controls on other screens. For example, a user can change the value of a slider on one screen, navigate to a different screen that uses that value in a formula, and determine how it affects what happens in the new screen. The user can then navigate back to the original screen and confirm that the slider has kept its value.

Context variables are also preserved when a user navigates between screens. You can use **Navigate** to set one or more context variables for the screen that the formula will display, which is the only way to set a context variable from outside the screen. You can use this approach to pass parameters to a screen. If you've used another programming tool, this approach is similar to passing parameters to procedures.

Use the **App** object's **StartScreen** property to control the first screen to be displayed.

You can use either function only within a behavior formula.

Navigate

Applies to: ✅ Canvas apps ✅ Model-driven apps

In the first argument, specify the name of the screen to display.

In the second argument, specify how the old screen changes to the new screen:

Expand table

Transition Argument	Description	Demonstration
ScreenTransition.Cover	The new screen slides into view, moving right to left, to cover the current screen.	ScreenTransition.CoverRight	The new screen slides into view, moving left to right, to cover the current screen.	ScreenTransition.Fade	The current screen fades away to reveal the new screen.	ScreenTransition.None (Default)	The new screen quickly replaces the current screen.	ScreenTransition.UnCover	The current screen slides out of view, moving right to left, to uncover the new screen.	ScreenTransition.UnCoverRight	The current screen slides out of view, moving left to right, to uncover the new screen.	
You can use **Navigate** to create or update context variables of the new screen. As an optional third argument, pass a record that contains the context-variable name as a column name and the new value for the context variable. This record is the same as the record that you use with the **UpdateContext** function.

Set the **OnHidden** property of the old screen, the **OnVisible** property of the new screen, or both to make additional changes during the transition. The **App.ActiveScreen** property will be updated to reflect the change.

Navigate normally returns **true** but will return **false** if an error is encountered.

Context variables for navigation are explained in the article navigate between screens.

Back

Applies to: Canvas apps

The **Back** function returns to the screen that was most recently displayed.

For each **Navigate** call, the app tracks the screen that appeared and the transition. You can use successive **Back** calls to return all the way to the screen that appeared when the user started the app.

When the **Back** function runs, the inverse transition is used by default. For example, if a screen appeared through the **CoverRight** transition, **Back** uses **UnCover** (which is to the left) to return. **Fade** and **None** are their own inverses. Pass an optional argument to **Back** to force a specific transition.

Back normally returns **true** but returns **false** if the user hasn't navigated to another screen since starting the app.

Syntax

Back([*Transition*])

- *Transition* - Optional. The visual transition to use between the current screen and the previous screen. Refer to the list of valid values for this argument earlier in this article. By default, the transition through which a screen returns is the inverse of the transition through which it appeared.

Navigate(*Screen* [, *Transition* [, *UpdateContextRecord*]])

- *Screen* - Required. The screen to display. In place of *Screen*, you can also use a control that is on the screen you wish to navigate to.
- *Transition* - Optional. The visual transition to use between the current screen and the next screen. See the list of valid values for this argument earlier in this article. The default value is **None**.
- *UpdateContextRecord* - Optional. A record that contains the name of at least one column and a value for each column. This record updates the context variables of the new screen as if passed to the **UpdateContext** function.

Examples

Expand table

Formula	Description	Result
Navigate(Details)	Displays the **Details** screen with no transition or change in value for a context variable.	The **Details** screen appears quickly.
Navigate(Details, ScreenTransition.Fade)	Displays the **Details** screen with a **Fade** transition. No value of a context variable is changed.	The current screen fades away to show the **Details** screen.
Navigate(Details, ScreenTransition.Fade, { ID: 12 })	Displays the **Details** screen with a **Fade** transition, and updates the value of the **ID** context variable to **12**.	The current screen fades away to show the **Details** screen, and the context variable **ID** on that screen is set to **12**.
Navigate(Details, ScreenTransition.Fade, { ID: 12 , Shade: Color.Red })	Displays the **Details** screen with a **Fade** transition. Updates the value of the **ID** context variable to **12**, and updates the value of the **Shade** context variable to **Color.Red**.	The current screen fades away to show the **Details** screen. The context variable **ID** on the **Details** screen is set to **12**, and the context variable **Shade** is set to **Color.Red**. If you set the **Fill** property of a control on the **Details** screen to **Shade**, that control would display as red.
Back()	Displays the previous screen with the default return transition.	Displays the previous screen through the inverse transition of the transition through which the current screen appeared.
Back(ScreenTransition.Cover)	Displays the previous screen with the **Cover** transition.	Displays the previous screen through the **Cover** transition, regardless of the transition through which the current screen appeared.

Step-by-step

1. Create a blank app.
2. Add a second screen to it.

   The app contains two blank screens: **Screen1** and **Screen2**.
3. Set the **Fill** property of **Screen2** to the value `Gray`.

4. On **Screen2**, add a button, and set its **OnSelect** property to this formula:

```
Power Apps
Navigate( Screen1, ScreenTransition.Cover )
```

5. While holding down the **Alt** key, select the button.

   Screen1 appears with a white background through a transition that covers to the left.

6. On **Screen1**, add a button, and set its **OnSelect** property to this formula:

```
Power Apps
Back()
```

7. While holding down the **Alt** key, select the button.

   The second screen appears with a gray background through a transition that uncovers to the right (the inverse of **Cover**).

8. Select the button on each screen repeatedly to bounce back and forth.

Using context variables

EditForm, NewForm, SubmitForm, ResetForm, and ViewForm functions

Article • 03/22/2024

Applies to: Canvas apps

View, edit, or create an item, save the contents, and reset the controls in an **Edit form** control.

Overview

These functions change the state of the **Edit form** control. The form control can be in one of these modes:

Expand table

Mode	Description
FormMode.Edit	The form is populated with an existing record and the user can modify the values of the fields. Once complete, the user can save the changes to the record.
FormMode.New	The form is populated with default values and the user can modify the values of the fields. Once complete, the user can add the record to the data source.
FormMode.View	The form is populated with an existing record but the user cannot modify the values of the fields.

Description

These functions are often invoked from the **OnSelect** formula of a **Button** or **Image** control so that the user can save edits, abandon edits, or create a record. You can use controls and these functions together to create a complete solution.

These functions return no values.

You can use these functions only in behavior formulas.

SubmitForm

Use the **SubmitForm** function in the **OnSelect** property of a Button control to save any changes in a Form control to the data source.

Before submitting any changes, this function checks for validation issues with any field that's marked as required or that has one or more constraints on its value. This behavior matches that of the **Validate** function.

SubmitForm also checks the **Valid** property of the Form, which is an aggregation of all the **Valid** properties of the **Card** controls that the Form control contains. If a problem occurs, the data isn't submitted, and the **Error** and **ErrorKind** properties of the Form control are set accordingly.

If validation passes, **SubmitForm** submits the change to the data source.

- If successful, the Form's **OnSuccess** behavior runs, and the **Error** and **ErrorKind** properties are cleared. If the form was in **FormMode.New** mode, it is returned to **FormMode.Edit** mode.
- If unsuccessful, the Form's **OnFailure** behavior runs, and the **Error** and **ErrorKind** properties are set accordingly. The mode of the form is unchanged.

EditForm

The **EditForm** function changes the Form control's mode to **FormMode.Edit**. In this mode, the contents of the Form control's **Item** property are used to populate the form. If the **SubmitForm** function runs when the form is in this mode, a record is changed, not created. **FormMode.Edit** is the default for the Form control.

> ⓘ **Note**
>
> When the form is in edit mode and Item is null, data card properties are not evaluated and will return default values.

NewForm

The **NewForm** function changes the Form control's mode to **FormMode.New**. In this mode, the contents of the Form control's **Item** property are ignored, and the default values of the Form's **DataSource** property populate the form. If the **SubmitForm** function runs when the form is in this mode, a record is created, not changed.

ResetForm

The **ResetForm** function resets the contents of a form to their initial values, before the user made any changes. If the form is in **FormMode.New** mode, the form is reset to **FormMode.Edit** mode. The **OnReset** behavior of the form control also runs. You can also reset individual controls with the **Reset** function but only from within the form.

ViewForm

The **ViewForm** function changes the Form control's mode to **FormMode.View**. In this mode, the contents of the Form control's **Item** property are used to populate the form. The **SubmitForm** and **ResetForm** functions have no effect when in this mode.

DisplayMode Property

The current mode can be read through the **Mode** property. The mode also determines the value of the **DisplayMode** property, which can be used by data cards and controls within the form control. Often, the data card's **DisplayMode** property will be set to **Parent.DisplayMode** (referencing the form) as will the control's **DisplayMode** property (referencing the data card):

Expand table

Mode	DisplayMode	Description
FormMode.Edit	**DisplayMode.Edit**	Data cards and controls are editable, ready to accept changes to a record.
FormMode.New	**DisplayMode.Edit**	Data cards and controls are editable, ready to accept a new record.
FormMode.View	**DisplayMode.View**	Data cards and controls are not editable and optimized for viewing.

Syntax

SubmitForm(*FormName*)

- *FormName* - Required. Form control to submit to the data source.

EditForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.Edit** mode.

NewForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.New** mode.

ResetForm(*FormName*)

- *FormName* - Required. Form control to reset to initial values. Also switches the form from **FormMode.New** mode to **FormMode.Edit** mode.

ViewForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.View** mode.

Examples

See Understand data forms for complete examples.

1. Add a Button control, set its **Text** property to show **Save**, and set its **OnSelect** property to this formula:

   SubmitForm(EditForm)

2. Set the **OnFailure** property of a Form control to blank and its **OnSuccess** property to this formula:

   Back()

3. Name a **Label** control **ErrorText**, and set its **Text** property to this formula:

   EditForm.Error

   When the user selects the **Save** button, any changes in the Form control are submitted to the underlying data source.

   - If the submission succeeds, any changes are saved or, if the Form control is in **New** mode, a record is created. **ErrorText** is *blank* and the previous screen reappears.
   - If the submission fails, **ErrorText** shows a user-friendly error message, and the current screen remains visible so that the user can correct the problem and try again.

4. Add a Button control, set its **Text** property to show **Cancel**, and set its **OnSelect** property to this formula:

   ResetForm(EditForm); Back()

   When the user selects the **Cancel** button, the values in the Form control are reset to what they were before the user started to edit it, the previous screen reappears,

and the Form control is returned to **Edit** mode if it was in **New** mode.

5. Add a Button control, set its Text property to show **New**, and set its OnSelect property to this formula:

   NewForm(EditForm); Navigate(EditScreen, None)

   When the user selects the **New** button, the Form control switches to **New** mode, the default values for the Form control's data source populate that control, and the screen that contains the Form control appears. When the **SubmitForm** function runs, a record is created instead of updated.

And, Or, and Not functions

Article • 06/10/2024

Applies to: Canvas apps Dataverse formula columns Desktop flows Model-driven apps Power Pages Power Platform CLI

Boolean logic functions, commonly used to manipulate the results of comparisons and tests.

Description

The **And** function returns **true** if all of its arguments are **true**.

The **Or** function returns **true** if any of its arguments are **true**.

The **Not** function returns **true** if its argument is **false**; it returns **false** if its argument is **true**.

These functions work the same way as they do in Excel. You can also use operators to perform these same operations, using either Visual Basic or JavaScript syntax:

Expand table

Function notation	Visual Basic operator notation	JavaScript operator notation
And(x, y)	x And y	x && y
Or(x, y)	x Or y	x || y
Not(x)	Not x	! x

These functions work with logical values. You can't pass them a number or a string directly; instead, you must make a comparison or a test. For example, this logical formula **x** > **1** evaluates to the Boolean value **true** if **x** is greater than **1**. If **x** is less than **1**, the formula evaluates to **false**.

Syntax

And(*LogicalFormula1*, *LogicalFormula2* [, *LogicalFormula3*, ...])
Or(*LogicalFormula1*, *LogicalFormula2* [, *LogicalFormula3*, ...])
Not(*LogicalFormula*)

- *LogicalFormula(s)* - Required. Logical formulas to evaluate and operate on.

Examples

The examples in this section use these global variables:

- **a** = *false*
- **b** = *true*
- **x** = 10
- **y** = 100
- **s** = "Hello World"

To create these global variables in an app, insert a **Button** control, and set its **OnSelect** property to this formula:

Power Apps

```
Set( a, false ); Set( b, true ); Set( x, 10 ); Set( y, 100 ); Set( s, "Hello World" )
```

Select the button (by clicking it while you hold down the Alt key), and then set the **Text** property of a **Label** control to a formula in the first column of the next table.

Expand table

Formula	Description	Result
And(a, b)	Tests the values of **a** and **b**. One of the arguments is *false*, so the function returns *false*.	*false*
a And b	Same as the previous example, using Visual Basic notation.	*false*
a && b	Same as the previous example, using JavaScript notation.	*false*
Or(a, b)	Tests the values of **a** and **b**. One of the arguments is *true*, so the function returns *true*.	*true*
a Or b	Same as the previous example, using Visual Basic notation.	*true*
a || b	Same as the previous example, using JavaScript notation.	*true*
Not(a)	Tests the value of **a**. The argument is *false*, so the function returns the opposite result.	*true*
Not a	Same as the previous example, using Visual Basic notation.	*true*
! a	Same as the previous example, using JavaScript notation.	*true*
Len(s) < 20 And Not IsBlank(s)	Tests whether the length of **s** is less than 20 and whether it isn't a **blank** value. The length is less than 20, and the value	*true*

Formula	Description	Result
	isn't blank. Therefore, the result is *true*.	
Or(Len(s) < 10, x < 100, y < 100)	Tests whether the length of **s** is less than 10, whether **x** is less than 100, and whether **y** is less than 100. The first and third arguments are false, but the second one is true. Therefore, the function returns *true*.	*true*
Not IsBlank(s)	Tests whether **s** is *blank*, which returns *false*. **Not** returns the opposite of this result, which is *true*.	*true*

Notify function

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps Power Platform CLI

Displays a banner message to the user.

Description

The **Notify** function displays a banner message to the user at the top of the screen. The notification remains until the user dismisses it or the timeout expires which defaults to 10 seconds.

An appropriate color and icon are used depending on the type of the message. The type is specified by the second argument to the function:

> **Note**
>
> The character limit for **Notify** function is 500 characters.

Expand table

NotificationType Argument	Description
NotificationType.Error	Displays the message as an error.
NotificationType.Information (Default)	Displays the message as informational.
NotificationType.Success	Displays the message as success.
NotificationType.Warning	Displays the message as a warning.

Messages are shown both when authoring your app and when end users are using your app.

Notify can only be used in behavior formulas.

Notify can be paired with the **IfError** function to detect and report errors with a custom error message.

Power Apps can also send push notifications using an entirely different mechanism from **Notify**. For more information, see Send a notification in Power Apps.

Notify always returns *true*.

Note: This function was previously named **ShowError** when it could only display error messages.

> ⓘ **Note**
>
> Notify can be used in standalone canvas app, custom page and Power Fx commanding experiences. The default values for NotificationType and Timeout vary by the experience its used in. You can specify the values you want set for NotificationType and Timeout by explicitly setting them in your Power Fx expression and these values will be respected regardless of the experience.

Syntax

Notify(*Message* [, *NotificationType* [, *Timeout*]])

- *Message* – Required. Message to display to the user.
- *NotificationType* – Optional. Type of the message to display from the table above. The default is **NotificationType.Information**.
- *Timeout* – Optional. Number of milliseconds to wait before automatically dismissing the notification. The default is 10 seconds (or 10,000 milliseconds). The notification is displayed indefinitely with a *Timeout* of 0.

Examples

Step by step

1. Add a **Button** control to your screen.

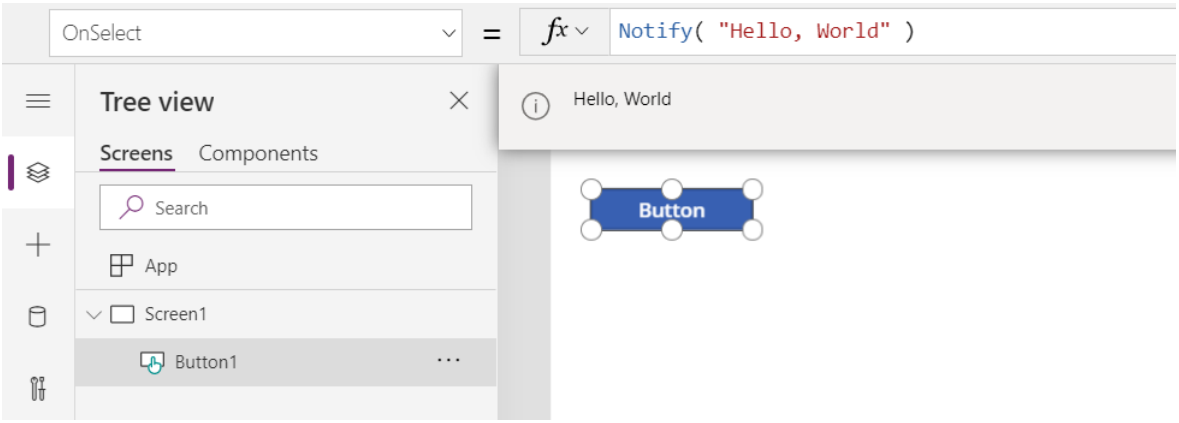
2. Set the **OnSelect** property of the **Button** to the formula:

   Power Apps

   ```
   Notify( "Hello, World" )
   ```

3. Click or press the button.

   Each time the button is clicked, the message **Hello, World** is displayed to the user as informational. It dismisses automatically in 10 seconds (default timeout) if the user doesn't dismiss it or press the button again.



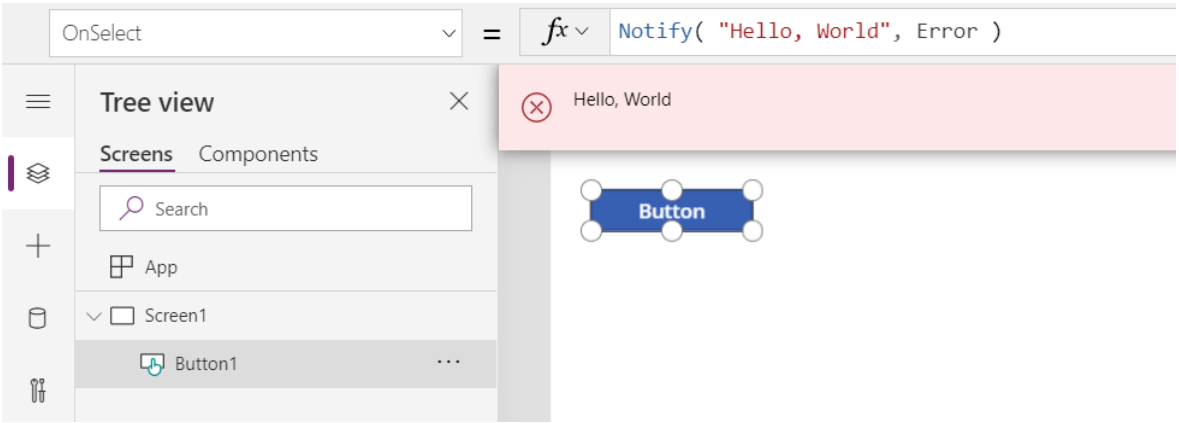
4. Change the type of message to indicate an error. Add a second argument to our formula:

```
Power Apps

Notify( "Hello, World", NotificationType.Error )
```

5. Click or press the button.

   Now each time the button is clicked, the message **Hello, World** is displayed to the user as an error. It dismisses automatically in 10 seconds (default timeout) if the user doesn't dismiss it or press the button again.



6. Change the type of message to indicate a warning. Change the second argument in our formula:

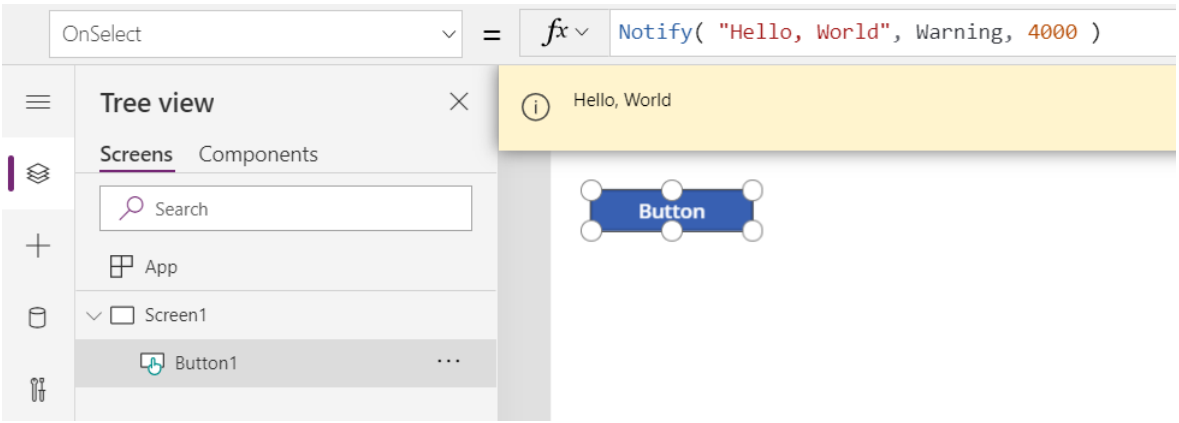
```
Power Apps

Notify( "Hello, World", NotificationType.Warning, 4000 )
```

7. Click or press the button.

   Now each time the button is clicked, the message **Hello, World** is displayed to the user as a warning. It dismisses automatically in 4 seconds (4,000 milliseconds) if the

user doesn't dismiss it or press the button again.



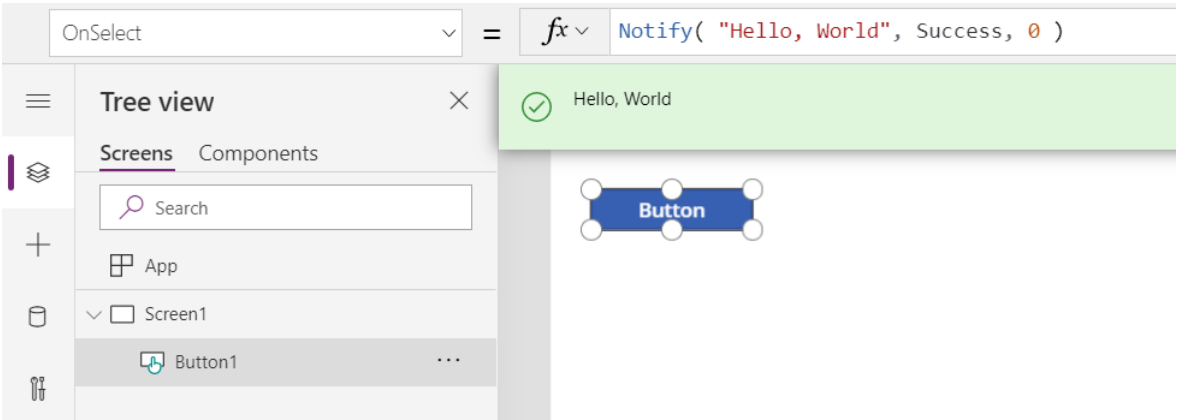
8. Change the type of message to indicate success. Change the second argument in our formula:

```
Power Apps

Notify( "Hello, World", NotificationType.Success, 0 )
```

9. Click or press the button.

   Now each time the button is clicked, the message **Hello, World** is displayed to the user as success. With a **0** timeout, the notification will only be dismissed by the user or by pressing the button again.



Now, Today, IsToday, UTCNow, UTCToday, IsUTCToday functions

Article • 04/20/2025

Expand table

Functions	Applies to
Now	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Today **IsToday**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
UTCNow **UTCToday**	✅ Dataverse formula columns ✅ Power Pages

Returns the current date and time, and tests whether a date/time value is today.

> ⓘ Note
>
> PAC CLI pac power-fx commands do not support the **UTCNow**, **UTCToday**, and **IsUTCToday** functions.

Description

The **Now** function returns the current date and time as a date/time value.

The **Today** function returns the current date as a date/time value. The time portion is midnight. **Today** has the same value throughout a day, from midnight today to midnight tomorrow.

The **IsToday** function tests whether a date/time value is between midnight today and midnight tomorrow. This function returns a Boolean (**true** or **false**) value.

Now, **Today**, and **IsToday** functions work with the local time of the current user.

UTCNow, **UTCToday**, and **IsUTCToday** functions are the same as their non-UTC counterparts but work with time zone independent values and use Coordinated Universal Time (UTC).

> ⓘ Note

- **UTCNow**, **UTCToday**, and **IsUTCToday** are only available in Microsoft Dataverse for Teams formula columns, and only for time-independent fields and values.
- **Now**, **Today**, and **IsToday** are not available in Dataverse for Teams formula columns as evaluations are done without the knowledge of the current user's local time zone. More information: Work with formula table columns in Dataverse for Teams

See Date, Time, and DateTime in the data types documentation and working with dates and times for more information.

Volatile Functions

Now, **Today**, **UTCNow**, and **UTCToday** are volatile functions. These functions return a different value for each evaluation.

When used in a data flow formula, a volatile function will only return a different value if the formula in which it appears is reevaluated. If nothing else changes in the formula then it will have the same value throughout the execution of your app.

For example, a label control with **Label1.Text = Now()** will not change while your app is active. Only closing and reopening the app will result in a new value.

The function will be reevaluated if it is part of a formula in which something else has changed. For example, if we change our example to involve a slider control with **Label1.Text = DateAdd(Now(), Slider1.Value, Minutes)** then the current time is retrieved each time the Slider control's value changes and the label's text property is reevaluated.

When used in a behavior formula, volatile functions will be evaluated each time the behavior formula is evaluated. See below for an example.

Syntax

Using the user's local time

Now()

Today()

IsToday(*DateTime*)

- *DateTime* - Required. The date/time value to test.

Using Coordinated Universal Time (UTC)

UTCNow()

UTCToday()

IsUTCToday(*TimeZoneIndependentTime*)

- *TimeZoneIndependentDateTime* - Required. The time zone independent date/time value to test.

Examples

For the examples in this section, the current time is **8:58 PM** on **July 11, 2021** in the Pacific Time Zone (UTC-8) and the language is **en-us**.

Expand table

Formula	Description	Result
Text(Now(), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date and time in the user's time zone, and displays it as a string.	"07/11/2021 20:58:00"
Text(Today(), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date only, leaving the time portion as midnight, and displays it as a string.	"07/12/2021 00:00:00"
IsToday(Now())	Tests whether the current date and time is between midnight today and midnight tomorrow.	**true**
IsToday(Today())	Tests whether the current date is between midnight today and midnight tomorrow.	**true**
Text(DateAdd(Now(), 12), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date and time, adds 12 days to the result, and displays it as a string.	"07/23/2021 20:58:00"
Text(DateAdd(Today(), 12), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date, adds 12 days to the result, and displays it as a string.	"07/23/2021 00:00:00"
IsToday(DateAdd(Now(), 12))	Tests whether the current date and time, plus 12 days, is between midnight today and midnight tomorrow.	**false**
IsToday(DateAdd(Today(), 12))	Tests whether the current date, plus 12 days, is between midnight today and midnight tomorrow.	**false**
Hour(UTCNow())	Retrieves the current date and time in UTC and extracts the hour only, which is 8 hours ahead of local time.	4

Formula	Description	Result
Day(UTCToday())	Retrieves the current date only in UTC and extracts the day, which is 1 day ahead of local time.	12
IsUTCToday(UTCNow())	Tests whether the current date and time is between midnight today and midnight tomorrow, all in UTC time.	**true**
IsUTCToday(UTCToday())	Tests whether the current date is between midnight today and midnight tomorrow, all in UTC time.	**true**

Display a clock that updates in real time

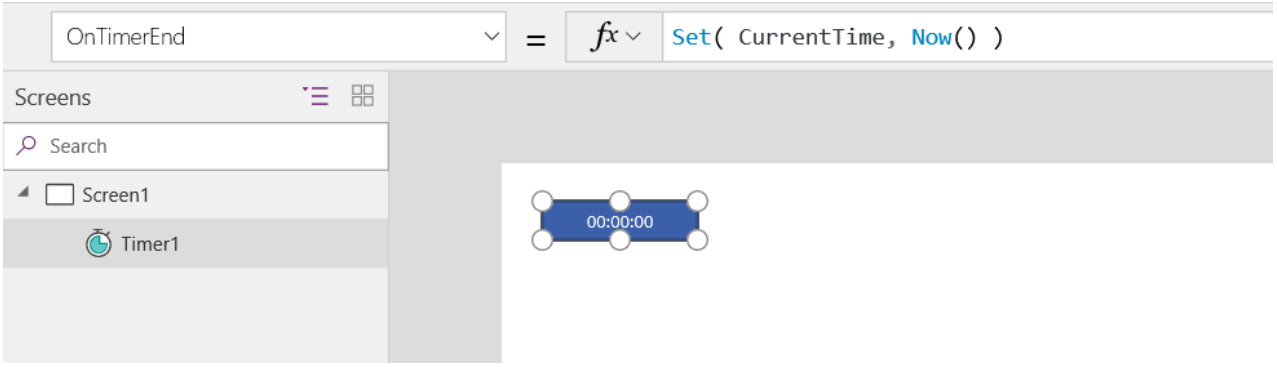
1. Add a Timer control, set its **Duration** property to **1000**, and set its **Repeat** property to **true**.

   The timer will run for one second, automatically start over, and continue that pattern.

2. Set the control's **OnTimerEnd** property to this formula:

   Set(CurrentTime, Now())

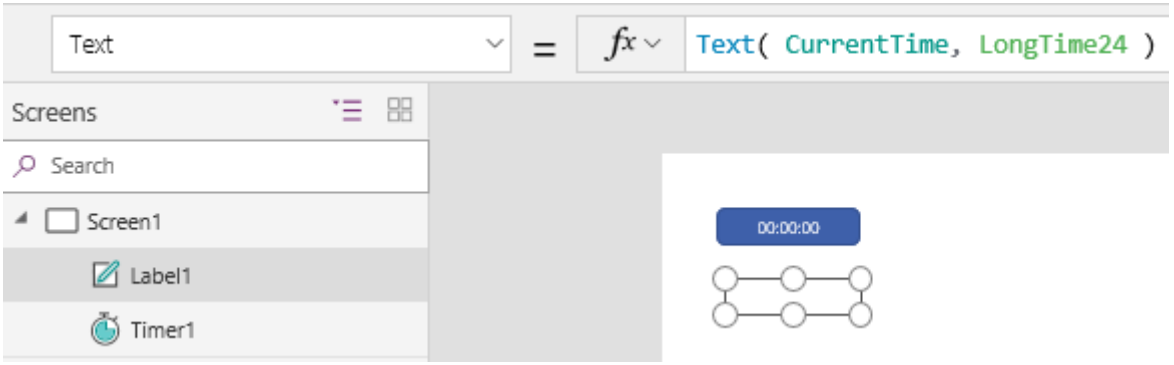
   Whenever the timer starts over (after each second), this formula sets the **CurrentTime** global variable to the current value of the **Now** function.

3. Add a Label control, and set its **Text** property to this formula:

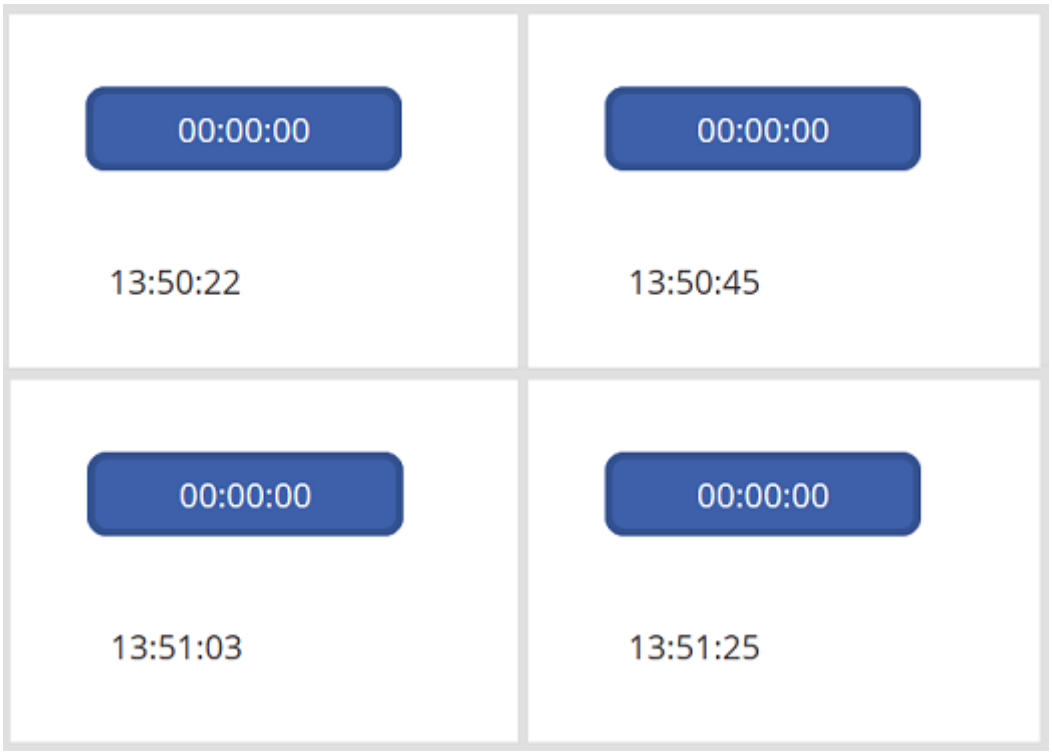
   Text(CurrentTime, LongTime24)

   Use the Text function to format the date and time however you want, or set this property to just **CurrentTime** to show hours and minutes but not seconds.



4. Preview the app by pressing F5, and then start the timer by clicking or tapping it.

   The label continually shows the current time, down to the second.



5. Set the timer's **AutoStart** property to **true** and its **Visible** property to **false**.

   The timer is invisible and starts automatically.

6. Set the screen's OnStart property so that the **CurrentTime** variable has a valid value, as in this example:

   Set(CurrentTime, Now())

   The label appears as soon as the app starts (before the timer runs for a full second).

Operators and Identifiers in Power Apps

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Some of these operators are dependent on the language of the author. For more information about language support in canvas apps, see Global apps.

Expand table

Symbol	Type	Example	Description
'...'	Identifier	**'Account Name'**	Identifiers that contain special characters, including spaces, are enclosed in single quotes
"..."	Text string	**"Hello, World"**	Text strings are enclosed in double quotes
$"..."	String interpolation	**$"Dear {FirstName},"**	Formulas embedded within a text string
.	Property Selector	**Slider1.Value** **Color.Red** **Acceleration.X**	Extracts a property from a table, control, signal, or enumeration. For backward compatibility, **!** may also be used.
. [language dependent]	Decimal separator	**1.23**	Separator between whole and fractional parts of a number. The character depends on the language.
( )	Parentheses	**Filter(T, A < 10)** **(1 + 2) * 3**	Enforces precedence order, and groups subexpressions in a larger expression
+	Arithmetic operators	**1 + 2**	Addition
-		**2 - 1**	Subtraction and sign
*		**2 * 3**	Multiplication
/		**2 / 3**	Division (also see the **Mod** function)
^		**2 ^ 3**	Exponentiation, equivalent to the **Power** function

Symbol	Type	Example	Description
%		**20%**	Percentage (equivalent to "* 1/100")
=	Comparison operators	**Price = 100**	Equal to
>		**Price > 100**	Greater than
>=		**Price >= 100**	Greater than or equal to
<		**Price < 100**	Less than
<=		**Price <= 100**	Less than or equal to
<>		**Price <> 100**	Not equal to
&	String concatenation operator	**"hello" & " " & "world"**	Makes multiple strings appear continuous
&& or **And**	Logical operators	**Price < 100 && Slider1.Value = 20** or **Price < 100 And Slider1.Value = 20**	Logical conjunction, equivalent to the **And** function
|| or **Or**		**Price < 100 || Slider1.Value = 20** or **Price < 100 Or Slider1.Value = 20**	Logical disjunction, equivalent to the **Or** function
! or **Not**		**!(Price < 100)** or **Not (Price < 100)**	Logical negation, equivalent to the **Not** function
exactin	Membership operators	**Gallery1.Selected exactin SavedItems**	Belonging to a collection or a table
exactin		**"Windows" exactin "To display windows in the Windows operating system..."**	Substring test (case-sensitive)
in		**Gallery1.Selected in SavedItems**	Belonging to a collection or a table
in		**"The" in "The keyboard and the monitor..."**	Substring test (case-insensitive)
@	Disambiguation operator	**MyTable[@fieldname]**	Field disambiguation
@		**[@MyVariable]**	Global disambiguation

Symbol	Type	Example	Description
, [language dependent]	List separator	**If(X < 10, "Low", "Good")** **{ X: 12, Y: 32 }** **[1, 2, 3]**	Separates: • arguments in function calls • fields in a record • records in a table This character depends on the language.
; [language dependent]	Formula chaining	**Collect(T, A); Navigate(S1, "")**	Separate invocations of functions in behavior properties. The chaining operator depends on the language.
As	As operator	**AllCustomers As Customer**	Overrides **ThisItem** and **ThisRecord** in galleries and record scope functions. **As** is useful for providing a better, specific name and is especially important in nested scenarios.
Self	Self operator	**Self.Fill**	Access to properties of the current control
Parent	Parent operator	**Parent.Fill**	Access to properties of a control container
ThisItem	ThisItem operator	**ThisItem.FirstName**	Access to fields of a Gallery or form control
ThisRecord	ThisRecord operator	**ThisRecord.FirstName**	Access to the complete record and individual fields of the record within **ForAll**, **Sum**, **With**, and other record scope functions. Can be overridden with the **As** operator.

> ⓘ Note
>
> The @ operator can also be used to validate the type of the record object against a data source. For example, `Collect(coll,Account@{'Account Number: 1111')`

in and exactin operators

Use the **in** and **exactin** operators to find a string in a data source, such as a collection or an imported table. The **in** operator identifies matches regardless of case, and the **exactin** operator identifies matches only if they're capitalized the same way. Here's an example:

1. Create or import a collection named **Inventory**, and show it in a gallery, as the first procedure in Show images and text in a gallery describes.

2. Set the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" in ProductName)

   The gallery shows all products except Callisto because the name of that product is the only one that doesn't contain the letter you specified.

3. Change the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" exactin ProductName)

   The gallery shows only Europa because only its name contains the letter that you specified in the case that you specified.

ThisItem, ThisRecord, and As operators

A few controls and functions apply formulas to individual records of a table. To refer to the individual record in a formula, use one of the following:

Expand table

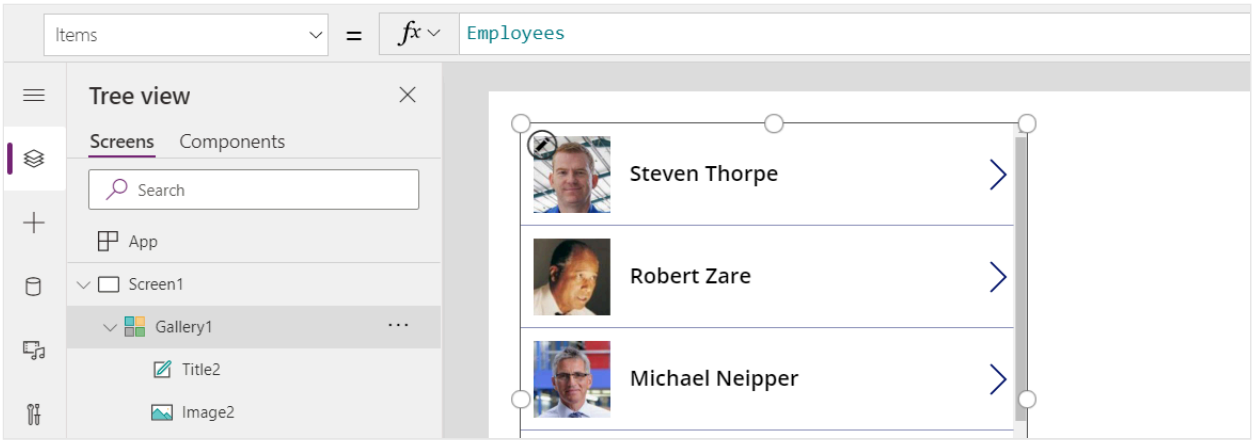
Operator	Applies to	Description
ThisItem	**Gallery** control **Edit form** control **Display form** control	The default name for the current record in a **Gallery** or form control.
ThisRecord	**ForAll**, **Filter**, **With**, **Sum** and other record scope functions	The default name for the current record in **ForAll** and other record scope functions.
As *name*	**Gallery** control **ForAll**, **Filter**, **With**, **Sum** and other record scope functions	Defines a *name* for the current record, replacing default **ThisItem** or **ThisRecord**. Use **As** to make formulas easier to understand and resolve ambiguity when nesting.

ThisItem operator

For example, in the following **Gallery** control, the **Items** property is set to the **Employees** data source (such as the **Employees** table included with the Northwind Traders sample):

Power Apps

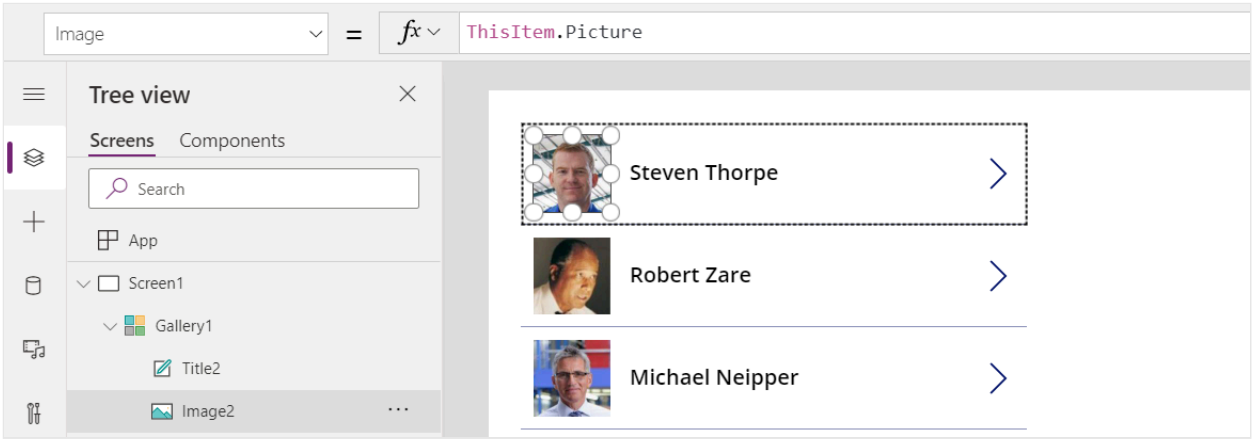
```
Employees
```



The first item in the gallery is a template that is replicated for each employee. In the template, the formula for the picture uses **ThisItem** to refer to the current item:

Power Apps

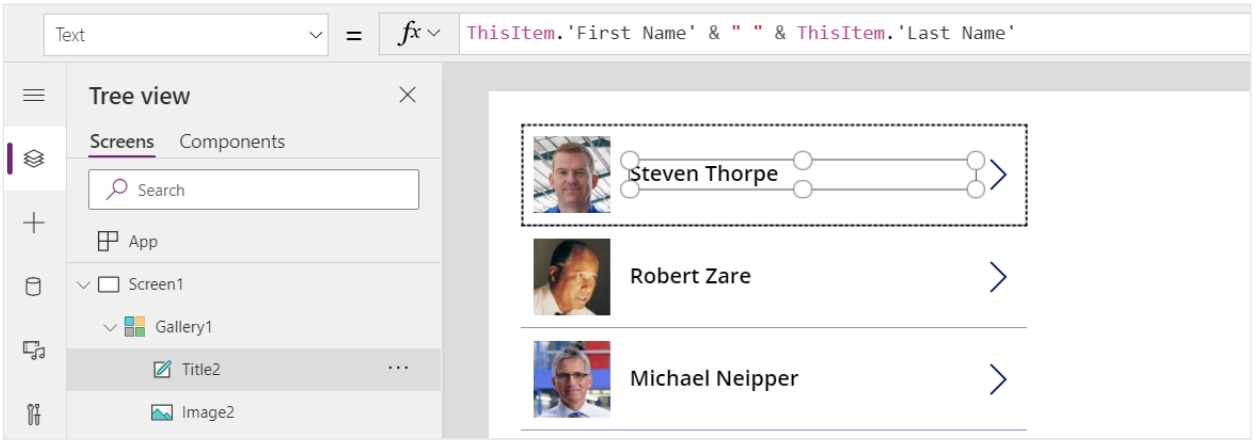
```
ThisItem.Picture
```



Likewise, the formula for the name also uses **ThisItem**:

Power Apps

```
ThisItem.'First Name' & " " & ThisItem.'Last Name'
```

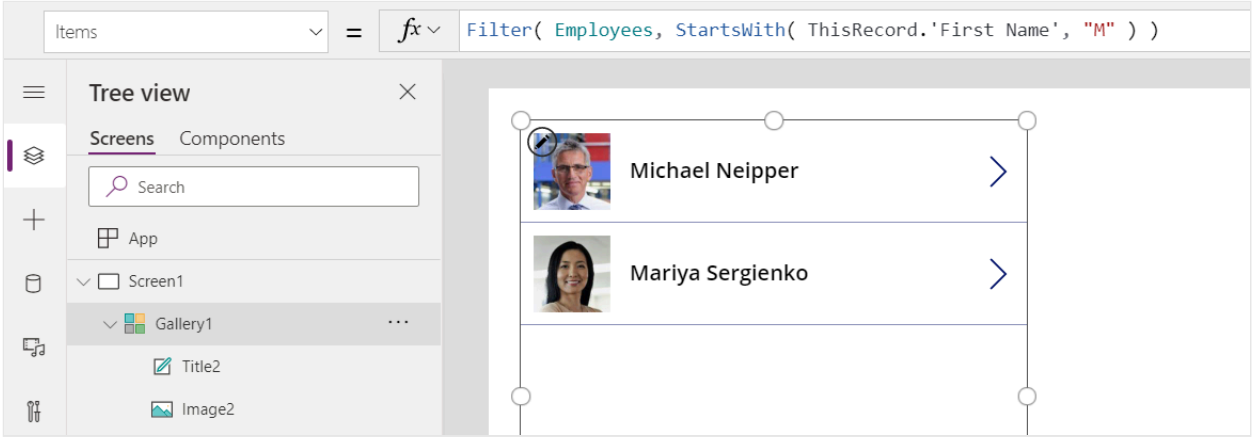


ThisRecord operator

ThisRecord is used in functions that have a record scope. For example, we can use the **Filter** function with our gallery's **Items** property to only show first names that being with *M*:

Power Apps

```
Filter( Employees, StartsWith( ThisRecord.Employee.'First Name', "M" ) )
```



ThisRecord is optional and implied by using the fields directly, for example, in this case, we could have written:

Power Apps

```
Filter( Employees, StartsWith( 'First Name', "M" ) )
```

Although optional, using **ThisRecord** can make formulas easier to understand and may be required in ambiguous situations where a field name may also be a relationship name. **ThisRecord** is optional while **ThisItem** is always required.

Use **ThisRecord** to reference the whole record with **Patch**, **Collect**, and other record scope functions. For example, the following formula sets the status for all inactive employees to active:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees,
              Patch( Employees, ThisRecord, { Status: 'Status
(Employees)'.Active } ) ) )
```

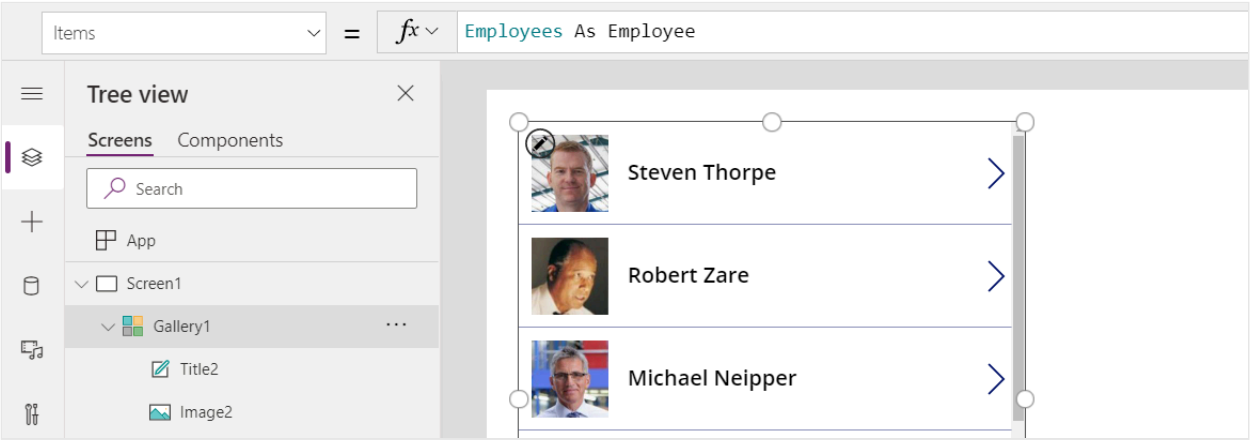
As operator

Use the **As** operator to name a record in a gallery or record scope function, overriding the default **ThisItem** or **ThisRecord**. Naming the record can make your formulas easier to understand and may be required in nested situations to access records in other scopes.

For example, you can modify the **Items** property of our gallery to use **As** to identify that we are working with an Employee:

Power Apps

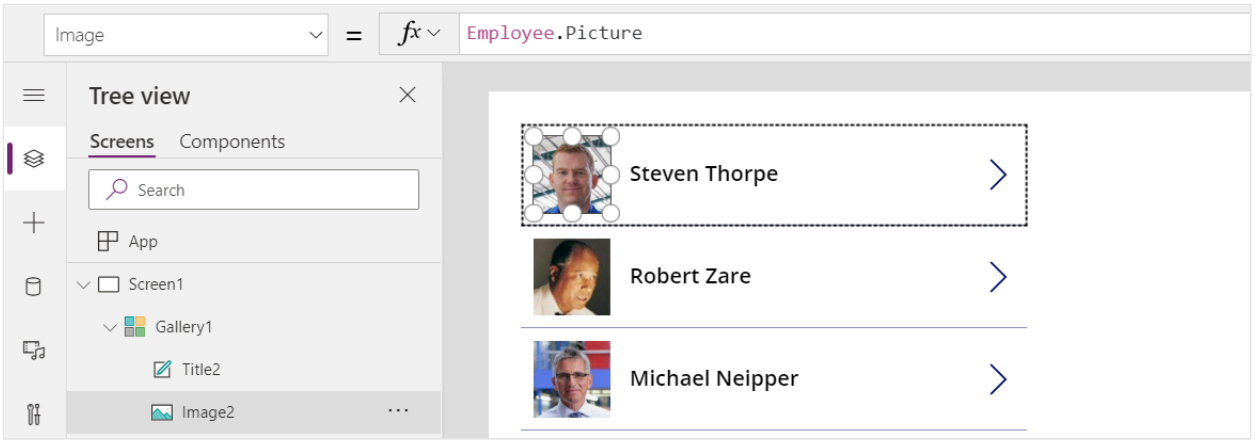
```
Employees As Employee
```



The formulas for the picture and name are adjusted to use this name for the current record:

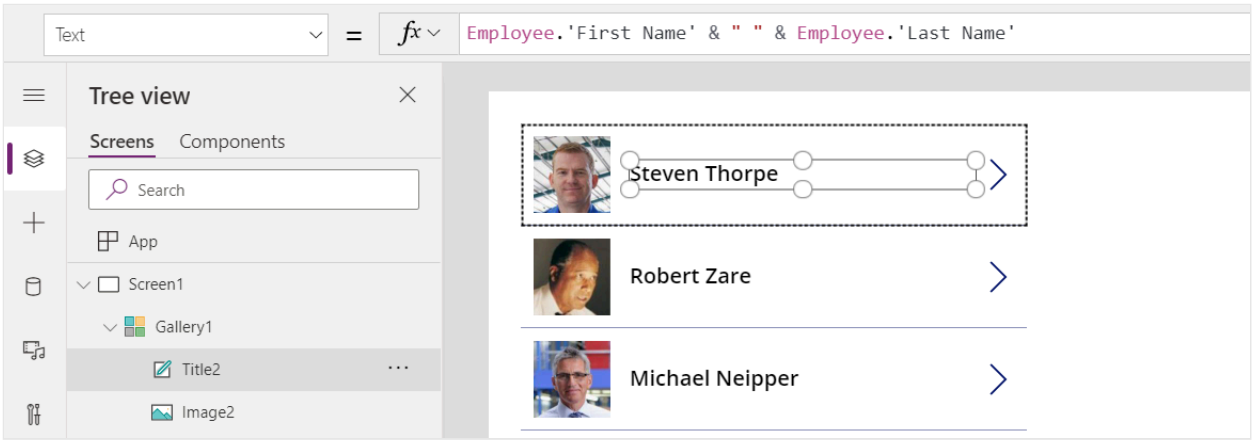
Power Apps

```
Employee.Picture
```



Power Apps

```
Employee.'First Name' & " " & Employee.'Last Name'
```



As can also be used with record scope functions to replace the default name **ThisRecord**. We can apply this to our previous example to clarify the record we're working with:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees As Employee,
              Patch( Employees, Employee, { Status: 'Status
(Employees)'.Active } ) ) )
```

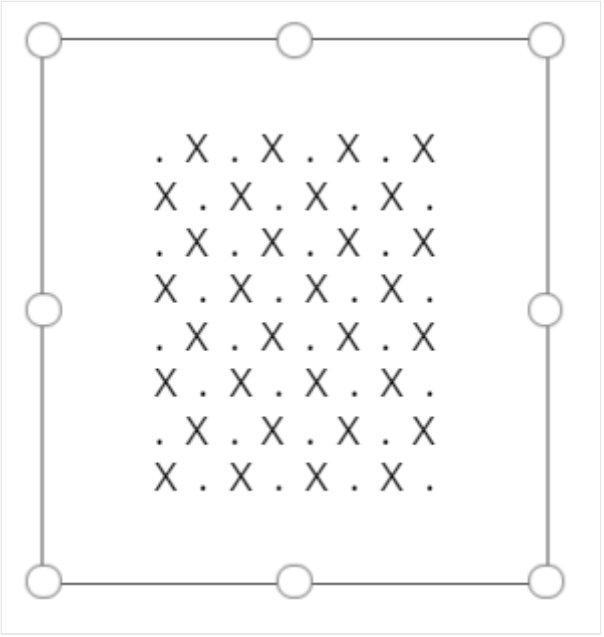
When nesting galleries and record scope functions, **ThisItem** and **ThisRecord** always refers to the inner most scope, leaving records in outer scopes unavailable. Use **As** to make all record scopes available by giving each a unique name.

For example, this formula produces a chessboard pattern as a text string by nesting two **ForAll** functions:

Power Apps

```
Concat(
    ForAll( Sequence(8) As Rank,
        Concat(
            ForAll( Sequence(8) As File,
                    If( Mod(Rank.Value + File.Value, 2) = 1, " X ", " . " )
            ),
            Value
        ) & Char(10)
    ),
    Value
)
```

Setting a **Label** control's **Text** property to this formula displays:



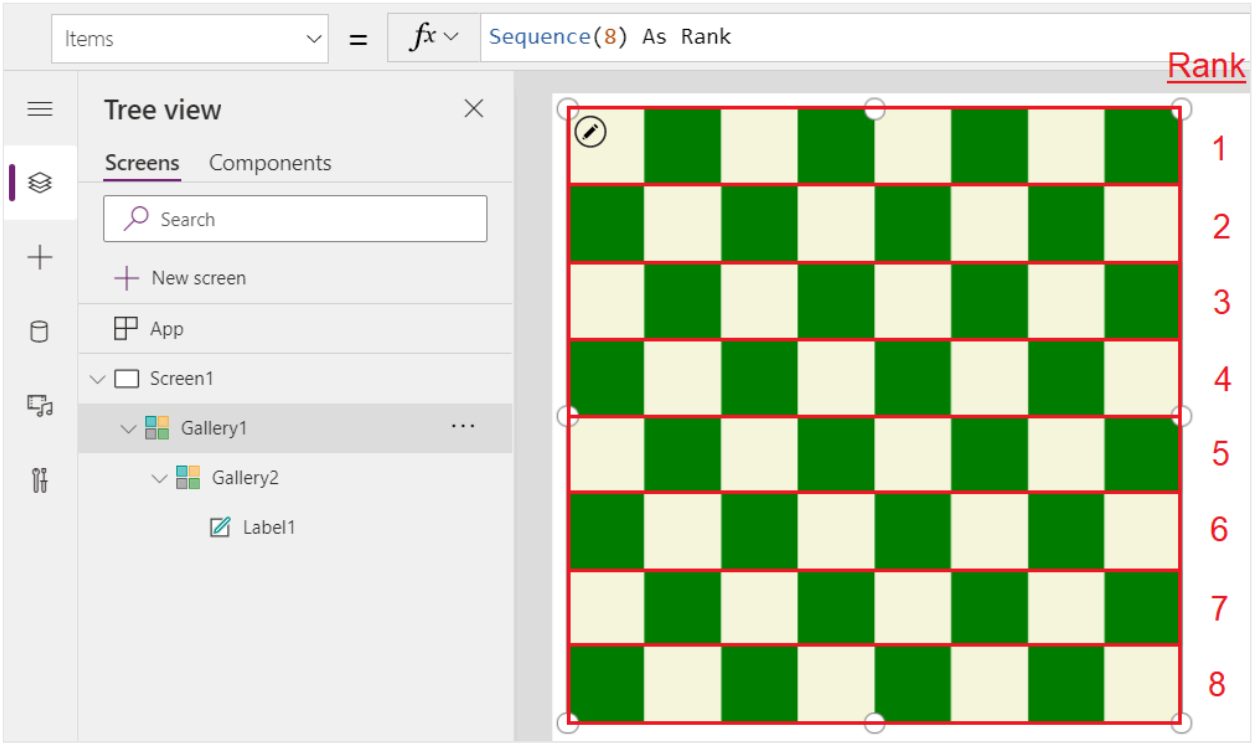
Let's unpack what is happening here:

- We start by iterating an unnamed table of 8 numbered records from the Sequence function. This loop is for each row of the board, which is commonly referred to as **Rank** and so we give it this name.
- For each row, we iterate another unnamed table of 8 columns, and we give the common name **File**.
- If **Rank.Value** + **File.Value** is an odd number, the square gets an **X**, otherwise a dot. This part of the formula is referencing both **ForAll** loops, made possible by using the **As** operator.
- Concat is used twice, first to assemble the columns and then the rows, with a Char(10) thrown in to create a new line.

A similar example is possible with nested **Gallery** controls instead of **ForAll** functions. Let's start with the vertical gallery for the **Rank**. This gallery control will have an **Items** formula of:

Power Apps

```
Sequence(8) as Rank
```



Within this gallery, we'll place a horizontal gallery for the **File**, that will be replicated for each **Rank**, with an **Items** property of:

Power Apps

```
Sequence(8) as File
```

And finally, within this gallery, we'll add a **Label** control that will be replicated for each **File** and each **Rank**. We'll size it to fill the entire space and use the **Fill** property to provide the color with this formula:

Power Apps

```
If( Mod( Rank.Value + File.Value, 2 ) = 1, Green, Beige )
```

Self and Parent operators

There are three ways to refer to a control and its properties within a formula:

Expand table

Method	Description
By control name	Any control can be referenced by name from anywhere within the app. For example, **Label1.Fill** refers to the fill property of the control who's name is **Label1**.
Self operator	It's often convenient to reference another property of the same control when writing a formula. Instead of using an absolute reference by name, it's easier and more portable to use a relative reference to one*self*. The **Self** operator provides that easy access to the current control. For example, **Self.Fill** refers to the fill color of the current control.

Method	Description
Parent operator	Some controls host other controls, such as the **Screen** and **Gallery** controls. The hosting control of the controls within it's called the *parent*. Like the **Self** operator, the **Parent** operator provides an easy relative reference to the container control. For example, **Parent.Fill** refers to the fill property of the control that is the container for the current control.

Self and **Parent** are operators and not properties on the controls themselves. Referring to **Parent.Parent**, **Self.Parent** or **Parent.Self** is not supported.

Identifier names

The names of variables, data sources, columns, and other objects can contain any Unicode.

Use single quotes around a name that contains a space or other special character. Use two single quotes together to represent one single quote in the name. Names that don't contain special characters don't require single quotes.

Here are some example column names you might encounter in a table, and how they're represented in a formula:

Expand table

Column name in a database	Column reference in a formula
SimpleName	`SimpleName`
NameWith123Numbers	`NameWith123Numbers`
Name with spaces	`'Name with spaces'`
Name with "double" quotes	`'Name with "double" quotes'`
Name with 'single' quotes	`'Name with ''single'' quotes'`
Name with an @ at sign	`'Name with an @ at sign'`

Double quotes are used to designate text strings.

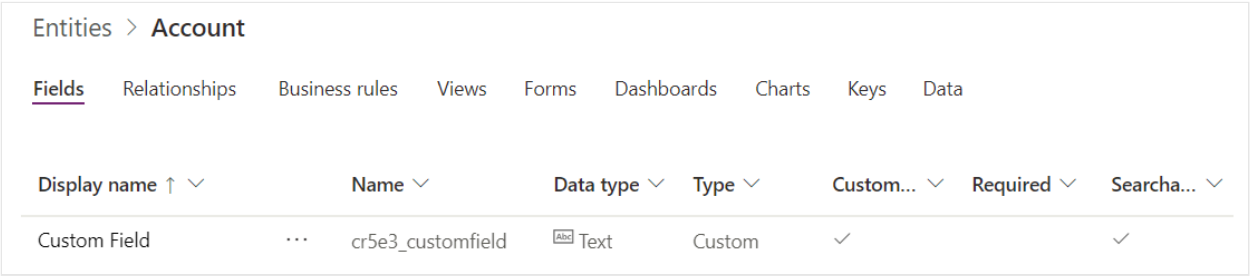
Display names and logical names

Some data sources such as SharePoint and Microsoft Dataverse have two different names to refer to the same table or column of data:

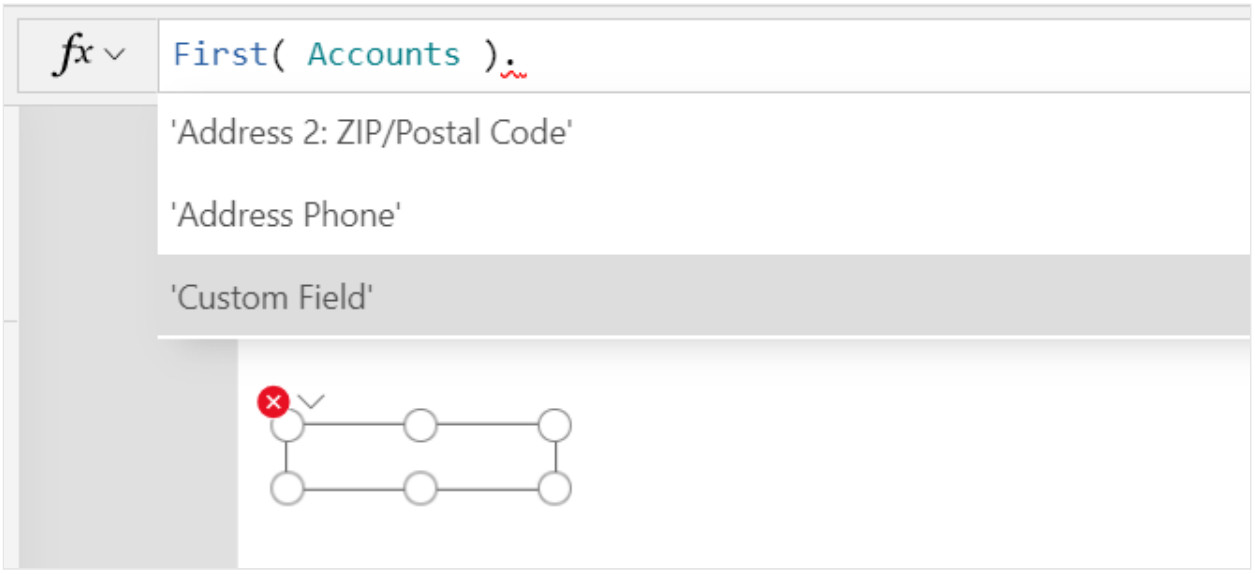
- **Logical name** - A name that is guaranteed to be unique, doesn't change after being created, usually doesn't allow spaces or other special characters, and isn't localized into different languages. As a result, the name can be cryptic. These names are used by professional developers. For example, **cra3a_customfield**. This name may also be referred to as **schema name** or just **name**.
- **Display name** - A name that is user-friendly and intended to be seen by end users. This name may not be unique, may change over time, may contain spaces and any Unicode character, and may be localized into different languages. Corresponding to the example above, the display name may be **Custom Field** with space in between the words.

Since display names are easier to understand, Canvas apps will suggest them as choices and not suggest logical names. Although logical names aren't suggested, they can still be used if typed indirectly.

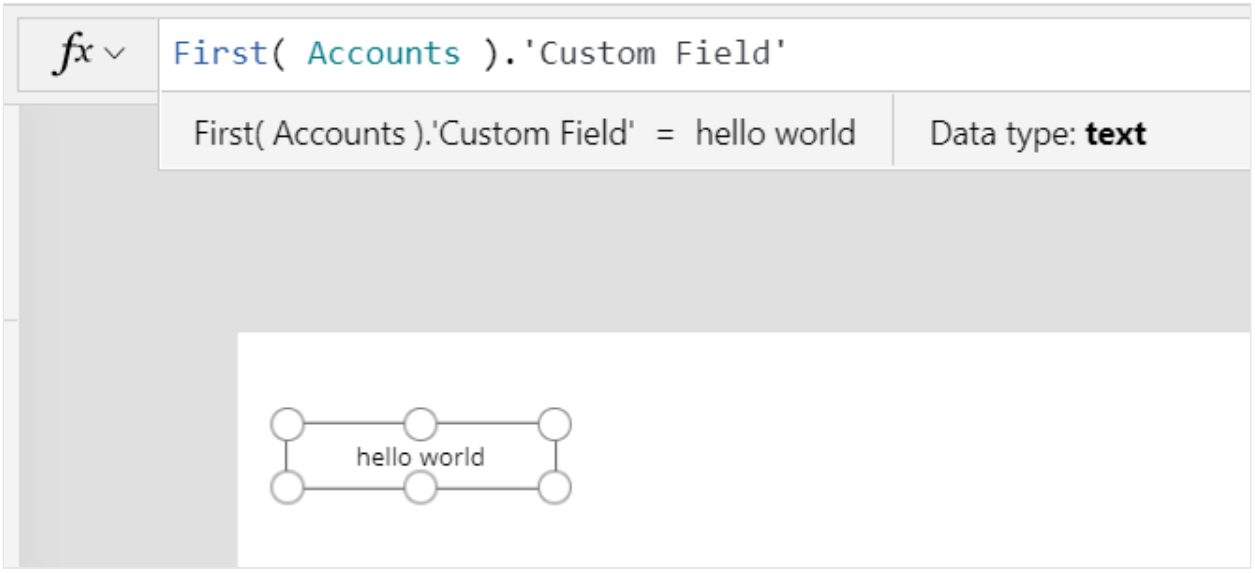
For example, imagine you've added a **Custom Field** to a table in Dataverse. A logical name will be assigned for you by the system, which you can modify only when creating the field. The result would look similar to:



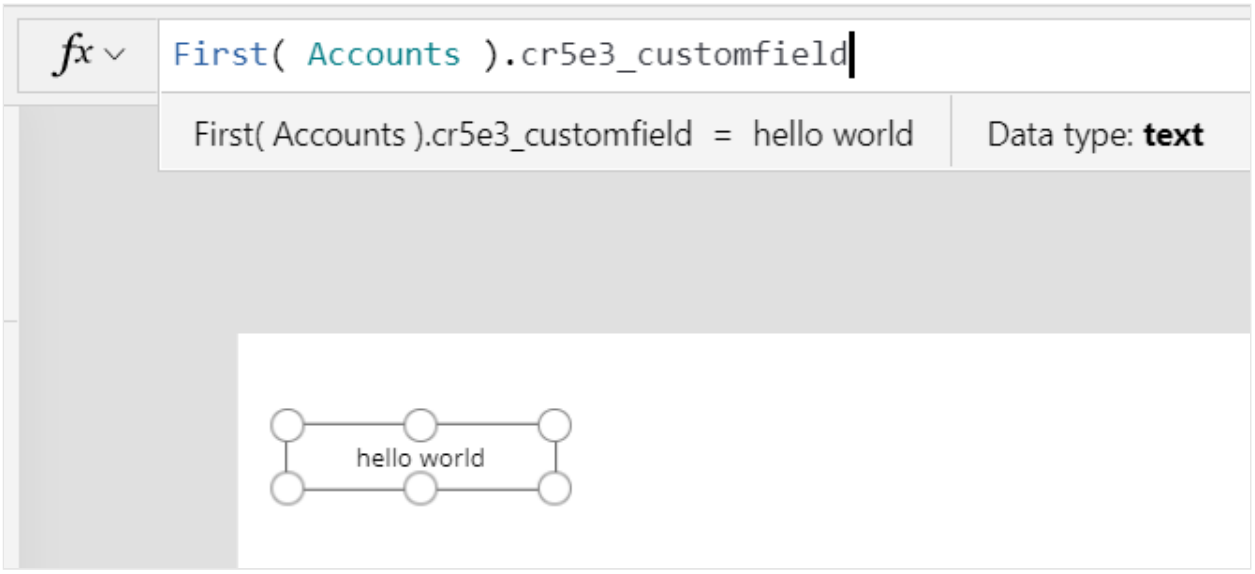
When authoring a reference to a field of Accounts, the suggestion will be made to use '**Custom Field**' since this is the display name. Single quotes must be used because this name has a space in it:



After selecting the suggestion, 'Custom Field' is shown in the formula bar and the data is retrieved:



Although it isn't suggested, we could also use the logical name for this field. This will result in the same data being retrieved. Single quotes are not required since this name doesn't contain spaces or special characters:

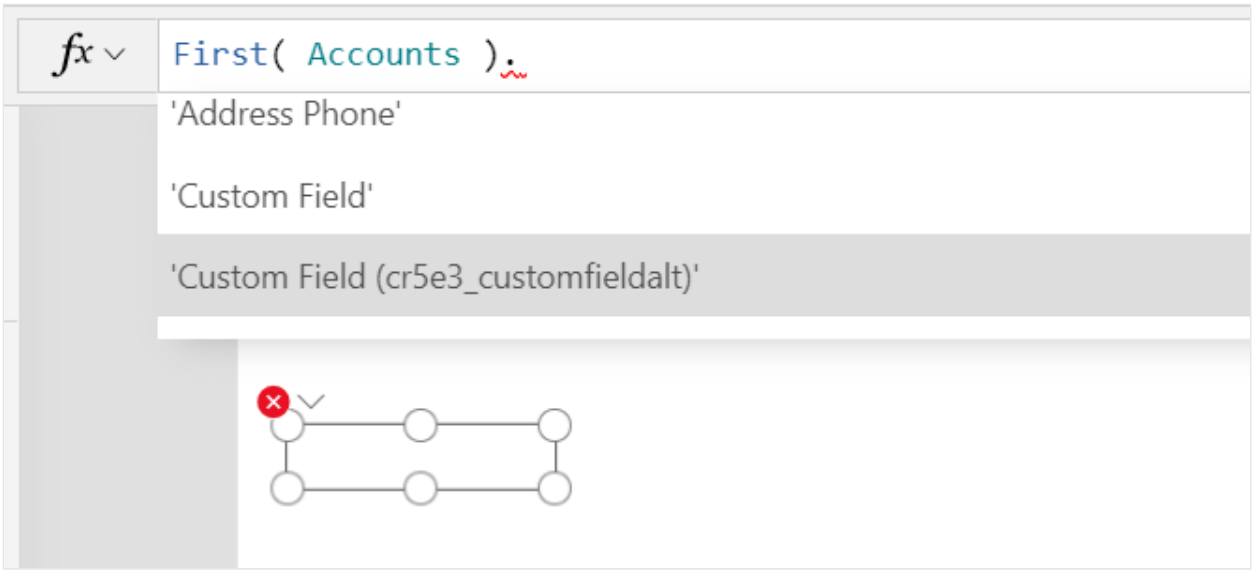


Behind the scenes, a mapping is maintained between the display names seen in formulas and the underlying logical names. Since logical names must be used to interact with the data source, this mapping is used to convert from the current display name to the logical name automatically and that is what is seen in the network traffic. This mapping is also used to convert back to logical names to switch into new display names, for example, if a display name changes or a maker in a different language edits the app.

> **Note**
>
> Logical names are not translated when moving an app between environments. For Dataverse system table and field names, this should not be a problem as logical names are consistent across environments. But any custom fields, such as **cra3a_customfield** in this example above, may have a different environment prefix (**cra3a** in this case). Display names are preferred as they can be matched against display names in the new environment.

Name disambiguation

Since display names aren't unique, the same display name may appear more than once in the same table. When this happens, the logical name will be added to the end of the display name in parentheses for one of more of the conflicting names. Building on the example above, if there was a second field with the same display name of **Custom Field** with a logical name of **cra3a_customfieldalt** then the suggestions would show:



Name disambiguation strings are added in other situations where name conflicts occur, such as the names of table, choices, and other Dataverse items.

Disambiguation operator

Some functions create record scopes for accessing the fields of table while processing each record, such as **Filter**, **AddColumns**, and **Sum**. Field names added with the record scope override the same names from elsewhere in the app. When this happens, you can still access values from outside the record scope with the @ disambiguation operator:

- To access values from nested record scopes, use the @ operator with the name of the table being operated upon using this pattern:
  Table[@*FieldName*]
- To access global values, such as data sources, collections, and context variables, use the pattern [@*ObjectName*] (without a table designation).

For more information and examples, see record scopes.

And, Or, and Not functions

Article • 06/10/2024

Applies to: Canvas apps Dataverse formula columns Desktop flows Model-driven apps Power Pages Power Platform CLI

Boolean logic functions, commonly used to manipulate the results of comparisons and tests.

Description

The **And** function returns **true** if all of its arguments are **true**.

The **Or** function returns **true** if any of its arguments are **true**.

The **Not** function returns **true** if its argument is **false**; it returns **false** if its argument is **true**.

These functions work the same way as they do in Excel. You can also use operators to perform these same operations, using either Visual Basic or JavaScript syntax:

Expand table

Function notation	Visual Basic operator notation	JavaScript operator notation
And(x, y)	x And y	x && y
Or(x, y)	x Or y	x || y
Not(x)	Not x	! x

These functions work with logical values. You can't pass them a number or a string directly; instead, you must make a comparison or a test. For example, this logical formula **x** > **1** evaluates to the Boolean value **true** if **x** is greater than **1**. If **x** is less than **1**, the formula evaluates to **false**.

Syntax

And(*LogicalFormula1*, *LogicalFormula2* [, *LogicalFormula3*, ...])
Or(*LogicalFormula1*, *LogicalFormula2* [, *LogicalFormula3*, ...])
Not(*LogicalFormula*)

- *LogicalFormula(s)* - Required. Logical formulas to evaluate and operate on.

Examples

The examples in this section use these global variables:

- **a** = *false*
- **b** = *true*
- **x** = 10
- **y** = 100
- **s** = "Hello World"

To create these global variables in an app, insert a **Button** control, and set its **OnSelect** property to this formula:

Power Apps

```
Set( a, false ); Set( b, true ); Set( x, 10 ); Set( y, 100 ); Set( s, "Hello World" )
```

Select the button (by clicking it while you hold down the Alt key), and then set the **Text** property of a **Label** control to a formula in the first column of the next table.

Expand table

Formula	Description	Result
And(a, b)	Tests the values of **a** and **b**. One of the arguments is *false*, so the function returns *false*.	*false*
a And b	Same as the previous example, using Visual Basic notation.	*false*
a && b	Same as the previous example, using JavaScript notation.	*false*
Or(a, b)	Tests the values of **a** and **b**. One of the arguments is *true*, so the function returns *true*.	*true*
a Or b	Same as the previous example, using Visual Basic notation.	*true*
a || b	Same as the previous example, using JavaScript notation.	*true*
Not(a)	Tests the value of **a**. The argument is *false*, so the function returns the opposite result.	*true*
Not a	Same as the previous example, using Visual Basic notation.	*true*
! a	Same as the previous example, using JavaScript notation.	*true*
Len(s) < 20 And Not IsBlank(s)	Tests whether the length of **s** is less than 20 and whether it isn't a **blank** value. The length is less than 20, and the value	*true*

Formula	Description	Result
	isn't blank. Therefore, the result is *true*.	
Or(Len(s) < 10, x < 100, y < 100)	Tests whether the length of **s** is less than 10, whether **x** is less than 100, and whether **y** is less than 100. The first and third arguments are false, but the second one is true. Therefore, the function returns *true*.	*true*
Not IsBlank(s)	Tests whether **s** is *blank*, which returns *false*. **Not** returns the opposite of this result, which is *true*.	*true*

Launch and Param functions

Article • 03/04/2025

Applies to: Canvas apps

Launches a webpage or a canvas app and provides access to launch parameters.

Launch

Launches a webpage or a canvas app. The function supports:

- **Address** (required), the URL of the webpage of the canvas app.
- **Parameters** (optional), named values to pass to the webpage or canvas app. In a canvas app, parameters can be read with the **Param** function.
- **Target** (optional), the browser tab in which to launch the webpage or canvas app.

Launch can only be used in behavior formulas.

> **Note**
>
> - If the Launch formula is used to open Power Apps and the app isn't visible to the end user, it's recommended to check if the app is blocked by a browser pop-up blocker or if the browser is wait for the user's response to a dialog box that asks whether they want to navigate to a new screen.
> - Only **https**: URIs are supported when using Launch in the Power Apps Visual in PowerBI.

Address

Webpages are launched via a URL address. For example:

Power Fx

```
Launch( "https://bing.com" )
```

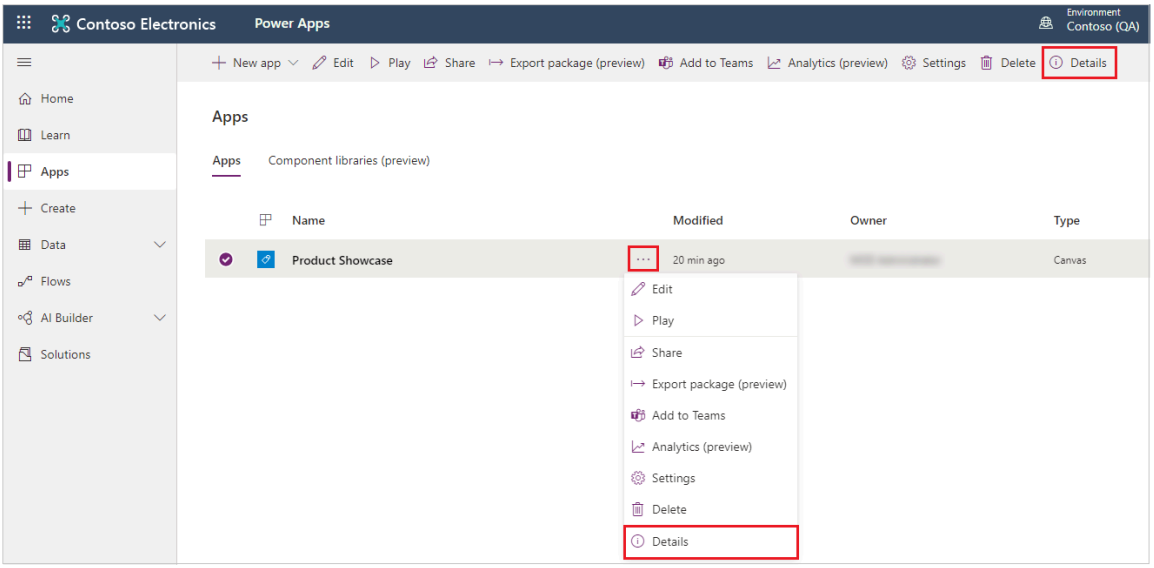
You can launch canvas apps with **Web link** or **App URI** (app id prefixed with `/providers/Microsoft.PowerApps/apps/`). To find these values for an app:

1. Go to Power Apps.

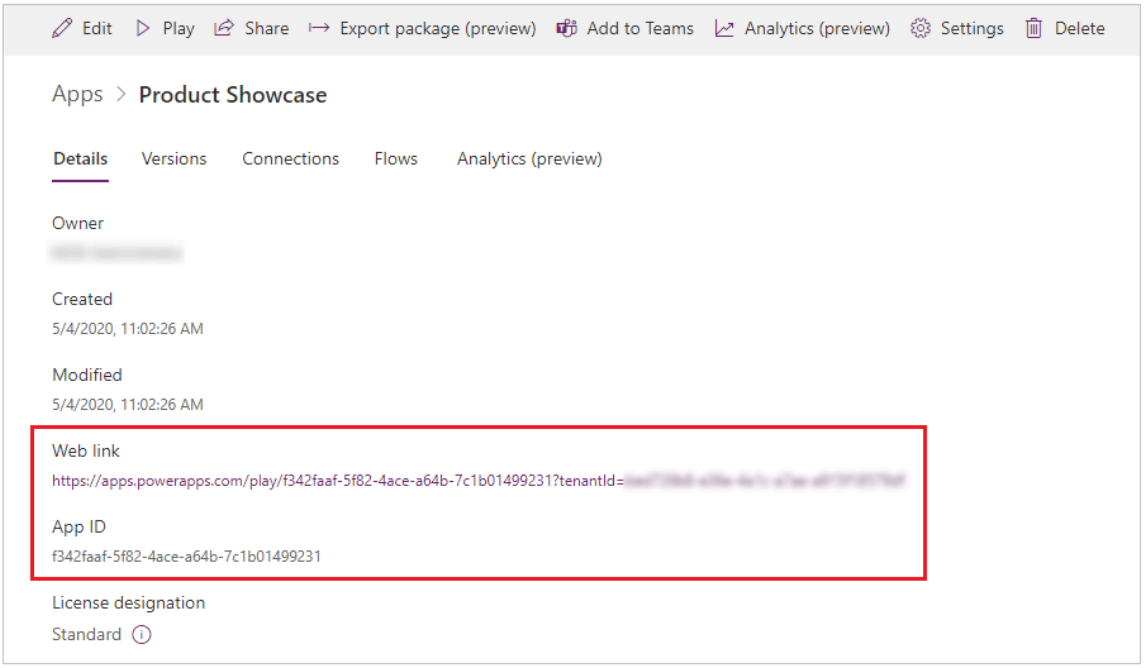
2. Select **Apps** from left navigation pane.

3. Select your app.

4. Select **Details** from top menu.
   You can also select **...** (**More Commands**) and then select **Details** from the drop-down menu.



5. Copy **Web link**.



The **Web link** can be used in any web page and will launch the canvas app. It can also be used with the **Launch** function. For example:

```
Power Fx
```

```
Launch( "https://apps.powerapps.com/e/{environment id}/a/{app id}?tenantId=
{tenantId}" )
```

Native apps on a device can't be launched directly. There may be indirect options available on some platforms, such as a native app installing a custom URL scheme or registering with the web browser to offer an option for specific web sites.

Parameters

Launch can pass parameters to the webpage or canvas app. Parameters can be provided in two ways:

- An argument list of name value pairs. For example:

  Power Fx

  ```
  Launch( "https://bing.com/search", "q", "Power Apps", "count", 1 )
  ```

- A record of field values. For example:

  Power Fx

  ```
  Launch( "https://bing.com/search", { q: "Power Apps", count: 1 } )
  ```

  This form can be easier to work with as it makes the association between name and value clearer. It's the only form that supports the optional *LaunchTarget* argument.

The address and parameters are URL encoded before being passed to replace certain non-alphanumeric characters with `%` and a hexadecimal number as if the **EncodeUrl** function has been used on each.

When launching a webpage, a query string of parameters can be included at the end of the URL address. Any additional parameters provided to **Launch** will be added to the end of the query string. Query strings don't work when launching a canvas app.

When launching an app on a mobile device where that app is already running, parameters will not be refreshed in the running app. An app reload is required for parameters to be refreshed.

Target

Use the *LaunchTarget* argument to specify the target browser window in which to open the webpage or app. Use one of the following **LaunchTarget** enum values or provide a custom window *name*.

Expand table

LaunchTarget enum	Description
New	The webpage or app is opened in a new window or tab.
Replace	The webpage or app replaces the current window or tab.
name	Instead of an enum value, use your own text string to *name* the window or tab. *Self* is an internal only name that is only used by the **Launch** function. It has no impact on nor will it match the title of the window that your users see. If a window or tab with the given *name* already exists, its contents will be replaced. Otherwise, a new window or tab will be created. *name* can't begin with the underscore character "_".

New is the default enum when running in a web browser with **Replace** and *name* as available options. In a mobile player, **New** is the default for webpages with *name* as an available option; while the current canvas app will always be replaced by another canvas app.

> **Note**
>
> - Using a *LaunchTarget* with any value other than **New** in embedded scenarios (for example, Power BI or SharePoint) is not supported and may result in unexpected behavior. In the future, this behavior may change, or may cause an error.

Param

The **Param** function retrieves a parameter passed to the app when it was launched. If the named parameter wasn't passed, **Param** returns *blank*.

- When launching a canvas app from another canvas app, use the *Parameter* arguments to the **Launch** function. Parameter names and values will be automatically URL encoded.
- When launching a canvas app from a web page, add parameters to the query string of the canvas app web link. This involves adding `&parametername=parametervalue` assuming the query string has already been

started for the `tenantId`. For example, adding `&First%20Name=Vicki&category=3` would pass two parameters: `First Name` with a value of `"Vicki"` and `category` with a value of `"3"` (value type is *text*). The parameter name and value must be URL encoded if they contain spaces or special characters, similar to using the **EncodeURL** function.

- Param names are case-sensitive.
- Param names and values will be automatically URL decoded for use in your app.
- Parameter values do not change unless the app is reloaded. Using **Launch** on a mobile device where the app is already running does not refresh the parameters.
- Even if the parameter contains a number, the type returned by **Param** will always be a text string. Conversion to other types will automatically occur or use explicit conversions such as the **Value** function to convert explicitly to a number.

> ⓘ **Note**
>
> For custom pages, the only parameters accepted by the page are: recordId and entityName.

Syntax

Launch(*Address* [, *ParameterName1*, *ParameterValue1*, ...])

- *Address* – Required. The address of a webpage or the ID of an app to launch.
- *ParameterName(s)* – Optional. Parameter name.
- *ParameterValue(s)* – Optional. Corresponding parameter values to pass to the app or the webpage.

Launch(*Address*, { [*ParameterName1*: *ParameterValue1*, ...] } [, *LaunchTarget*])

- *Address* – Required. The address of a webpage or the ID of an app to launch.
- *ParameterName(s)* – Optional. Parameter name.
- *ParameterValue(s)* – Optional. Corresponding parameter values to pass to the app or the webpage.
- *LaunchTarget* – Optional. A **LaunchTarget** enum value or a custom *name*.

Param(*ParameterName*)

- *ParameterName* - Required. The name of the parameter passed to the app.

Reserved parameters

The following keywords are reserved (regardless of case) for internal use, and shouldn't be used as a custom parameter in the **Param()** function:

- amp%3Bauthmode
- amp%3Benableonbehalfof
- amp%3Bhidenavbar
- amp%3Blocale
- appmetadataversion
- authmode
- channeltype
- cordovapath
- correlationid
- debug
- delegatelaunchurl
- delegatelaunchurl
- disablepreviewredirect
- embedderorigin
- enableonbehalfof
- groupid
- hideappsplash
- hidenavbar
- hint
- hostclienttype
- hostmode
- iframecontainerid
- isfullscreen
- ispreviewmode
- loader
- loaderType
- locale
- location
- packagekind
- packageproperties
- playerresourcespath
- playersessionid
- powerappslanguage
- screencolor
- sdkversion
- site
- skipappmetadata
- skipiframecreation

- skiplaunchappcache
- source
- sourcetime
- standaloneconsent
- teamid
- teamtype
- tenantId
- theme
- uselocalpackagehostresources
- userteamrole

Examples

Simple Launch

From a canvas app to a web page:

Expand table

Formula	Description
Launch("http://bing.com/search", "q", "Power Apps", "count", 1)	Opens the webpage **https://bing.com/search?q=Power%20Apps&count=1**. A new window or tab is opened.
Launch("http://bing.com/search", { q: "Power Apps", count: 1 })	The same as the previous examples using the equivalent record notation. A new window or tab is opened.
Launch("http://bing.com/search", { q: "Power Apps", count: 1 }, LaunchTarget.Replace)	The same as the previous examples, replacing the current window or tab with the result if running in a web browser.
Launch("http://bing.com/search", { q: "Power Apps", count: 1 }, "Search Results")	The same as the previous example, creating or replacing the contents of the window or tab named **Search Results**.

From a canvas app to a canvas app

Update the app ID, screen name, and record number as appropriate.

```
Power Fx
```

```
Launch( "/providers/Microsoft.PowerApps/apps/YOUR-APP-ID",
        { Navigate: "Second Screen", Record: 34 }
)
```

From a web page to a canvas app

Update the app ID, tenant ID, screen name, and record number as appropriate.

HTML

```
<html>
  <body>
    <a
      href="https://apps.powerapps.com/play/e/YOUR-APP-ENVIRONMENT-
ID/a/YOUR-APP-ID?tenantId=YOUR-TENANT-ID&Navigate=Second%20Screen&Record=34"
    >
      Launch canvas app
    </a>
  </body>
</html>
```

Simple Param

Simple launch examples above to launch canvas app from web page or from another canvas app show simple examples for Param function:

Expand table

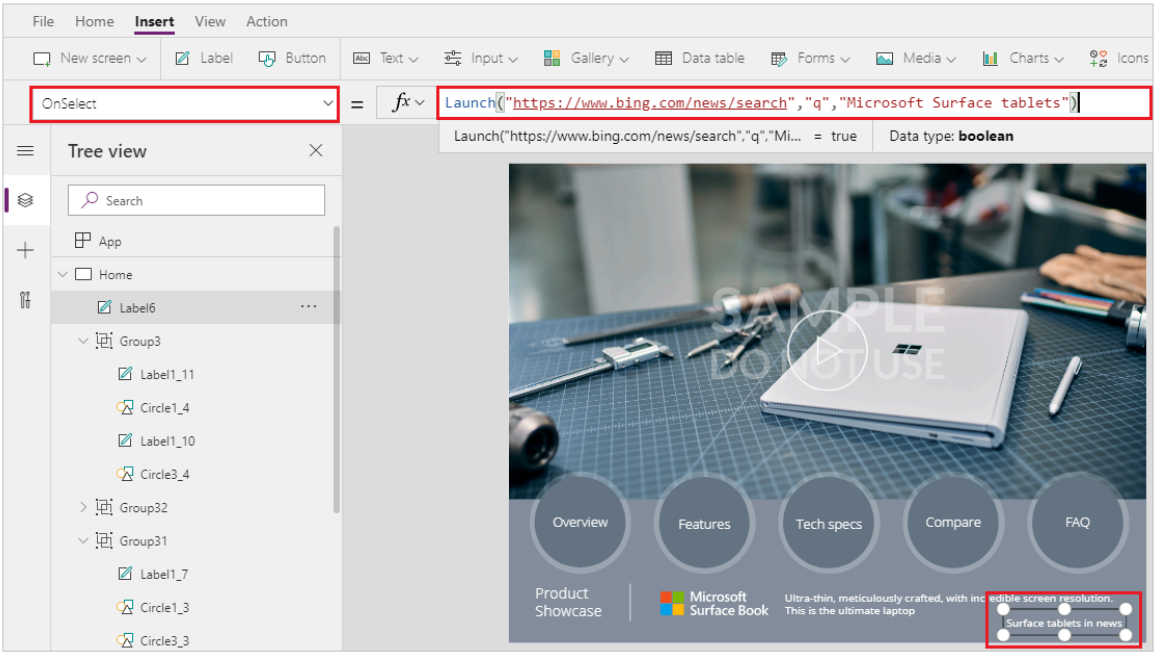
Formula	Description	Result
Param("Navigate")	The **Navigate** parameter was provided when the app was launched and is returned.	"Second Screen"
Param("Record")	The **Record** parameter was provided when the app was launched. Even though it was passed in as a number to the **Launch** function, the result from **Param** will be a text string that can be implicitly or explicitly converted to other types.	"34"
Param("User")	The **User** parameter wasn't provided. A *blank* value is returned that can be tested with the **IsBlank** function.	*blank*

Step by Step examples for Launch and Param

The **Product Showcase** tablet layout template was used for the following examples. To create an app with this template, follow the steps from create an app article and select the **Product Showcase** template. You can also use your own app.

Example - Launch

1. Go to Power Apps.
2. Select **Apps** from left navigation pane.
3. Select your app and then select **Edit**.
4. Select **Insert** from the menu and then select **Label**.
5. Move the label to the bottom right of the screen.
6. From the properties pane on the right-side, select **Color** as *white* and set **Border thickness** at *1*.
7. Select the **Text** property from right-side and enter text as *Surface tablets in news*.
8. From property list on top left, select **OnSelect**.
9. Enter formula as `Launch("https://www.bing.com/news/search","q","Microsoft Surface tablets")`. You can also use any other URL, parameter, and keywords of your choice.



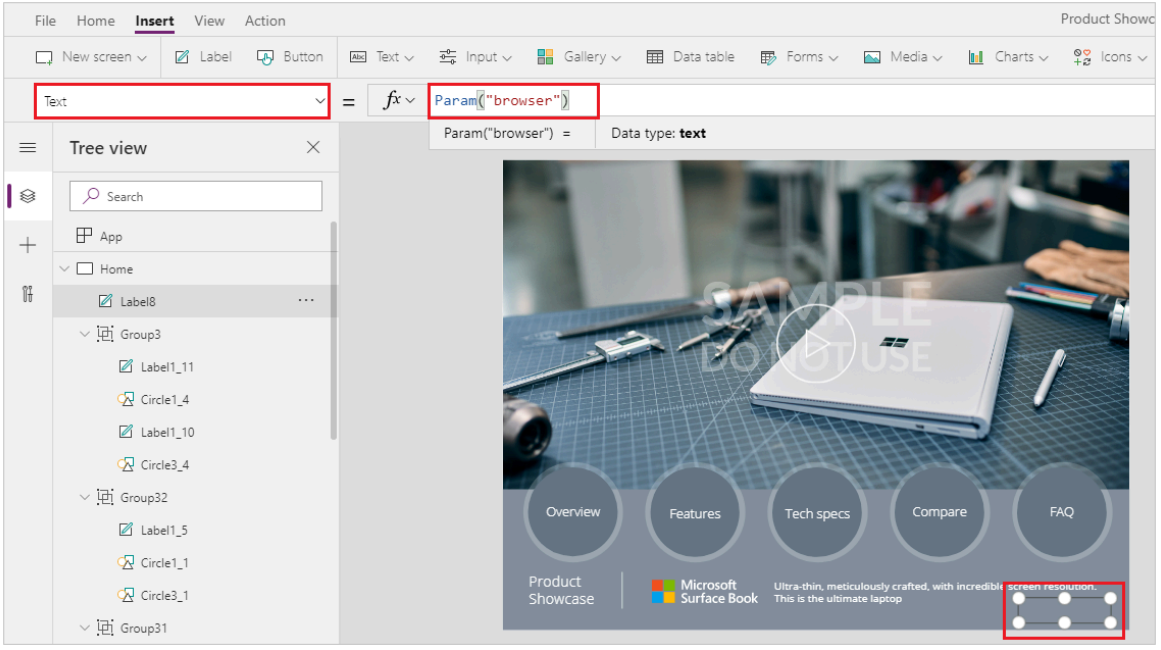
10. Save and publish the app.
11. Play the app.

12. Select label **Surface tablets in news** to launch news search with keywords *Microsoft Surface tablets*.

> **Tip**
>
> For scalability, you can replace the manually entered keywords in Launch function with variables.

Example - Param

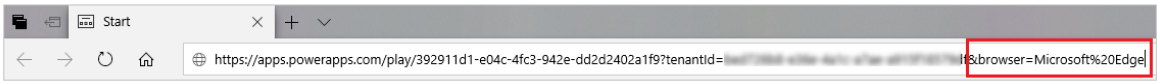
1. Go to Power Apps.
2. Select **Apps** from left navigation pane.
3. Select your app and then select **Edit**.
4. Select **Insert** from the menu and then select **Label**.
5. Move the label to the bottom right of the screen.
6. Select **Text** property for the label from top left.
7. Enter formula as `Param("browser")`. You can also use a different parameter of your choice.



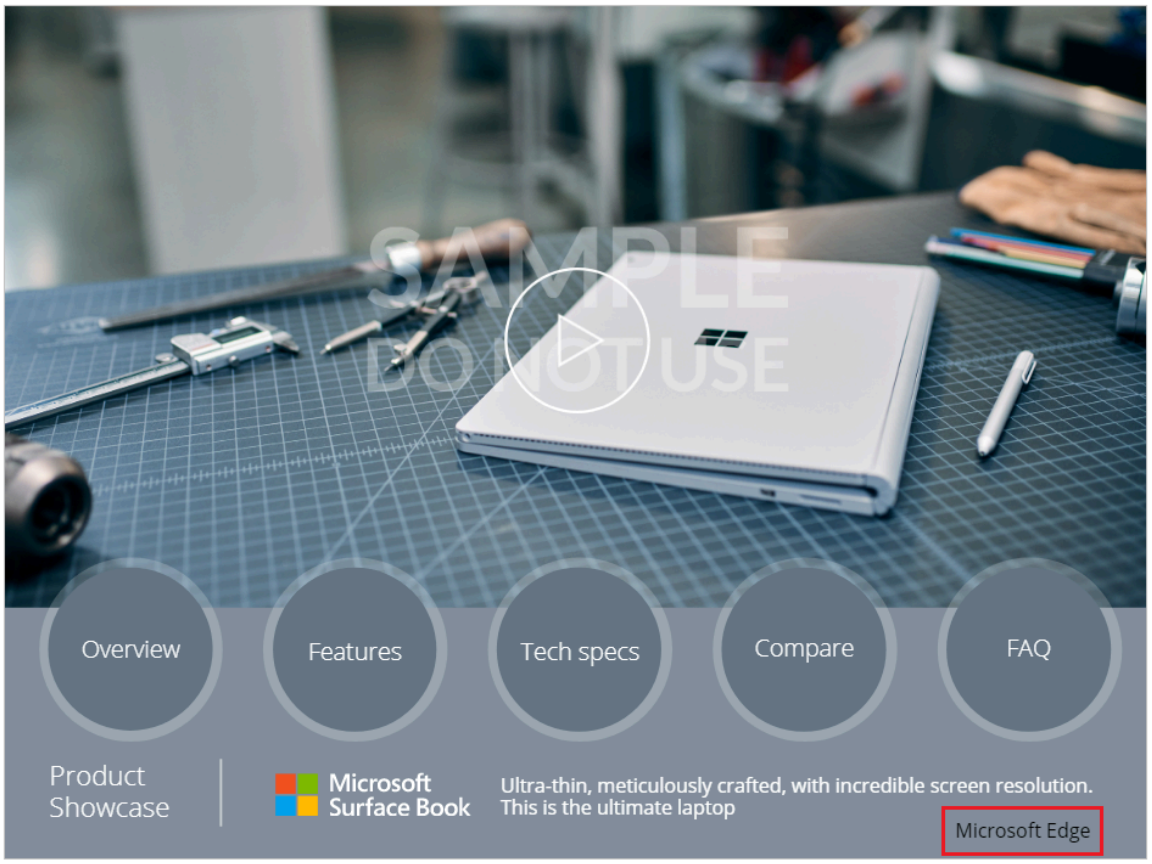
8. Save and publish the app.
9. Copy web link for your app from Power Apps.

10. Open a new browser.

11. Paste the app web link in the browser and append `&browser=Microsoft%20Edge` at the end.



12. When your app launches, the label shows the parameter value passed.

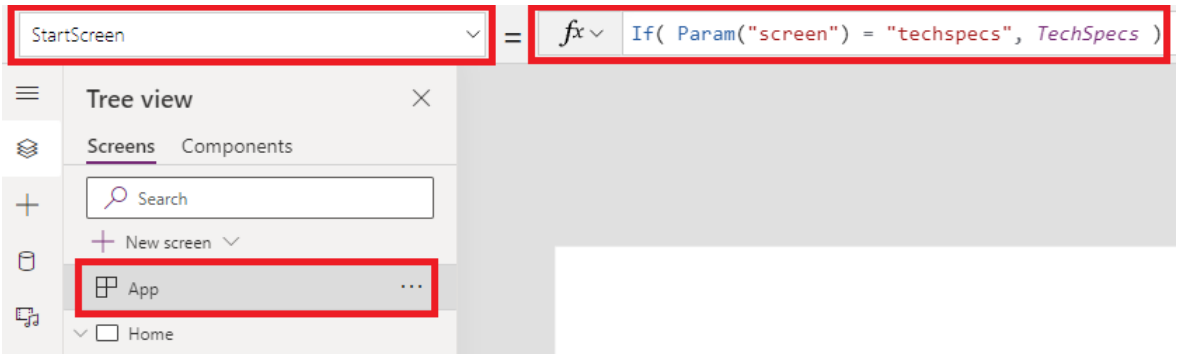


13. Close the app player and edit the app.

14. Select **App** from the Tree view on left navigation.

15. Select **StartScreen** property on top left.

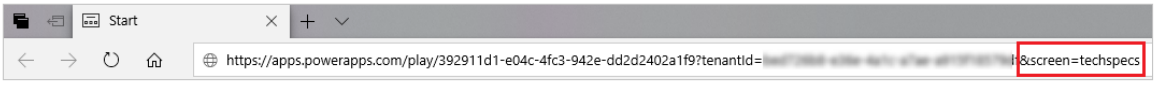
16. Enter the formula as `If( Param("screen") = "techspecs", TechSpecs )`.



If function in StartScreen property checks if parameter equals a certain value, in this case the value *techspecs*. And if it matches, returns the *TechSpecs* screen control to the **StartScreen** property.

> **Note**
>
> Replace the **TechSpecs** control name in the **If** function with the name of a screen control in your own app if you're not using the **Product Showcase** app template.

17. Save and publish the app.
18. Open a new browser.
19. Paste the app web link in the browser and append `&screen=techspecs` at the end.



20. The app directly launches with **TechSpecs** as the startscreen.

Operators and Identifiers in Power Apps

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Some of these operators are dependent on the language of the author. For more information about language support in canvas apps, see Global apps.

Expand table

Symbol	Type	Example	Description
'...'	Identifier	**'Account Name'**	Identifiers that contain special characters, including spaces, are enclosed in single quotes
"..."	Text string	**"Hello, World"**	Text strings are enclosed in double quotes
$"..."	String interpolation	**$"Dear {FirstName},"**	Formulas embedded within a text string
.	Property Selector	**Slider1.Value** **Color.Red** **Acceleration.X**	Extracts a property from a table, control, signal, or enumeration. For backward compatibility, **!** may also be used.
. [language dependent]	Decimal separator	**1.23**	Separator between whole and fractional parts of a number. The character depends on the language.
( )	Parentheses	**Filter(T, A < 10)** **(1 + 2) * 3**	Enforces precedence order, and groups subexpressions in a larger expression
+	Arithmetic operators	**1 + 2**	Addition
-		**2 - 1**	Subtraction and sign
*		**2 * 3**	Multiplication
/		**2 / 3**	Division (also see the **Mod** function)
^		**2 ^ 3**	Exponentiation, equivalent to the **Power** function

Symbol	Type	Example	Description
%		**20%**	Percentage (equivalent to "* 1/100")
=	Comparison operators	**Price = 100**	Equal to
>		**Price > 100**	Greater than
>=		**Price >= 100**	Greater than or equal to
<		**Price < 100**	Less than
<=		**Price <= 100**	Less than or equal to
<>		**Price <> 100**	Not equal to
&	String concatenation operator	**"hello" & " " & "world"**	Makes multiple strings appear continuous
&& or **And**	Logical operators	**Price < 100 && Slider1.Value = 20** or **Price < 100 And Slider1.Value = 20**	Logical conjunction, equivalent to the **And** function
|| or **Or**		**Price < 100 || Slider1.Value = 20** or **Price < 100 Or Slider1.Value = 20**	Logical disjunction, equivalent to the **Or** function
! or **Not**		**!(Price < 100)** or **Not (Price < 100)**	Logical negation, equivalent to the **Not** function
exactin	Membership operators	**Gallery1.Selected exactin SavedItems**	Belonging to a collection or a table
exactin		**"Windows" exactin "To display windows in the Windows operating system..."**	Substring test (case-sensitive)
in		**Gallery1.Selected in SavedItems**	Belonging to a collection or a table
in		**"The" in "The keyboard and the monitor..."**	Substring test (case-insensitive)
@	Disambiguation operator	**MyTable[@fieldname]**	Field disambiguation
@		**[@MyVariable]**	Global disambiguation

Symbol	Type	Example	Description
, [language dependent]	List separator	**If(X < 10, "Low", "Good")** **{ X: 12, Y: 32 }** **[1, 2, 3]**	Separates: • arguments in function calls • fields in a record • records in a table This character depends on the language.
; [language dependent]	Formula chaining	**Collect(T, A); Navigate(S1, "")**	Separate invocations of functions in behavior properties. The chaining operator depends on the language.
As	As operator	**AllCustomers As Customer**	Overrides **ThisItem** and **ThisRecord** in galleries and record scope functions. **As** is useful for providing a better, specific name and is especially important in nested scenarios.
Self	Self operator	**Self.Fill**	Access to properties of the current control
Parent	Parent operator	**Parent.Fill**	Access to properties of a control container
ThisItem	ThisItem operator	**ThisItem.FirstName**	Access to fields of a Gallery or form control
ThisRecord	ThisRecord operator	**ThisRecord.FirstName**	Access to the complete record and individual fields of the record within **ForAll**, **Sum**, **With**, and other record scope functions. Can be overridden with the **As** operator.

> ⓘ Note
>
> The @ operator can also be used to validate the type of the record object against a data source. For example, `Collect(coll,Account@{'Account Number: 1111')`

in and exactin operators

Use the **in** and **exactin** operators to find a string in a data source, such as a collection or an imported table. The **in** operator identifies matches regardless of case, and the **exactin** operator identifies matches only if they're capitalized the same way. Here's an example:

1. Create or import a collection named **Inventory**, and show it in a gallery, as the first procedure in Show images and text in a gallery describes.

2. Set the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" in ProductName)

   The gallery shows all products except Callisto because the name of that product is the only one that doesn't contain the letter you specified.

3. Change the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" exactin ProductName)

   The gallery shows only Europa because only its name contains the letter that you specified in the case that you specified.

ThisItem, ThisRecord, and As operators

A few controls and functions apply formulas to individual records of a table. To refer to the individual record in a formula, use one of the following:

Expand table

Operator	Applies to	Description
ThisItem	**Gallery** control **Edit form** control **Display form** control	The default name for the current record in a **Gallery** or form control.
ThisRecord	**ForAll**, **Filter**, **With**, **Sum** and other record scope functions	The default name for the current record in **ForAll** and other record scope functions.
As *name*	**Gallery** control **ForAll**, **Filter**, **With**, **Sum** and other record scope functions	Defines a *name* for the current record, replacing default **ThisItem** or **ThisRecord**. Use **As** to make formulas easier to understand and resolve ambiguity when nesting.

ThisItem operator

For example, in the following **Gallery** control, the **Items** property is set to the **Employees** data source (such as the **Employees** table included with the Northwind Traders sample):

Power Apps

```
Employees
```

The first item in the gallery is a template that is replicated for each employee. In the template, the formula for the picture uses **ThisItem** to refer to the current item:

Power Apps

```
ThisItem.Picture
```

Likewise, the formula for the name also uses **ThisItem**:

Power Apps

```
ThisItem.'First Name' & " " & ThisItem.'Last Name'
```

ThisRecord operator

ThisRecord is used in functions that have a record scope. For example, we can use the **Filter** function with our gallery's **Items** property to only show first names that being with *M*:

Power Apps

```
Filter( Employees, StartsWith( ThisRecord.Employee.'First Name', "M" ) )
```

ThisRecord is optional and implied by using the fields directly, for example, in this case, we could have written:

Power Apps

```
Filter( Employees, StartsWith( 'First Name', "M" ) )
```

Although optional, using **ThisRecord** can make formulas easier to understand and may be required in ambiguous situations where a field name may also be a relationship name. **ThisRecord** is optional while **ThisItem** is always required.

Use **ThisRecord** to reference the whole record with **Patch**, **Collect**, and other record scope functions. For example, the following formula sets the status for all inactive employees to active:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees,
              Patch( Employees, ThisRecord, { Status: 'Status
(Employees)'.Active } ) ) )
```

As operator

Use the **As** operator to name a record in a gallery or record scope function, overriding the default **ThisItem** or **ThisRecord**. Naming the record can make your formulas easier to understand and may be required in nested situations to access records in other scopes.

For example, you can modify the **Items** property of our gallery to use **As** to identify that we are working with an Employee:

Power Apps

```
Employees As Employee
```

The formulas for the picture and name are adjusted to use this name for the current record:

Power Apps

```
Employee.Picture
```

Power Apps

```
Employee.'First Name' & " " & Employee.'Last Name'
```

As can also be used with record scope functions to replace the default name **ThisRecord**. We can apply this to our previous example to clarify the record we're working with:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees As Employee,
              Patch( Employees, Employee, { Status: 'Status
(Employees)'.Active } ) ) )
```

When nesting galleries and record scope functions, **ThisItem** and **ThisRecord** always refers to the inner most scope, leaving records in outer scopes unavailable. Use **As** to make all record scopes available by giving each a unique name.

For example, this formula produces a chessboard pattern as a text string by nesting two **ForAll** functions:

Power Apps

```
Concat(
    ForAll( Sequence(8) As Rank,
        Concat(
            ForAll( Sequence(8) As File,
                    If( Mod(Rank.Value + File.Value, 2) = 1, " X ", " . " )
            ),
            Value
        ) & Char(10)
    ),
    Value
)
```

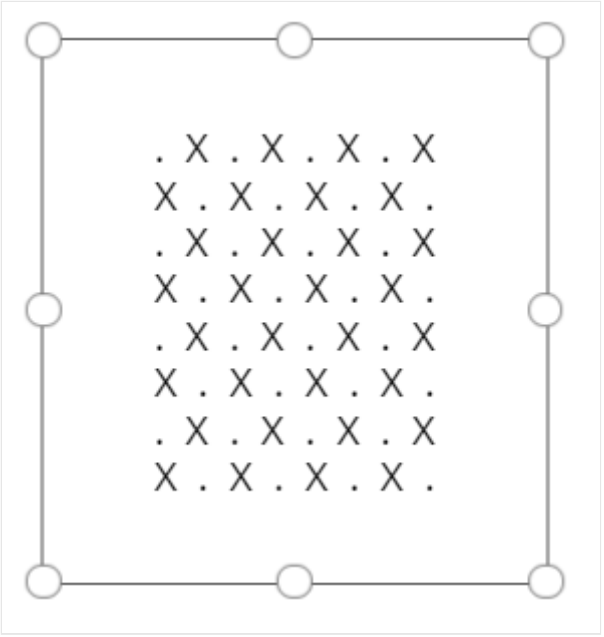
Setting a **Label** control's **Text** property to this formula displays:



Let's unpack what is happening here:

- We start by iterating an unnamed table of 8 numbered records from the Sequence function. This loop is for each row of the board, which is commonly referred to as **Rank** and so we give it this name.
- For each row, we iterate another unnamed table of 8 columns, and we give the common name **File**.
- If **Rank.Value** + **File.Value** is an odd number, the square gets an **X**, otherwise a dot. This part of the formula is referencing both **ForAll** loops, made possible by using the **As** operator.
- Concat is used twice, first to assemble the columns and then the rows, with a Char(10) thrown in to create a new line.

A similar example is possible with nested **Gallery** controls instead of **ForAll** functions. Let's start with the vertical gallery for the **Rank**. This gallery control will have an **Items** formula of:

Power Apps

```
Sequence(8) as Rank
```

Within this gallery, we'll place a horizontal gallery for the **File**, that will be replicated for each **Rank**, with an **Items** property of:

Power Apps

```
Sequence(8) as File
```

And finally, within this gallery, we'll add a **Label** control that will be replicated for each **File** and each **Rank**. We'll size it to fill the entire space and use the **Fill** property to provide the color with this formula:

Power Apps

```
If( Mod( Rank.Value + File.Value, 2 ) = 1, Green, Beige )
```

Self and Parent operators

There are three ways to refer to a control and its properties within a formula:

Expand table

Method	Description
By control name	Any control can be referenced by name from anywhere within the app. For example, **Label1.Fill** refers to the fill property of the control who's name is **Label1**.
Self operator	It's often convenient to reference another property of the same control when writing a formula. Instead of using an absolute reference by name, it's easier and more portable to use a relative reference to one*self*. The **Self** operator provides that easy access to the current control. For example, **Self.Fill** refers to the fill color of the current control.

Method	Description
Parent operator	Some controls host other controls, such as the **Screen** and **Gallery** controls. The hosting control of the controls within it's called the *parent*. Like the **Self** operator, the **Parent** operator provides an easy relative reference to the container control. For example, **Parent.Fill** refers to the fill property of the control that is the container for the current control.

Self and **Parent** are operators and not properties on the controls themselves. Referring to **Parent.Parent**, **Self.Parent** or **Parent.Self** is not supported.

Identifier names

The names of variables, data sources, columns, and other objects can contain any Unicode.

Use single quotes around a name that contains a space or other special character. Use two single quotes together to represent one single quote in the name. Names that don't contain special characters don't require single quotes.

Here are some example column names you might encounter in a table, and how they're represented in a formula:

Expand table

Column name in a database	Column reference in a formula
SimpleName	`SimpleName`
NameWith123Numbers	`NameWith123Numbers`
Name with spaces	`'Name with spaces'`
Name with "double" quotes	`'Name with "double" quotes'`
Name with 'single' quotes	`'Name with ''single'' quotes'`
Name with an @ at sign	`'Name with an @ at sign'`

Double quotes are used to designate text strings.

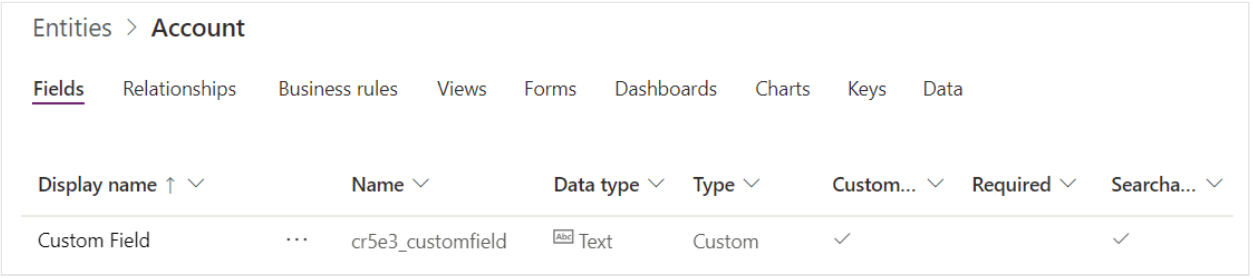
Display names and logical names

Some data sources such as SharePoint and Microsoft Dataverse have two different names to refer to the same table or column of data:

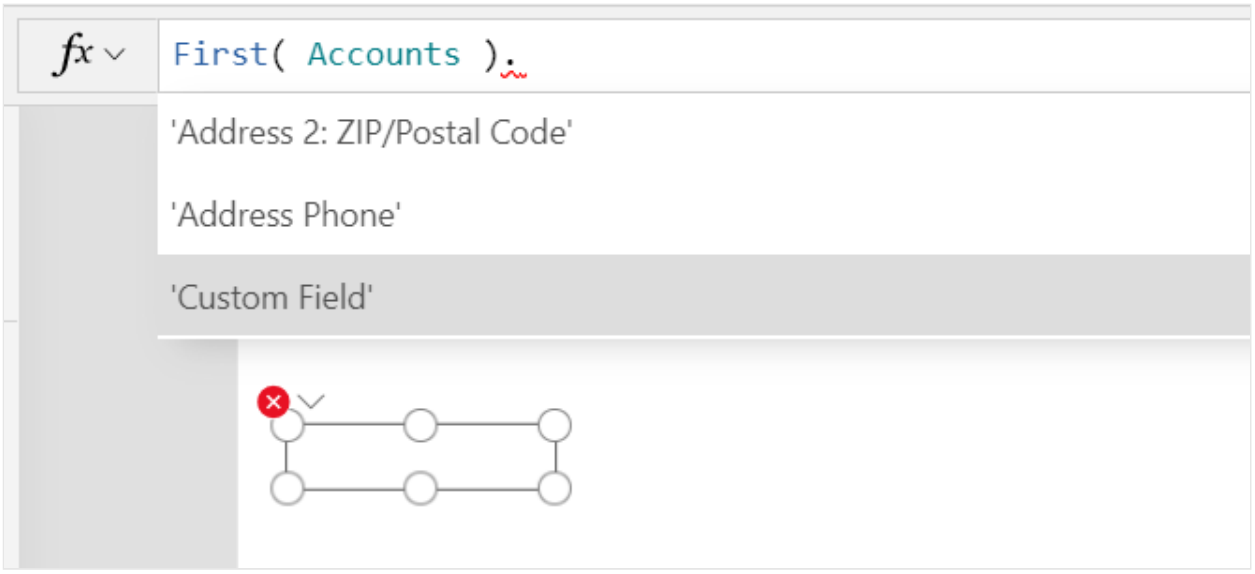
- **Logical name** - A name that is guaranteed to be unique, doesn't change after being created, usually doesn't allow spaces or other special characters, and isn't localized into different languages. As a result, the name can be cryptic. These names are used by professional developers. For example, **cra3a_customfield**. This name may also be referred to as **schema name** or just **name**.
- **Display name** - A name that is user-friendly and intended to be seen by end users. This name may not be unique, may change over time, may contain spaces and any Unicode character, and may be localized into different languages. Corresponding to the example above, the display name may be **Custom Field** with space in between the words.

Since display names are easier to understand, Canvas apps will suggest them as choices and not suggest logical names. Although logical names aren't suggested, they can still be used if typed indirectly.

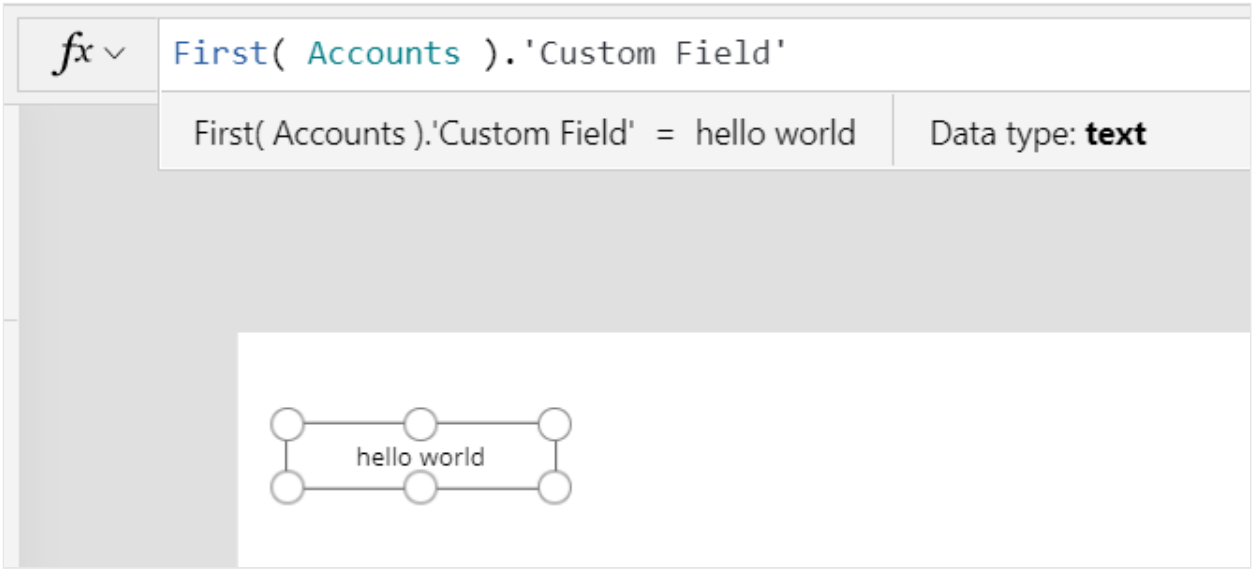
For example, imagine you've added a **Custom Field** to a table in Dataverse. A logical name will be assigned for you by the system, which you can modify only when creating the field. The result would look similar to:



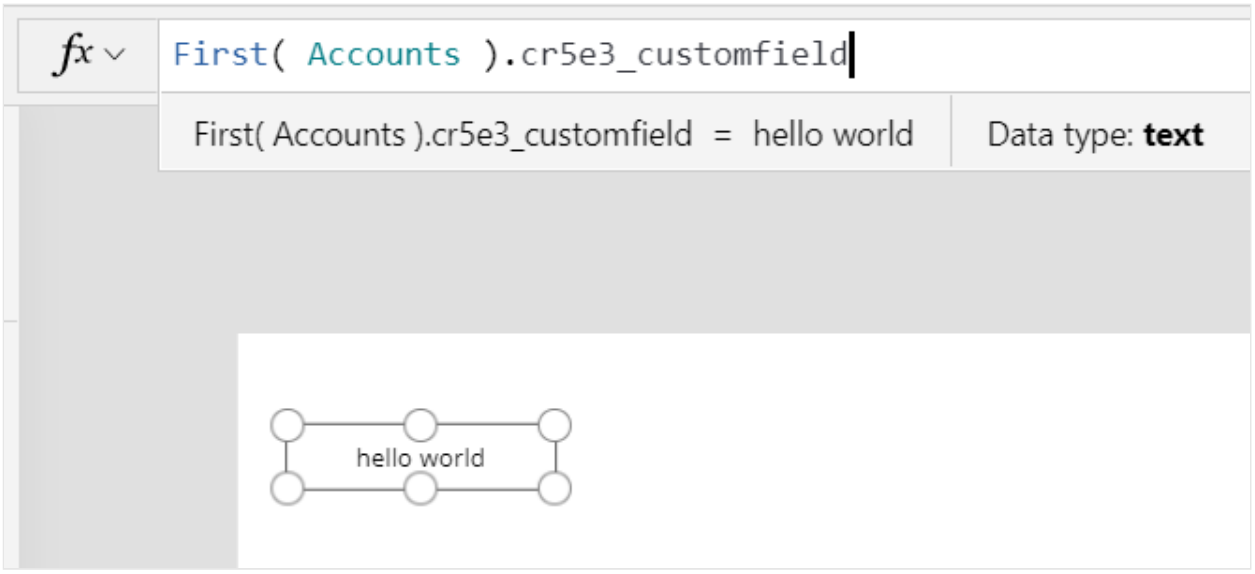
When authoring a reference to a field of Accounts, the suggestion will be made to use '**Custom Field**' since this is the display name. Single quotes must be used because this name has a space in it:



After selecting the suggestion, 'Custom Field' is shown in the formula bar and the data is retrieved:



Although it isn't suggested, we could also use the logical name for this field. This will result in the same data being retrieved. Single quotes are not required since this name doesn't contain spaces or special characters:

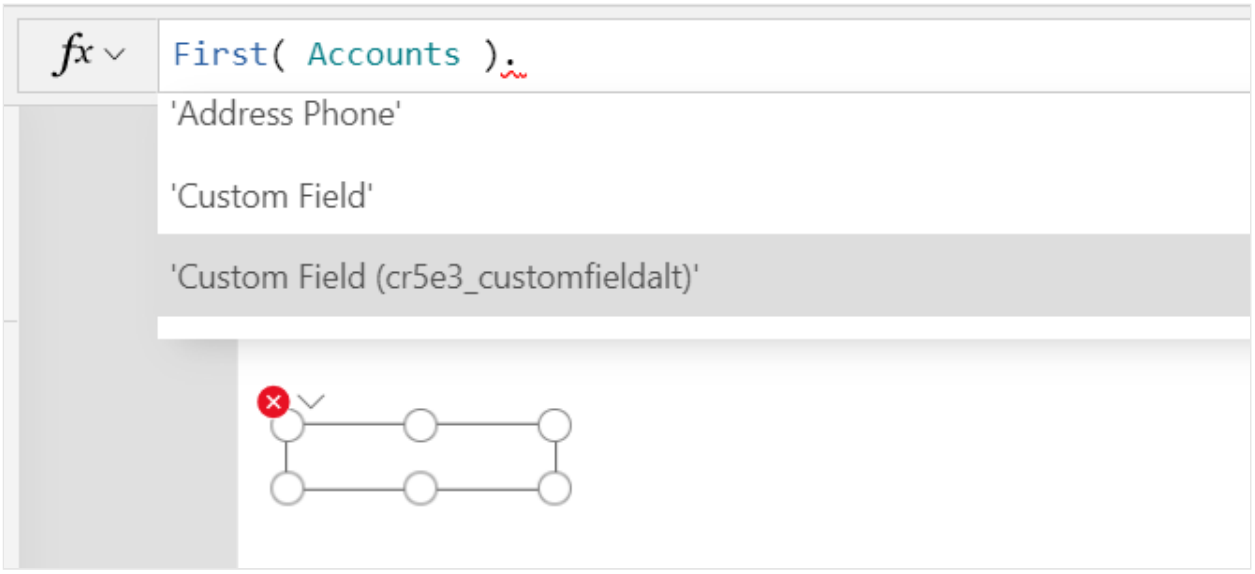


Behind the scenes, a mapping is maintained between the display names seen in formulas and the underlying logical names. Since logical names must be used to interact with the data source, this mapping is used to convert from the current display name to the logical name automatically and that is what is seen in the network traffic. This mapping is also used to convert back to logical names to switch into new display names, for example, if a display name changes or a maker in a different language edits the app.

> **Note**
>
> Logical names are not translated when moving an app between environments. For Dataverse system table and field names, this should not be a problem as logical names are consistent across environments. But any custom fields, such as **cra3a_customfield** in this example above, may have a different environment prefix (**cra3a** in this case). Display names are preferred as they can be matched against display names in the new environment.

Name disambiguation

Since display names aren't unique, the same display name may appear more than once in the same table. When this happens, the logical name will be added to the end of the display name in parentheses for one of more of the conflicting names. Building on the example above, if there was a second field with the same display name of **Custom Field** with a logical name of **cra3a_customfieldalt** then the suggestions would show:



Name disambiguation strings are added in other situations where name conflicts occur, such as the names of table, choices, and other Dataverse items.

Disambiguation operator

Some functions create record scopes for accessing the fields of table while processing each record, such as **Filter**, **AddColumns**, and **Sum**. Field names added with the record scope override the same names from elsewhere in the app. When this happens, you can still access values from outside the record scope with the @ disambiguation operator:

- To access values from nested record scopes, use the @ operator with the name of the table being operated upon using this pattern:
  Table[@*FieldName*]
- To access global values, such as data sources, collections, and context variables, use the pattern [@*ObjectName*] (without a table designation).

For more information and examples, see record scopes.

Patch function

06/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions

Modifies or creates one or more records in a data source, or merges records outside of a data source.

Use the **Patch** function to modify records in complex situations, such as when you do updates that require no user interaction or use forms that span multiple screens.

To update records in a data source more easily for simple changes, use the **Edit form** control instead. When you add an **Edit form** control, you provide users with a form to fill in and then save the changes to a data source. For more information, see Understand data forms.

Watch this video to learn how to use the Patch function:
https://learn-video.azurefd.net/vod/player?id=4f09e796-64f3-4895-89d9-70c8462dac37&locale=en-us&embedUrl=%2Fpower-platform%2Fpower-fx%2Freference%2Ffunction-patch

Overview

Use the **Patch** function to modify one or more records of a data source. The values of specific fields are modified without affecting other properties. For example, this formula changes the phone number for a customer named Contoso:

```
Patch( Customers, LookUp( Customers, Name = "Contoso" ), { Phone: "1-212-555-1234" } )
```

Use **Patch** with the **Defaults** function to create records. Use this behavior to build a single screen for both creating and editing records. For example, this formula creates a record for a customer named Contoso:

```
Patch( Customers, Defaults( Customers ), { Name: "Contoso" } )
```

> **Note**
>
> When you patch a collection using a record from a data source with default values, the patch operation updates the collection with both the specified patch values and the default values from the data source. The DataSource of the patch statement and the DataSource of the Defaults function must match in order to create a new record.

Even if you're not working with a data source, you can use **Patch** to merge two or more records. For example, this formula merges two records into one that identifies both the phone number and the location for Contoso:

```
Patch( { Name: "Contoso", Phone: "1-212-555-1234" }, { Name: "Contoso", Location: "Midtown" } )
```

Description

Modify or create a record in a data source

To use this function with a data source, specify the data source, and then specify a base record:

- To modify a record, the base record needs to have come from a data source. The base record might have come through a gallery's **Items** property, been placed in a context variable, or come through some other path. But, you can trace the base record back to the data source. This is important as the record includes additional information to help find the record again for modification.
- To create a record, use the **Defaults** function to create a base record with default values.

Then specify one or more change records, each of which contains new property values that override property values in the base record. Change records are processed in order from the beginning of the argument list to the end, with later property values overriding earlier ones.

The return value of **Patch** is the record that you modified or created. If you created a record, the return value might include properties that the data source generated automatically. However, the return value doesn't provide a value for fields of a related table.

For example, you use `Set(MyAccount, Patch(Accounts, First(Account), 'Account Name': "Example name"));` and then `MyAccount.'Primary Contact'.'Full Name'`. You can't yield a full name in this case. Instead, to access the fields of a related table, use a separate lookup such as:

Power Fx

```
LookUp(Accounts, Account = MyAccount.Account).'Primary Contact'.'Full Name'
```

When you update a data source, one or more issues might arise. Use **IfError** and **IsError** with the return value from **Patch** to detect and respond to errors, as Error Handling describes. You can also use the **Errors** function to identify and examine issues, as Working with Data Sources describes.

Related functions include the **Update** function to replace an entire record, and the **Collect** function to create a record. Use the **UpdateIf** function to modify specific properties of multiple records based on a condition.

Modify or create a set of records in a data source

Patch can also be used to create or modify multiple records with a single call.

Instead of passing a single base record, a table of base records can be provided in the second argument. Change records are provided in a table as well, corresponding one-for-one with the base records. The number of records in each change table must be the same as the number of records in the base table.

When using **Patch** in this manner, the return value is also a table with each record corresponding one-for-one with the base and change records.

Merge records outside of a data source

Specify two or more records that you want to merge. Records are processed in the order from the beginning of the argument list to the end, with later property values overriding earlier ones.

Patch returns the merged record and doesn't modify its arguments or records in any data sources.

Syntax

Modify or create a record in a data source

Patch(*DataSource*, *BaseRecord*, *ChangeRecord1* [, *ChangeRecord2*, ...])

- *DataSource* – Required. The data source that contains the record that you want to modify or will contain the record that you want to create.
- *BaseRecord* – Required. The record to modify or create. If the record came from a data source, the record is found and modified. If the result of **Defaults** is used, a record is created. The DataSource of the patch statement and the DataSource of the Defaults function must match in order to create a new record.
- *ChangeRecord(s)* – Required. One or more records that contain properties to modify in the *BaseRecord*. Change records are processed in order from the beginning of the argument list to the end, with later property values overriding earlier ones.

Modify or create a set of records in a data source

Patch(*DataSource*, *BaseRecordsTable*, *ChangeRecordTable1* [, *ChangeRecordTable2*, ...])

- *DataSource* – Required. The data source that contains the records that you want to modify or will contain the records that you want to create.
- *BaseRecordTable* – Required. A table of records to modify or create. If the record came from a data source, the record is found and modified. If the result of **Defaults** is used, a record is created. The DataSource of the patch statement and the DataSource of the Defaults function must match in order to create a new record.
- *ChangeRecordTable(s)* – Required. One or more tables of records that contain properties to modify for each record of the *BaseRecordTable*. Change records are processed in order from the beginning of the argument list to the end, with later property values overriding earlier ones.

Merge records

Patch(*Record1*, *Record2* [, ...])

- *Record(s)* - Required. At least two records that you want to merge. Records are processed in order from the beginning of the argument list to the end, with later property values overriding earlier ones.

Examples

Modify or create a record (in a data source)

In these examples, you'll modify or create a record in a data source, named **IceCream**, that contains the data in this table and automatically generates the values in the **ID** column:

ID (auto generated)	Flavor	Quantity
1	"Chocolate"	100
2	"Vanilla"	200

Expand table

Formula	Description	Result
Patch(IceCream, LookUp(IceCream, Flavor = "Chocolate"), { Quantity: 400 })	Modifies a record in the **IceCream** data source:	{ ID: 1, Flavor: "Chocolate", Quantity: 400 } The **Chocolate** entry in the

Formula	Description	Result
	• The **ID** column of the record to modify contains the value of **1**. (The **Chocolate** record has that ID.) • The value in the **Quantity** column changes to **400**.	**IceCream** data source has been modified.
Patch(IceCream, Defaults(IceCream), { Flavor: "Strawberry" })	Creates a record in the **IceCream** data source: • The **ID** column contains the value **3**, which the data source generates automatically. • The **Quantity** column contains **0**, which is the default value for that column in the **IceCream** data source, as the Defaults function specifies. • The **Flavor** column contains the value of **Strawberry**.	{ ID: 3, Flavor: "Strawberry", Quantity: 0 } The **Strawberry** entry in the **IceCream** data source has been created.

After the previous formulas have been evaluated, the data source ends with these values:

ID (auto generated)	Flavor	Quantity
1	"Chocolate"	400
2	"Vanilla"	200
3	"Strawberry"	0

Merge records (outside of a data source)

Expand table

Formula	Description	Result
Patch({ Name: "James", Score: 90 }, { Name: "Jim", Passed: true })	Merges two records outside of a data source: • The values in the **Name** column of each record don't match. The result contains the value (**Jim**) in the record that's closer to the end of the argument list instead of the value (**James**) in the record that's closer to the start.	{ Name: "Jim", Score: 90, Passed: true }

Formula	Description	Result
	• The first record contains a column (**Score**) that doesn't exist in the second record. The result contains that column with its value (**90**). • The second record contains a column (**Passed**) that doesn't exist in the first record. The result contains that column with its value (**true**).	

Use of As or ThisRecord

Using the **As** or **ThisRecord** keyword in the formula avoids ambiguous evaluation context.

In the example below, consider the first lookup in the `If` statement. `(OrderID = A[@OrderID])` is expected to compare the `OrderId` in the lookup scope with the `OrderId` of collection `A` in the `ForAll` scope. In this case, you likely want `A[@OrderId]` to be resolved as a local parameter. But it is ambiguous.

Power Apps currently interprets both the left-hand side `OrderId` and right-hand side `A[@OrderId]` as a field in the lookup scope. Therefore, lookup will always find the first row in `[dbo].[Orders1]` because the condition is always true (that is, any row's `OrderId` is equal to itself.)

Power Fx

```
ClearCollect(
    A,
    Filter(
        '[dbo].[Orders1]',
        OrderId = 8888888
    )
);
ForAll(
    A,
    If(
        LookUp(
            '[dbo].[Orders1]',
            OrderId = A[@OrderId],
            "OK"
        ) = "OK",
        Patch(
            '[dbo].[Orders1]',
            LookUp(
                '[dbo].[Orders1]',
                OrderId = A[@OrderId]
            ),
```

```
            {
      OrderName: "val1"
       }
   ),
   Patch(
            '[dbo].[Orders1]',
            Defaults('[dbo].[Orders1]'),
            {
      OrderName: "val2"
       }
   )
    )
)
```

Using As or ThisRecord

Whenever possible use the **As** operator or the **ThisRecord** to disambiguate the left-hand side. **As** is recommended for the above scenario.

When your formula uses multiple scopes with `ForAll`, `Filter`, and `Lookup` on the same data source or table, it is possible that the scope parameters may collide with a same field elsewhere. Therefore, it is recommended to use the **As** operator or **ThisRecord** to resolve the field name and avoid ambiguity.

For example, you can use the **As** operator to disambiguate in the example below.

Power Fx

```
ClearCollect(
    A,
    Filter(
        '[dbo].[Orders1]',
        OrderId = 8888888
    )
);
ForAll(
    A,
    If(
        LookUp(
            '[dbo].[Orders1]' As B,
            B.OrderId = A[@OrderId],
            "OK"
        ) = "OK",
        Patch(
            '[dbo].[Orders1]',
            LookUp(
                '[dbo].[Orders1]' As C,
                C.OrderId = A[@OrderId]
            ),
            {
```

```
      OrderName: "val1"
       }
   ),
   Patch(
            '[dbo].[Orders1]',
            Defaults('[dbo].[Orders1]'),
            {
      OrderName: "val2"
       }
   )
    )
)
```

Alternatively, you can use **ThisRecord** for the same purpose.

Power Fx

```
ClearCollect(
    A,
    Filter(
        '[dbo].[Orders1]',
        OrderId = 8888888
    )
);
ForAll(
    A,
    If(
        LookUp(
            '[dbo].[Orders1]',
            ThisRecord.OrderId = A[@OrderId],
            "OK"
        ) = "OK",
        Patch(
            '[dbo].[Orders1]',
            LookUp(
                '[dbo].[Orders1]',
                ThisRecord.OrderId = A[@OrderId]
            ),
            {
      OrderName: "val1"
       }
   ),
   Patch(
            '[dbo].[Orders1]',
            Defaults('[dbo].[Orders1]'),
            {
      OrderName: "val2"
       }
   )
    )
)
```

To learn more about the usage of **As** operator and **ThisRecord** see Operators article.

Acos, Acot, Asin, Atan, Atan2, Cos, Cot, Degrees, Pi, Radians, Sin, and Tan functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Calculates trigonometric values.

Description

Primary functions

The **Cos** function returns the cosine of its argument, an angle specified in radians.

The **Cot** function returns the cotangent of its argument, an angle specified in radians.

The **Sin** function returns the sine of its argument, an angle specified in radians.

The **Tan** function returns the tangent of its argument, an angle specified in radians.

Inverse functions

The **Acos** function returns the arccosine, or inverse cosine, of its argument. The arccosine is the angle whose cosine is the argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Acot** function returns the principal value of the arccotangent, or inverse cotangent, of its argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Asin** function returns the arcsine, or inverse sine, of its argument. The arcsine is the angle whose sine is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan** function returns the arctangent, or inverse tangent, of its argument. The arctangent is the angle whose tangent is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan2** function returns the arctangent, or inverse tangent, of the specified *x* and *y* coordinates as arguments. The arctangent is the angle from the *x*-axis to a line that contains the origin (0, 0) and a point with coordinates (*x*, *y*). The angle is given in radians between -π and π, excluding -π. A positive result represents a counterclockwise angle from the *x*-axis; a negative result represents a clockwise angle. **Atan2(*a*, *b*)** equals **Atan(*b*/*a*)**, except that ***a*** can equal 0 (zero) with the **Atan2** function.

Helper functions

The **Degrees** function converts radians to degrees. π radians equals 180 degrees.

The **Pi** function returns the transcendental number π, which begins 3.141592...

The **Radians** function converts degrees to radians.

Notes

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results with a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined value, the result is *blank*. This can happen, for example, when using inverse functions with arguments that are out of range.

Syntax

Primary Functions

Cos(*Radians*)
Cot(*Radians*)
Sin(*Radians*)
Tan(*Radians*)

- *Radians* - Required. Angle to operate on.

Cos(*SingleColumnTable*)
Cot(*SingleColumnTable*)
Sin(*SingleColumnTable*)
Tan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of angles to operate on.

Inverse Functions

Acos(*Number*)
Acot(*Number*)
Asin(*Number*)
Atan(*Number*)

- *Number* - Required. Number to operate on.

Acos(*SingleColumnTable*)
Acot(*SingleColumnTable*)
Asin(*SingleColumnTable*)
Atan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Atan2(*X*, *Y*)

- *X* - Required. *X*-axis coordinate.
- *Y* - Required. *Y*-axis coordinate.

Helper Functions

Degrees(*Radians*)

- *Radians* - Required. Angle in radians to convert to degrees.

Pi()

Radians(*Degrees*)

- *Degrees* - Required. Angle in degrees to convert to radians.

Examples

Single number

Expand table

Formula	Description	Result
Cos(1.047197)	Returns the cosine of 1.047197 radians or 60 degrees.	0.5
Cot(Pi()/4)	Returns the cotangent of 0.785398... radians or 45 degrees.	1
Sin(Pi()/2)	Returns the sine of 1.570796... radians or 90 degrees.	1
Tan(Radians(60))	Returns the tangent of 1.047197... radians or 60 degrees.	1.732050...
Acos(0.5)	Returns the arccosine of 0.5, in radians.	1.047197...
Acot(1)	Returns the arccotangent of 1, in radians.	0.785398...
Asin(1)	Returns the arcsine of 1, in radians.	1.570796...
Atan(1.732050)	Returns the arctangent of 1.732050, in radians.	1.047197...
Atan2(5, 3)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (5,3), which is approximately 31 degrees.	0.540419...
Atan2(4, 4)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (4,4), which is exactly π/4 radians or 45 degrees.	0.785398...
Degrees(1.047197)	Returns the equivalent number of degrees for 1.047197 radians.	60
Pi()	Returns the transcendental number π.	3.141592...
Radians(15)	Returns the equivalent number of radians for 15 degrees.	0.261799...

Single-column table

The examples in this section use a data source that's named **ValueTable** and that contains the following data. The last record in the table is π/2 radians or 90 degrees.

Expand table

Value
0.5
-2
1.570796...

Expand table

Formula	Description	Result
Cos(ValueTable)	Returns the cosine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.877582..., -0.416146..., 0
Cot(ValueTable)	Returns the cotangent of each number in the table.	A single-column table with a `Value` column containing the following values: 1.830487..., 0.457657..., 0
Sin(ValueTable)	Returns the sine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.479425, -0.909297..., 1
Tan(ValueTable)	Returns the tangent of each number in the table.	A single-column table with a `Value` column containing the following values: 0.546302..., 2.185039..., 3060023.306952...
Acos(ValueTable)	Returns the arccosine of each number in the table.	A single-column table with a `Value` column containing the following values: 1.047197..., Blank(), Blank()
Acot(ValueTable)	Returns the arccotangent of each number in the table.	A single-column table with a `Value` column containing the following values: 1.107138..., 2.677945..., 0.566911...
Asin(ValueTable)	Returns the arcsine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.523598..., Blank(), Blank()
Atan(ValueTable)	Returns the arctangent of each number in the table.	A single-column table with a `Value` column containing the following values: 0.463647..., -1.107148..., 1.00388...
Degrees(ValueTable)	Returns the equivalent number of degrees for each number in the table, assumed to be angles in radians.	A single-column table with a `Value` column containing the following values: 28.647889..., -114.591559..., 90
Radians(ValueTable)	Returns the equivalent number of radians for each number in the table, assumed to be angles in degrees.	A single-column table with a `Value` column containing the following values: 0.008726..., -0.034906..., 0.027415...

EncodeHTML, EncodeUrl, and PlainText functions

Article • 04/20/2025

Expand table

Functions	Applies to
EncodeHTML	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions
EncodeUrl **PlainText**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Encodes and decodes strings.

Description

The **EncodeUrl** function encodes a URL string, replacing certain non-alphanumeric characters with % and a hexadecimal number.

The **EncodeHTML** function encodes a string, replacing certain characters that need to be escaped to appear properly in an HTML context. For example, the characters <, >, and & are replaced by <, >, and &, respectively.

The **PlainText** function removes HTML and XML tags, converting certain tags such as these to an appropriate symbol:

- ** **
- **"**

The return value from these functions is the encoded or decoded string. This function doesn't remove all HTML and XML tags.

Syntax

EncodeUrl(*String*)

- *String* - Required. URL to be encoded.

EncodeHTML(*String*)

- *String* - Required. HTML to be encoded.

PlainText(*String*)

- *String* - Required. String from which HTML and XML tags are stripped.

Examples

If you show an RSS feed in a text gallery and then set the **Text** property of a label in that gallery to **ThisItem.description**, the label might show raw HTML or XML code as in this example:

HTML

```
<p>
  We have done an unusually &quot;deep&quot; globalization and
  localization.
</p>
```

If you set the **Text** property of the label to **PlainText(ThisItem.description)**, the text appears as in this example:

```
    We have done an unusually "deep" globalization and localization.
```

With the formula **EncodeHTML(ThisItem.description)**, the HTML tags are encoded so that they show up as text when interpreted as HTML, which can be useful to see the HTML structure:

```
&lt;p&gt;
  We have done an unusually&amp;nbsp;&amp;quot;deep&amp;quot; globalization and
  localization.
&lt;/p&gt;
```

If instead of a label you have an HTML text control in the gallery, and you set the **HtmlText** property of that control to **ThisItem.description** you also see the decoded text, because the HTML text control is interpreting the tags as HTML.

Abs, Exp, Ln, Power, Log, and Sqrt functions

Article • 04/20/2025

Expand table

Functions	Applies to
Abs **Exp** **Ln** **Power** **Sqrt**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Log	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Calculates absolute values, logarithms, square roots, and the results of raising *e* or any number to specified powers.

Description

The **Abs** function returns the non-negative value of its argument. If a number is negative, **Abs** returns the positive equivalent.

The **Exp** function returns *e* raised to the power of its argument. The transcendental number *e* begins 2.7182818...

The **Ln** function returns the natural logarithm (base *e*) of its argument.

The **Power** function returns a number raised to a power. It's equivalent to using the ^ operator.

The **Log** function returns the logarithm of its first argument in the base specified by its second argument (or 10 if not specified).

The **Sqrt** function returns the number that, when multiplied by itself, equals its argument.

If you pass a single number, the return value is a single result based on the function called. If you pass a single-column table that contains numbers, the return value is a single-column table of results in a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined valued, the result is *blank*. Which can happen with square roots and logarithms of negative numbers.

Syntax

Abs(*Number*)
Exp(*Number*)
Ln(*Number*)
Sqrt(*Number*)

- *Number* - Required. Number to operate on.

Power(*Base*, *Exponent*)

- *Base* - Required. Base number to raise.
- *Exponent* - Required. The exponent to which the base number is raised.

Log(*Number*, *Base*)

- *Number* - Required. Number to calculate the logarithm.
- *Base* - Optional. The base of the logarithm to calculate. By default, 10 (when not specified).

Abs(*SingleColumnTable*)
Exp(*SingleColumnTable*)
Ln(*SingleColumnTable*)
Sqrt(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Examples

Single number

Expand table

Formula	Description	Result
Abs(-55)	Returns the number without the negative sign.	55
Exp(2)	Returns *e* raised to the power of 2, or *e* * *e*.	7.389056...
Ln(100)	Returns the natural logarithm (base *e*) of the number 100.	4.605170...
Log(100)	Returns the logarithm in base 10 of the number 100.	2
Log(64, 2)	Returns the logarithm in base 2 of the number 64.	6

Formula	Description	Result
Power(5, 3)	Returns 5 raised to the power of 3, or 5 * 5 * 5.	125
Sqrt(9)	Returns the number that, when multiplied by itself, results in 9.	3

Single-column table

The examples in this section use a data source that's named **ValueTable** and that contains this data:

Expand table

Value
9
-4
2

Expand table

Formula	Description	Result
Abs(ValueTable)	Returns the absolute value of each number in the table.	A single-column table with a `Value` column containing the following values: 9, 4, 2
Exp(ValueTable)	Returns *e* raised to the power of each number in the table.	A single-column table with a `Value` column containing the following values: 8103.083927..., 0.018315..., 7.389056...
Ln(ValueTable)	Returns the natural logarithm of each number in the table.	A single-column table with a `Value` column containing the following values: 2.197224..., Blank(), 0.693147...
Sqrt(ValueTable)	Returns the square root of each number in the table	A single-column table with a `Value` column containing the following values: 3, Blank(), 1.414213...

Step-by-step example

1. Add a **Text input** control, and name it **Source**.
2. Add a **Label** control, and set its **Text** property to this formula:
   Sqrt(Value(Source.Text))

3. Type a number into **Source**, and confirm that the **Label** control shows the square root of the number that you typed.

Print function

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

Opens the current screen in the default browser print dialog.

Description

The print function allows you to select any screen and fit it to a page in order to send it to a printer for printing or allows you to save it as a PDF file.

The different configurations of the screen enable different printing outcomes. For fixed screens, they fit the size of the page, for use of the screen templates/special sized screens, we will fit the content to the size of the print.

> **Note**
>
> You can only print the screen you have added a button and defined **Print** function on `OnSelect` property of the button. For example, if you have added a button on `screen 2` and when you select the button, only the content in the `screen 2` gets printed.

Syntax

Print()

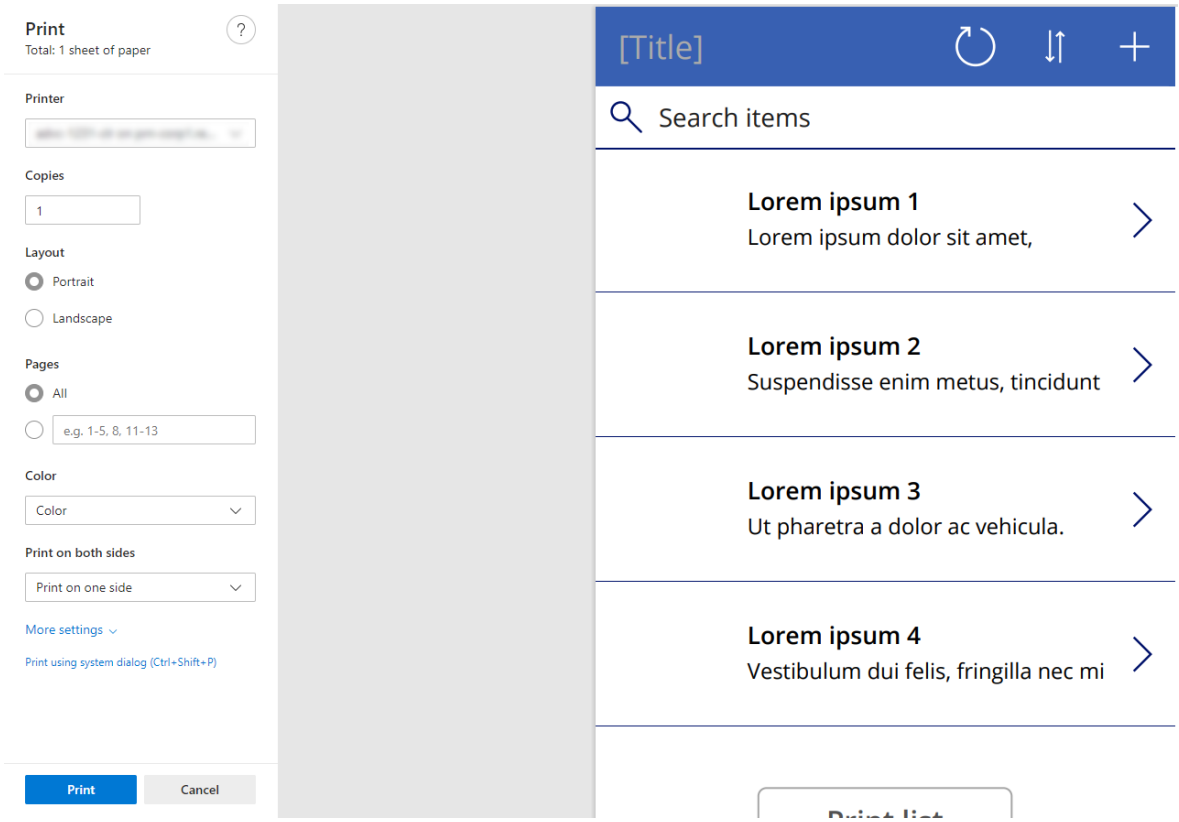
Examples

1. Go to Power Apps.
2. Select **Apps** from the left navigation pane.
3. Select your app or create an app from scratch.
4. Select **Insert** from the menu and then select **Button**.
5. From the property list on the top left, select **OnSelect**.
6. Enter the formula `Print()`.

7. Save and publish the app.

8. Play the app.

9. Select the button that you added. When you select the button, a default print browser pops up and allows you to choose from the available options to print or save it as a PDF file.



Hide controls while printing

To enable more customizable content, you can access the screen when the screen is printing to the change properties of the canvas app. For example, hiding buttons, or changing a form to view mode.

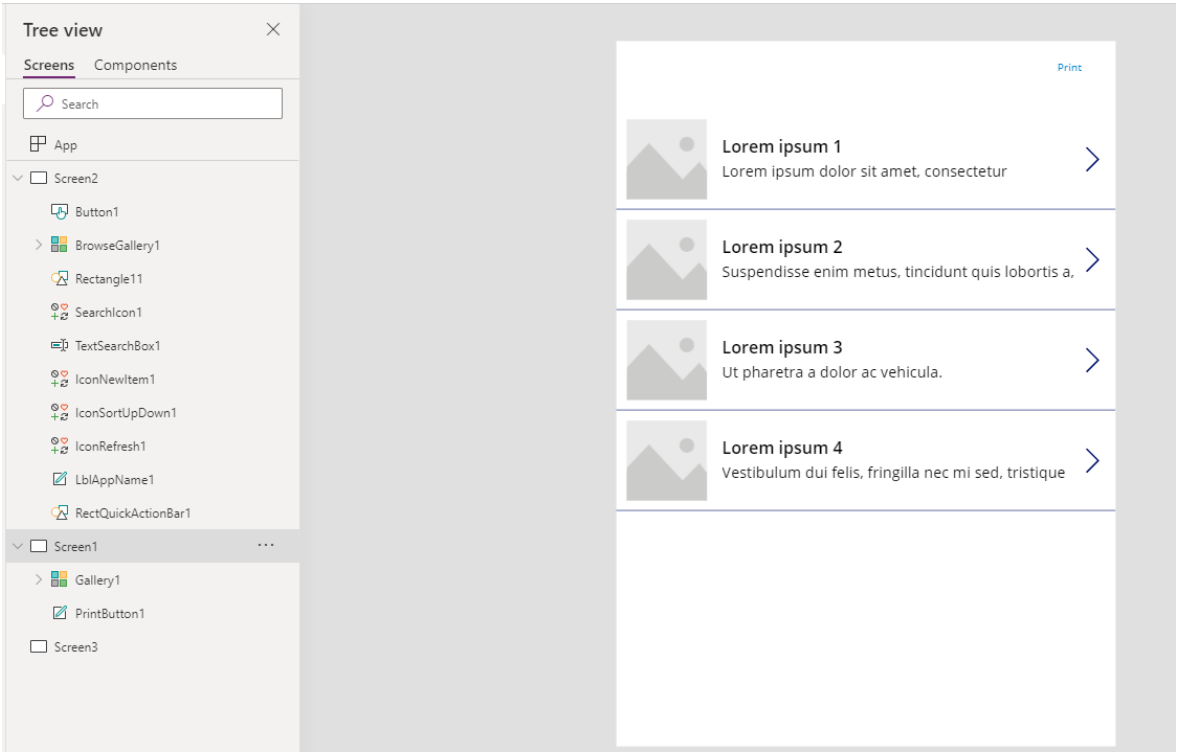
From the above example, where you insert a button on the screen and when you print the screen, you notice that the button is also gets printed. To remove the button from the screen while printing, on the button's **Visible** property add the formula `Not Screen1.Printing`. Preview the app and select the button. Observe that the button does not show in the content in the browser preview print dialog.

Use a screen template

An easy way to get started is to use a screen template to size your print to the letter size.

- Open or create a new canvas app.
- Select **New Screen** and select **Portrait print** option.

- Observe that the screen is sized differently from other screens with the print button on the top-right corner.



- Add content to this screen.
- Observe that the content is sized to the print. This enables more custom control over the experience.

Screen sizes for common prints

To build out a print for a specific size, you can build a responsive app, or create a special screen to manage your print.

Expand table

Print size	Screen height	Screen width
A4 portrait	1123	794
A4 landscape	794	1123
Letter portrait	1056	816
Letter landscape	816	1056

Known limitations

- The **Print** function currently doesn't work on mobile devices and on SharePoint forms.

- The **Print** function currently doesn't work on custom pages or embedded scenarios.
- The default browser printers are the ones that will be available to print to.
- In some browser print dialogs, a setting called **Background graphics** should be enabled to see all the images and colors in the print.
- The **Print** function can't print multiple pages.

Lower, Upper, and Proper functions

Article • 04/20/2025

Expand table

Functions	Applies to
Lower **Upper**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Proper	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Converts letters in a string of text to all lowercase, all uppercase, or proper case.

Description

The **Lower**, **Upper**, and **Proper** functions convert the case of letters in strings.

- **Lower** converts any uppercase letters to lowercase.
- **Upper** converts any lowercase letters to uppercase.
- **Proper** converts the first letter in each word to uppercase if it's lowercase and converts any other uppercase letters to lowercase.

All three functions ignore characters that aren't letters.

If you pass a single string, the return value is the converted version of that string. If you pass a single-column table that contains strings, the return value is a single-column table of converted strings. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

Syntax

Lower(*String*)
Upper(*String*)
Proper(*String*)

- *String* - Required. The string to convert.

Lower(*SingleColumnTable*)
Upper(*SingleColumnTable*)
Proper(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of strings to convert.

Examples

Single string

The examples in this section use a text-input control, named **Author**, as their data source. The control contains the string "E. E. CummINGS".

Expand table

Formula	Description	Result
Lower(Author.Text)	Converts any uppercase letters in the string to lowercase.	"e. e. cummings"
Upper(Author.Text)	Converts any lowercase letters in the string to uppercase.	"E. E. CUMMINGS"
Proper(Author.Text)	Converts the first letter of each word to uppercase if it's lowercase, and converts any other uppercase letters to lowercase.	"E. E. Cummings"

Single-column table

The examples in this section convert strings from the **Address** column of the **People** data source, which contains this data:

Expand table

Name	Address
"Jean"	"123 Main St NE"
"Fred"	"789 SW 39th #3B"

Each formula returns a single-column table that contains the converted strings.

Expand table

Formula	Description	Result
Lower(ShowColumns(People, "Address"))	Converts any letter that's lowercase to uppercase.	A single-column table with a `Value` column containing the

Formula	Description	Result
		following values: "123 main st ne", "789 sw 39th #3b"
Upper(ShowColumns(People, "Address"))	Converts any letter that's lowercase to uppercase.	A single-column table with a `Value` column containing the following values: "123 MAIN ST NE", "789 SW 39TH #3B"
Proper(ShowColumns(People, "Address"))	Converts any first letter of a word that's lowercase to uppercase, and converts any other letter that's uppercase to lowercase.	A single-column table with a `Value` column containing the following values: "123 Main St Ne", "789 Sw 39th #3b"

Step-by-step example

1. Add a **Text input** control, and name it **Source**.
2. Add a label, and set its **Text** property to this function:
   Proper(Source.Text)
3. Press F5, and then type **WE ARE THE BEST!** into the **Source** box.
   The label shows **We Are The Best!**

Acos, Acot, Asin, Atan, Atan2, Cos, Cot, Degrees, Pi, Radians, Sin, and Tan functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Calculates trigonometric values.

Description

Primary functions

The **Cos** function returns the cosine of its argument, an angle specified in radians.

The **Cot** function returns the cotangent of its argument, an angle specified in radians.

The **Sin** function returns the sine of its argument, an angle specified in radians.

The **Tan** function returns the tangent of its argument, an angle specified in radians.

Inverse functions

The **Acos** function returns the arccosine, or inverse cosine, of its argument. The arccosine is the angle whose cosine is the argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Acot** function returns the principal value of the arccotangent, or inverse cotangent, of its argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Asin** function returns the arcsine, or inverse sine, of its argument. The arcsine is the angle whose sine is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan** function returns the arctangent, or inverse tangent, of its argument. The arctangent is the angle whose tangent is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan2** function returns the arctangent, or inverse tangent, of the specified *x* and *y* coordinates as arguments. The arctangent is the angle from the *x*-axis to a line that contains the origin (0, 0) and a point with coordinates (*x*, *y*). The angle is given in radians between -π and π, excluding -π. A positive result represents a counterclockwise angle from the *x*-axis; a negative result represents a clockwise angle. **Atan2(*a*, *b*)** equals **Atan(*b*/*a*)**, except that ***a*** can equal 0 (zero) with the **Atan2** function.

Helper functions

The **Degrees** function converts radians to degrees. π radians equals 180 degrees.

The **Pi** function returns the transcendental number π, which begins 3.141592...

The **Radians** function converts degrees to radians.

Notes

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results with a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined value, the result is *blank*. This can happen, for example, when using inverse functions with arguments that are out of range.

Syntax

Primary Functions

Cos(*Radians*)
Cot(*Radians*)
Sin(*Radians*)
Tan(*Radians*)

- *Radians* - Required. Angle to operate on.

Cos(*SingleColumnTable*)
Cot(*SingleColumnTable*)
Sin(*SingleColumnTable*)
Tan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of angles to operate on.

Inverse Functions

Acos(*Number*)
Acot(*Number*)
Asin(*Number*)
Atan(*Number*)

- *Number* - Required. Number to operate on.

Acos(*SingleColumnTable*)
Acot(*SingleColumnTable*)
Asin(*SingleColumnTable*)
Atan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Atan2(*X*, *Y*)

- *X* - Required. *X*-axis coordinate.
- *Y* - Required. *Y*-axis coordinate.

Helper Functions

Degrees(*Radians*)

- *Radians* - Required. Angle in radians to convert to degrees.

Pi()

Radians(*Degrees*)

- *Degrees* - Required. Angle in degrees to convert to radians.

Examples

Single number

Expand table

Formula	Description	Result
Cos(1.047197)	Returns the cosine of 1.047197 radians or 60 degrees.	0.5
Cot(Pi()/4)	Returns the cotangent of 0.785398... radians or 45 degrees.	1
Sin(Pi()/2)	Returns the sine of 1.570796... radians or 90 degrees.	1
Tan(Radians(60))	Returns the tangent of 1.047197... radians or 60 degrees.	1.732050...
Acos(0.5)	Returns the arccosine of 0.5, in radians.	1.047197...
Acot(1)	Returns the arccotangent of 1, in radians.	0.785398...
Asin(1)	Returns the arcsine of 1, in radians.	1.570796...
Atan(1.732050)	Returns the arctangent of 1.732050, in radians.	1.047197...
Atan2(5, 3)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (5,3), which is approximately 31 degrees.	0.540419...
Atan2(4, 4)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (4,4), which is exactly π/4 radians or 45 degrees.	0.785398...
Degrees(1.047197)	Returns the equivalent number of degrees for 1.047197 radians.	60
Pi()	Returns the transcendental number π.	3.141592...
Radians(15)	Returns the equivalent number of radians for 15 degrees.	0.261799...

Single-column table

The examples in this section use a data source that's named **ValueTable** and that contains the following data. The last record in the table is π/2 radians or 90 degrees.

Expand table

Value
0.5
-2
1.570796...

Expand table

Formula	Description	Result
Cos(ValueTable)	Returns the cosine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.877582..., -0.416146..., 0
Cot(ValueTable)	Returns the cotangent of each number in the table.	A single-column table with a `Value` column containing the following values: 1.830487..., 0.457657..., 0
Sin(ValueTable)	Returns the sine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.479425, -0.909297..., 1
Tan(ValueTable)	Returns the tangent of each number in the table.	A single-column table with a `Value` column containing the following values: 0.546302..., 2.185039..., 3060023.306952...
Acos(ValueTable)	Returns the arccosine of each number in the table.	A single-column table with a `Value` column containing the following values: 1.047197..., Blank(), Blank()
Acot(ValueTable)	Returns the arccotangent of each number in the table.	A single-column table with a `Value` column containing the following values: 1.107138..., 2.677945..., 0.566911...
Asin(ValueTable)	Returns the arcsine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.523598..., Blank(), Blank()
Atan(ValueTable)	Returns the arctangent of each number in the table.	A single-column table with a `Value` column containing the following values: 0.463647..., -1.107148..., 1.00388...
Degrees(ValueTable)	Returns the equivalent number of degrees for each number in the table, assumed to be angles in radians.	A single-column table with a `Value` column containing the following values: 28.647889..., -114.591559..., 90
Radians(ValueTable)	Returns the equivalent number of radians for each number in the table, assumed to be angles in degrees.	A single-column table with a `Value` column containing the following values: 0.008726..., -0.034906..., 0.027415...

Rand and RandBetween functions

Article • 06/10/2024

Applies to: Canvas apps Desktop flows Model-driven apps Power Pages Power Platform CLI

Returns a pseudo-random number.

Description

The **Rand** function returns a pseudo-random number that's greater than or equal to 0 and less than 1. For example, **Rand()** might return **0.43147** and could return **0** but not **1**.

The **RandBetween** function returns a pseudo-random integer (whole number with no decimal portion) that is between two numbers, inclusive. For example, **RandBetween(1, 3)** may return **1**, **2**, or **3**.

Volatile Functions

Rand and **RandBetween** are volatile function. Each time the function is evaluated it returns a different value.

When used in a data flow formula, a volatile function will only return a different value if the formula in which it appears is reevaluated. If nothing else changes in the formula then it will have the same value throughout the execution of your app.

For example, a label control with **Label1.Text = Rand()** won't change while your app is active. Only closing and reopening the app will result in a new value.

The function will be reevaluated if it's part of a formula in which something else has changed. For example, if we change our example to involve a slider control with **Label1.Text = Slider1.Value + Rand()** then a new random number is generated each time the Slider control's value changes and the label's text property is reevaluated. See below for this example.

When used in a behavior formula, **Rand** and **RandBetween** will be evaluated each time the behavior formula is evaluated. See below for an example.

Syntax

Rand()

RandBetween(*Bottom*, *Top*)

- *Bottom* - Required. The smallest integer that the function can return.
- *Top* - Required. The largest integer that the function can return. Must be equal to or greater than *Bottom*.

Examples

Basic usage

Expand table

Formula	Description	Result
Rand()	Returns a pseudo-random number that's greater than or equal to 0 and less than 1.	Varies with each evaluation, for example **0.874252**.
Rand() * 100	Building on the previous example, uses multiplication to extend the range to greater than or equal to 0 and less than 100.	Varies with each evaluation, for example **78.42521**.
Int(Rand() * 100)	Building on the previous example, uses the **Int** function to remove the decimal portion, resulting in an integer greater than or equal to 0 and less than 100	Varies with each evaluation, for example **84**.
RandBetween(0, 99)	Building on the previous example, performs the same operation using the **RandBetween** function	Varies with each evaluation, for example **21**.
RandBetween(-1, 1)	Returns a pseudo-random number that is between -1 and 1 inclusive: **-1**, **0**, or **1**.	Varies with each evaluation, for example **-1**.

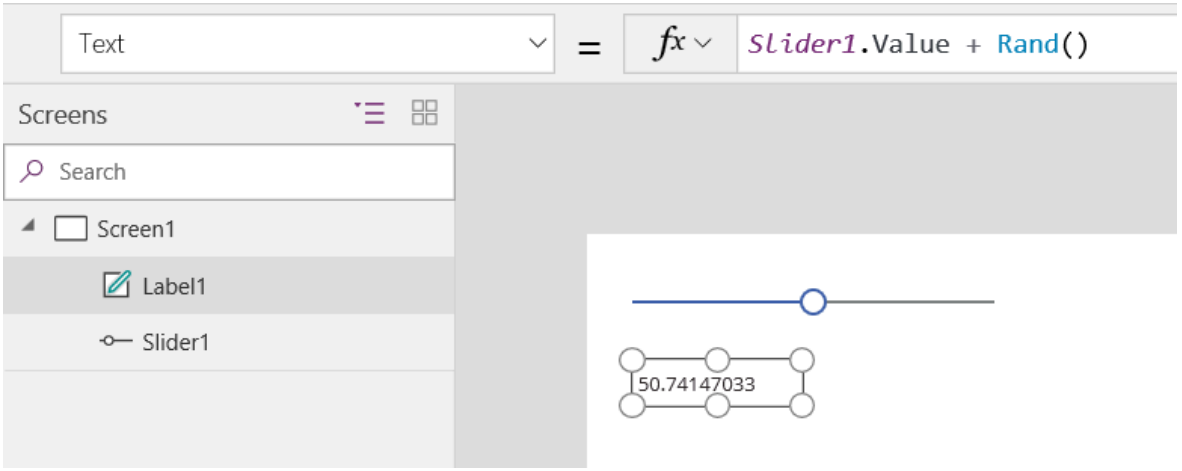
Display a different random number as user input changes with Rand

1. Add a Slider control, and rename it **Slider1** if it has a different name.

2. Add a Label control, and set its **Text** property to this formula:

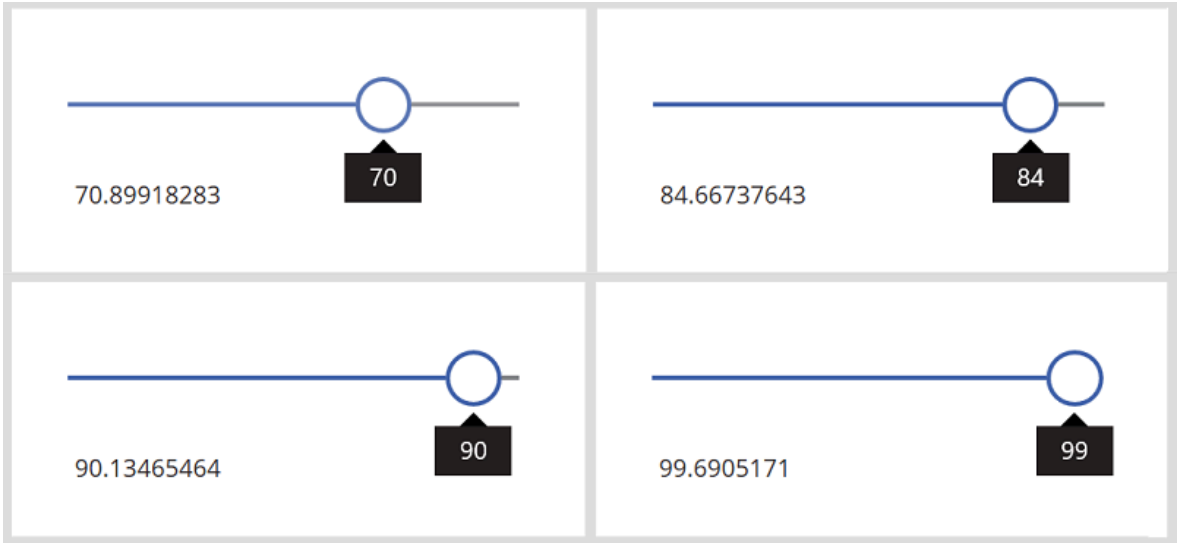
   Slider1.Value + Rand()

   The label shows **50** (the default value for the slider) plus a random decimal:



3. While holding down the Alt key, change the value of the slider.

   Every time you change the value of the slider, the decimal portion of the label shows a different random number:



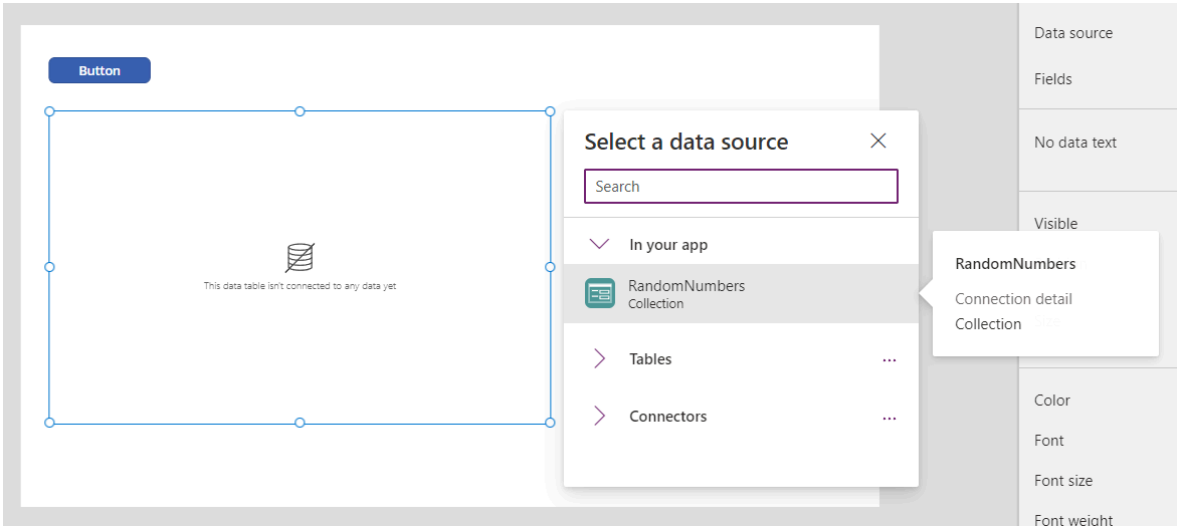
Create a table of random numbers with RandBetween

1. Add a **Button** control, and set its **OnSelect** property to this formula:

   ClearCollect(RandomNumbers, ForAll(Sequence(100), RandBetween(1, 20)))

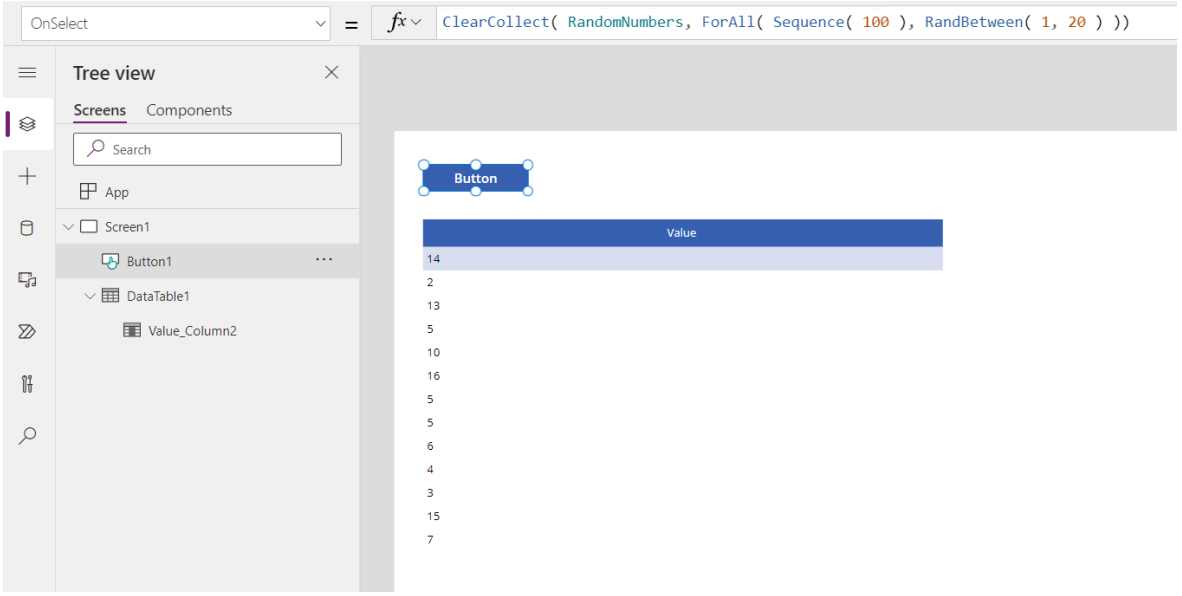
   This formula creates a single-column table that's used to iterate 100 times, resulting in 100 random numbers.

2. Add a **Data table**, set its **Items** property to **RandomNumbers**, and show the **Value** field.

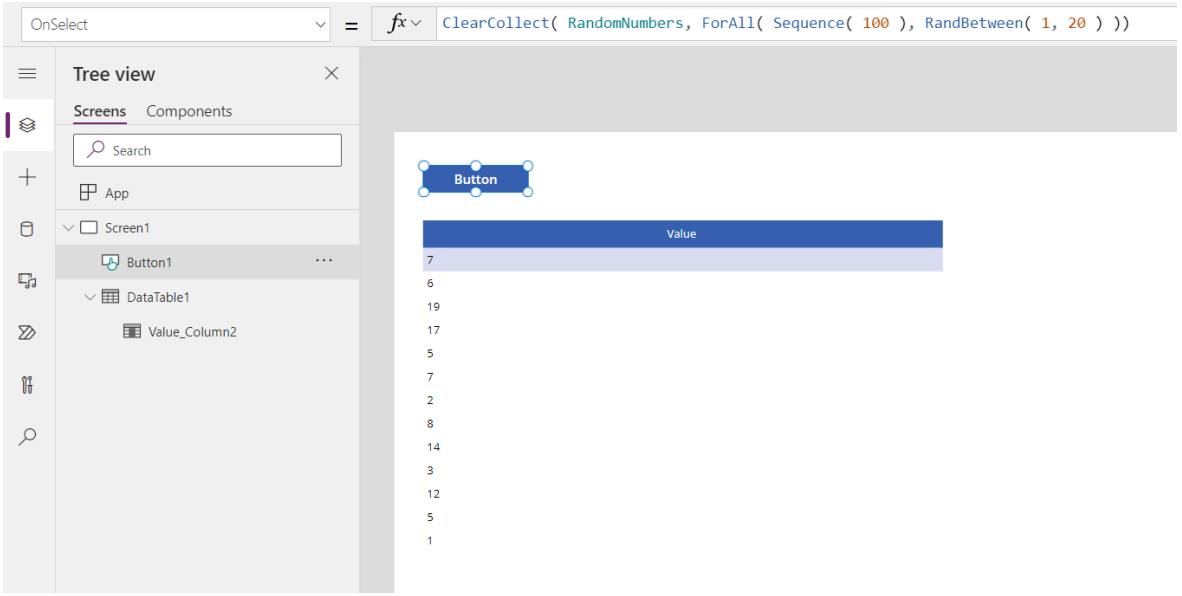


3. While holding down the **Alt** key, select the button by clicking or tapping it.

   The data table shows 100 hundred random numbers between 1 and 20:



4. Select the button again to show a different list of random numbers:



To generate a single random number instead of a table, use **Set(RandomNumber, Rand())** or **Set(RandNumber, RandBetween(1, 20))**.

Rand and RandBetween functions

Article • 06/10/2024

Applies to: Canvas apps Desktop flows Model-driven apps Power Pages Power Platform CLI

Returns a pseudo-random number.

Description

The **Rand** function returns a pseudo-random number that's greater than or equal to 0 and less than 1. For example, **Rand()** might return **0.43147** and could return **0** but not **1**.

The **RandBetween** function returns a pseudo-random integer (whole number with no decimal portion) that is between two numbers, inclusive. For example, **RandBetween(1, 3)** may return **1**, **2**, or **3**.

Volatile Functions

Rand and **RandBetween** are volatile function. Each time the function is evaluated it returns a different value.

When used in a data flow formula, a volatile function will only return a different value if the formula in which it appears is reevaluated. If nothing else changes in the formula then it will have the same value throughout the execution of your app.

For example, a label control with **Label1.Text = Rand()** won't change while your app is active. Only closing and reopening the app will result in a new value.

The function will be reevaluated if it's part of a formula in which something else has changed. For example, if we change our example to involve a slider control with **Label1.Text = Slider1.Value + Rand()** then a new random number is generated each time the Slider control's value changes and the label's text property is reevaluated. See below for this example.

When used in a behavior formula, **Rand** and **RandBetween** will be evaluated each time the behavior formula is evaluated. See below for an example.

Syntax

Rand()

RandBetween(*Bottom*, *Top*)

- *Bottom* - Required. The smallest integer that the function can return.
- *Top* - Required. The largest integer that the function can return. Must be equal to or greater than *Bottom*.

Examples

Basic usage

Expand table

Formula	Description	Result
Rand()	Returns a pseudo-random number that's greater than or equal to 0 and less than 1.	Varies with each evaluation, for example **0.874252**.
Rand() * 100	Building on the previous example, uses multiplication to extend the range to greater than or equal to 0 and less than 100.	Varies with each evaluation, for example **78.42521**.
Int(Rand() * 100)	Building on the previous example, uses the **Int** function to remove the decimal portion, resulting in an integer greater than or equal to 0 and less than 100	Varies with each evaluation, for example **84**.
RandBetween(0, 99)	Building on the previous example, performs the same operation using the **RandBetween** function	Varies with each evaluation, for example **21**.
RandBetween(-1, 1)	Returns a pseudo-random number that is between -1 and 1 inclusive: **-1**, **0**, or **1**.	Varies with each evaluation, for example **-1**.

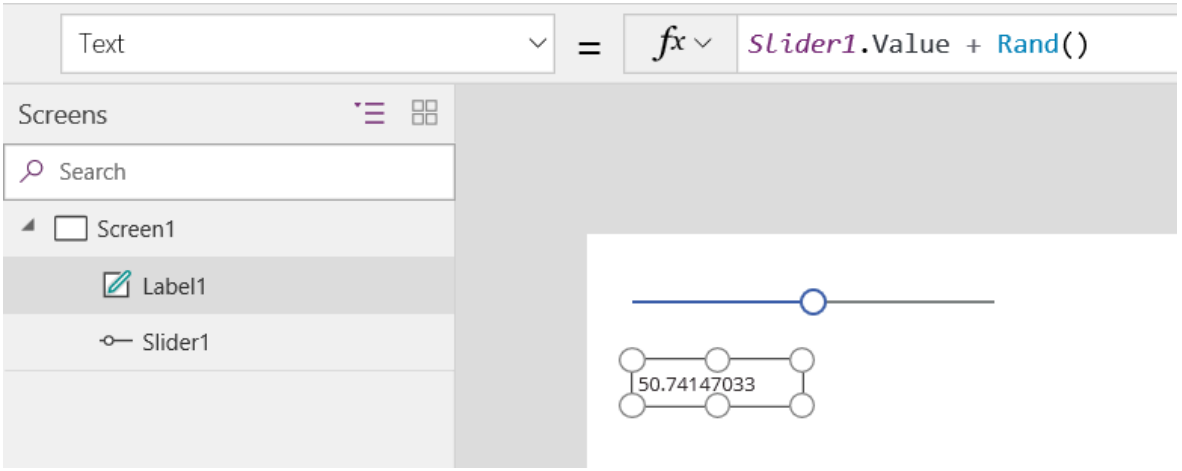
Display a different random number as user input changes with Rand

1. Add a Slider control, and rename it **Slider1** if it has a different name.

2. Add a Label control, and set its **Text** property to this formula:

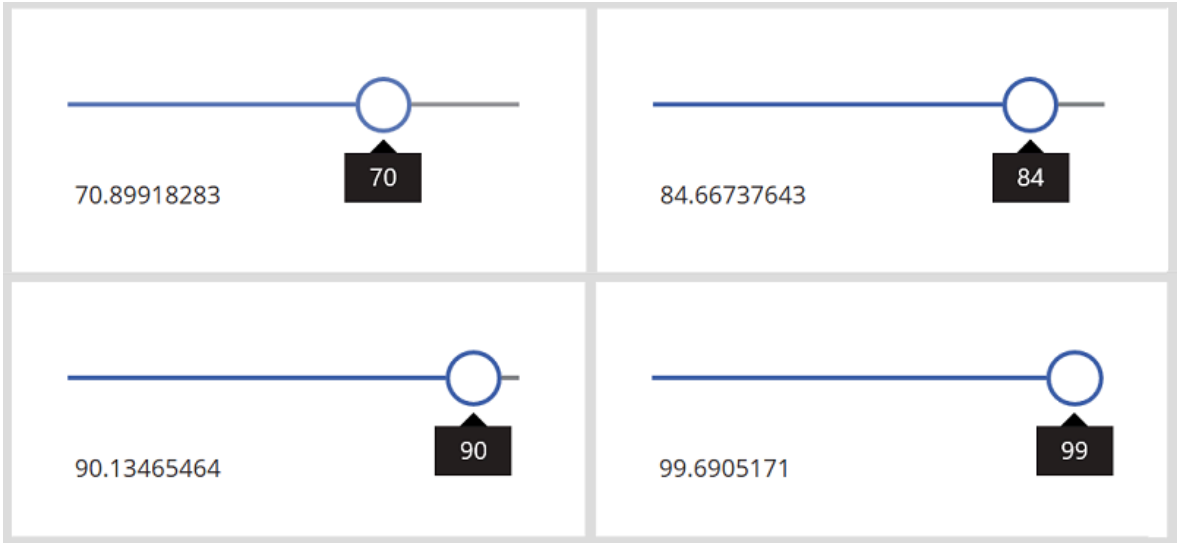
   Slider1.Value + Rand()

   The label shows **50** (the default value for the slider) plus a random decimal:



3. While holding down the Alt key, change the value of the slider.

   Every time you change the value of the slider, the decimal portion of the label shows a different random number:



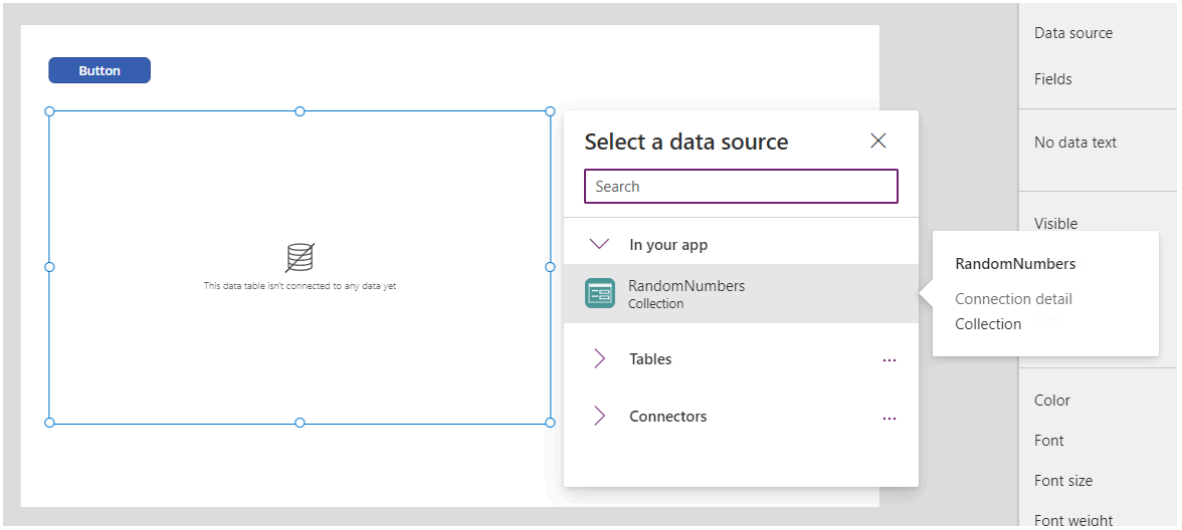
Create a table of random numbers with RandBetween

1. Add a **Button** control, and set its **OnSelect** property to this formula:

   ClearCollect(RandomNumbers, ForAll(Sequence(100), RandBetween(1, 20)))

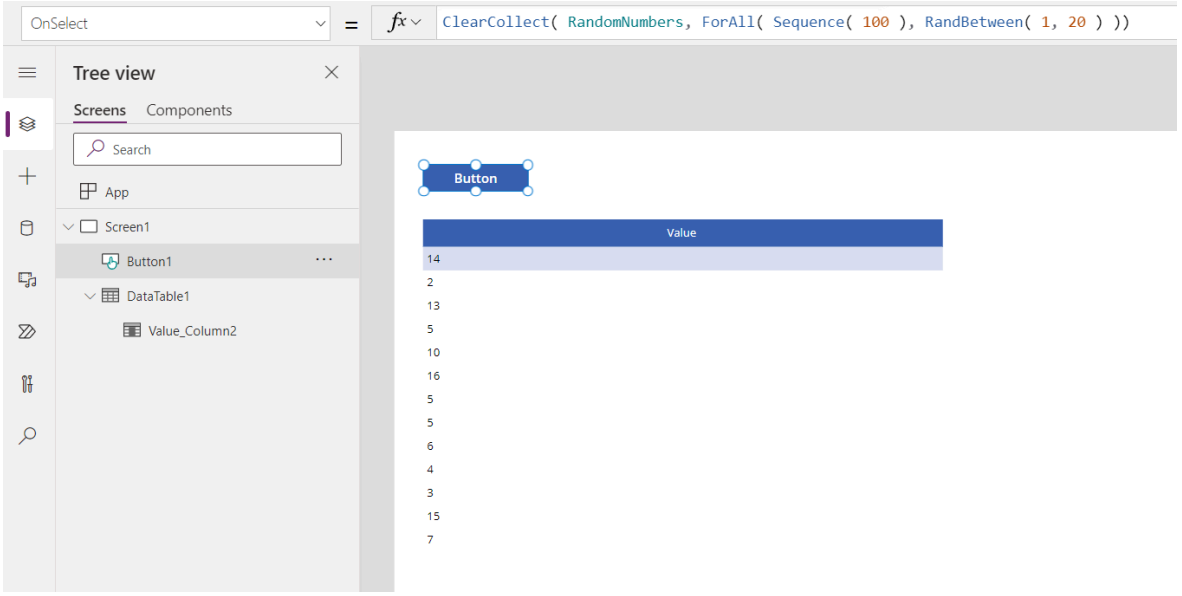
   This formula creates a single-column table that's used to iterate 100 times, resulting in 100 random numbers.

2. Add a **Data table**, set its **Items** property to **RandomNumbers**, and show the **Value** field.

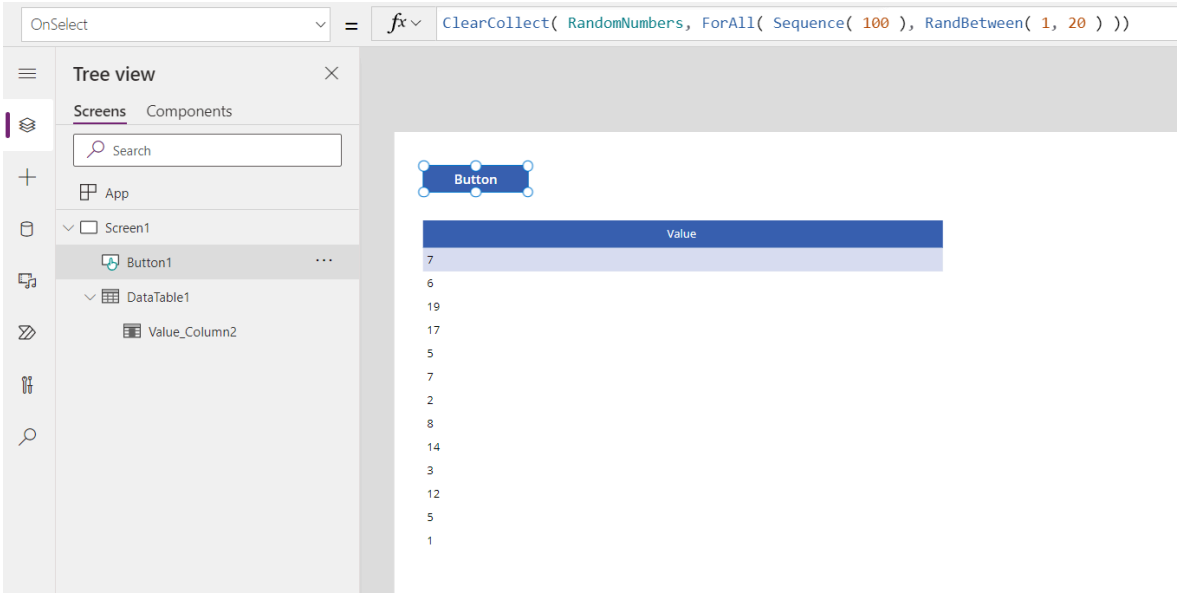


3. While holding down the **Alt** key, select the button by clicking or tapping it.

   The data table shows 100 hundred random numbers between 1 and 20:



4. Select the button again to show a different list of random numbers:



To generate a single random number instead of a table, use **Set(RandomNumber, Rand())** or **Set(RandNumber, RandBetween(1, 20))**.

ReadNFC function

Article • 03/22/2024

Applies to: Canvas apps

Reads a Near Field Communication (NFC) tag.

Description

Use the **ReadNFC** function to read an NFC tag that is close to your device. When invoked, the screen displays instructions for scanning an NFC tag, and only returns after the tag has been scanned or it times out.

Expand table

Column	Type	Description
Identifier	Text	The NFC tags identifier if available.
NDEFRecords	Table	The supported NDEF records found on the tag.

A single **NDEFRecord** contains the following columns:

Expand table

Column	Type	Description
RTD	Text	The tag's Record Type Definition (RTD). Only *Text* and *URI* are supported at this time.
TNF	Number	The tag's Type Name Format (TNF). Only TNFs of *Well Known(1)* are supported at this time.
Text	Text	The text payload of the NFC tag if RTD is *TEXT*, *blank* otherwise.
URI	Hyperlink	The URI payload of the NFC tag if RTD is *URI*, *blank* otherwise.

If the NDEF record isn't supported (for example, the TNF isn't of type *Well Known*), then it won't be returned as part of the **NDEFRecords** table.

Always check the payload values for *blank* using the **IsBlank** function before using it. You don't need to check the **RTD** and **TNF** values yourself as they must be the correct values for **Text** and **URI** to have a non-*blank* value.

Additional **RTD** and **TNF** values may be supported in the future. If more values are supported, additional payload columns will also be added. The raw **RTD** and **TNF** values are provided for informational purposes and don't need to be consulted if the payload column is checked for *blank*. More information about these values and their use is available through the NFC Forum.

ReadNFC doesn't require a tag containing NDEF records to be used, but you may still get the tag identifier if one is available.

ReadNFC can only be used in behavior formulas.

> **Note**
>
> - **ReadNFC** is only supported when running the app on a native mobile app, such as the iOS and Android apps. Even with a supported player, a device may not support NFC. If your application has **Formula-level error management** turned on, the function will return an error. Otherwise, an error message will be shown to the user and the function will return a *blank* record.
> - Ensure your device has the NFC setting enabled to use this capability.

Syntax

ReadNFC()

Examples

Expand table

Formula	Description	Result
`ReadNFC().Identifier`	Returns the identifier of the NFC tag if one exists.	`04A1C301314003`
`ReadNFC().NDEFRecords`	Returns a table of NDEF records found on the NFC tag if they're a supported type and payload.	<table><tr><th>RTD</th><th>TNF</th><th>Text</th><th>URI</th></tr><tr><td>T</td><td>1</td><td>Blue</td><td></td></tr><tr><td>U</td><td>1</td><td></td><td>microsoft.com</td></tr></table>

Step-by-step example

1. Create a blank canvas app with **Phone** format.

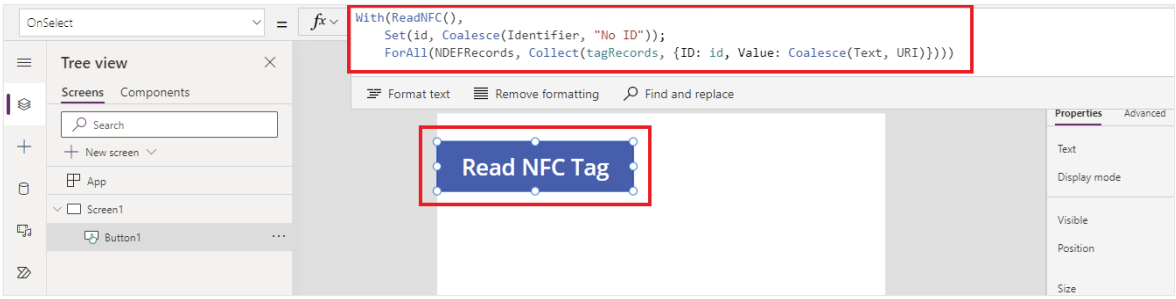
2. Add a **Button** control.

3. Double-click the button control to change the button text to **Read NFC Tag** (or modify the **Text** property).

4. Set the **OnSelect** property of the button control to this formula that will add an item to our collection:

```
Power Apps

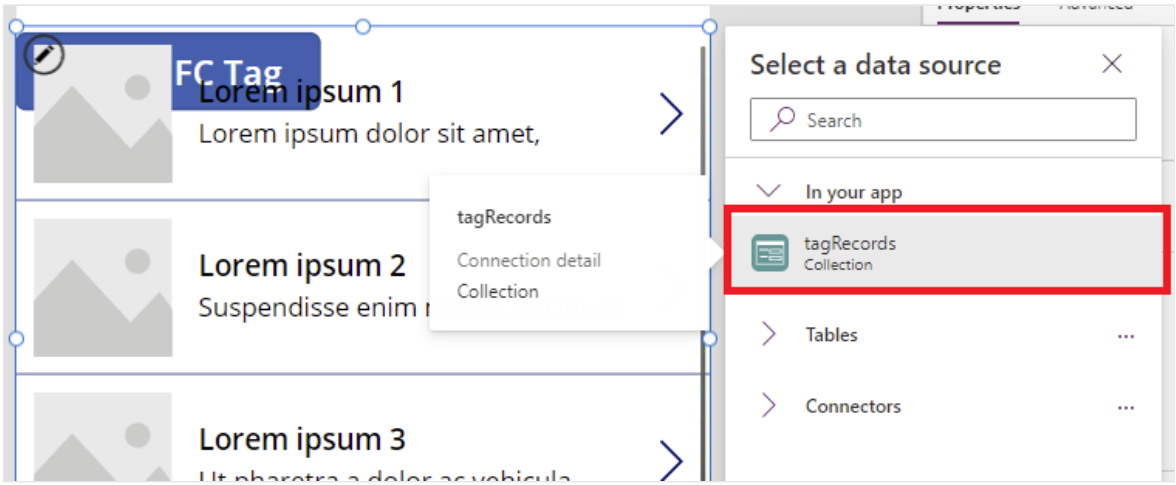
With(ReadNFC(),
    Set(id, Coalesce(Identifier, "No ID"));
    ForAll(NDEFRecords, Collect(tagRecords, {ID: id, Value:
Coalesce(Text, URI)})))
```



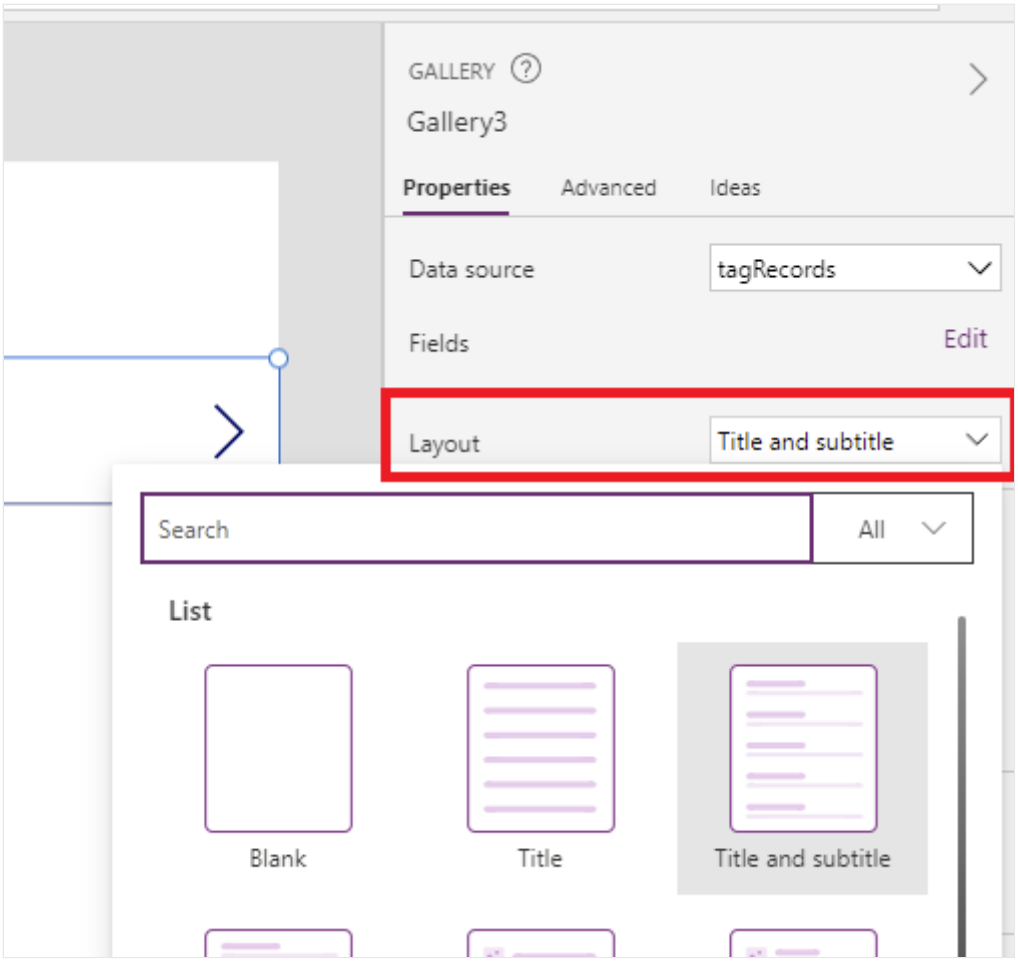
This formula reads an NFC tag using the `ReadNFC()` function, and displays type information about the result. Then it collects the read NFC tags to populate the `tagRecords` collection to be used for the gallery in the next steps.

5. Add a **Gallery** control with a vertical layout.

6. When prompted, select the **tagRecords** collection as the data source for this gallery. This action will set the **Items** property of the **Gallery** control.



7. Reposition the gallery control so that it doesn't overlap the button, and change the layout type to **Title and subtitle**.



8. Change the **Title** formula in the gallery control to **ThisItem.Value** and change the **Subtitle** formula in the gallery control to **ThisItem.ID**.

   You can also delete the **NextArrow** from the gallery control since it's not used.

9. Save and publish the app.

10. Since the function `ReadNFC()` can't be used in Power Apps Studio or in a web browser, open your app on a mobile device.

    > **Tip**
    >
    > The app might take a few moments to appear on your mobile device. If you don't see the app listed, try refreshing your app list.

11. Select **Read NFC Tag** and scan a tag. Repeat the process to add multiple tags to your collection.

RecordInfo function

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

Provides information about a record of a data source.

Use **RecordInfo** to obtain information about a particular record of a data source. The data source must be tabular and compatible with the **Remove** and **Patch** functions.

At this time, only Microsoft Dataverse is supported. Records from all other data sources will result in a formula error.

The information available:

Expand table

Information argument	Description
RecordInfo.DeletePermission	Does the current user have permission to remove this record from the data source?
RecordInfo.EditPermission	Does the current user have permission to modify this record in the data source?
RecordInfo.ReadPermission	Does the current user have permission to read this record from the data source?

RecordInfo returns a Boolean value:

Expand table

Return value	Description
true	The user has the permission.
false	The user does not have permission. If the record is *blank* then **RecordInfo** will also return *false*.

RecordInfo takes into account permissions at the data source level too. For example, if the user has permission at the record level to modify a record, but the user does not have permissions at the table level, then it will return *false* for **ModifyPermission**. Use the **DataSourceInfo** function to obtain information about the data source as a whole.

Syntax

RecordInfo(*Record*, *Information*)

- *Record* – Required. The record to test.
- *Information* – Required. The desired information for the record.

Examples

Power Apps

```
RecordInfo( First(Accounts), RecordInfo.EditPermission )
```

Checks the edit permission for the first record in the `Accounts` data source, which could be in Dataverse, SharePoint, SQL Server, or another tabular data source. If the user has permission to edit this record and modify the `Accounts` data source in general, then **RecordInfo** will return *true*.

Power Apps

```
With( { MyRecord: First( Accounts ) },
      RecordInfo( MyRecord, RecordInfo.EditPermission ) )
```

Captures a record using the **With** function and then passes this value to the `RecordInfo` function. The result will be the same as the last example.

Power Apps

```
Collect( MyAccounts, FirstN( Accounts, 10 ) );
RecordInfo( First( MyAccounts ), RecordInfo.EditPermission ) )
```

Captures the first 10 records from the `Accounts` data source into the `MyAccounts` collection. Since the records originated from a data source, they can be used with the **RecordInfo** function. The result will be the same as the last example.

Power Apps

```
Collect( MyCollection, [ 1, 2, 3 ] );
RecordInfo( First(MyCollection), RecordInfo.DeletePermission )
```

Creates the `MyCollection` collection and tests the first record to determine if it can be removed. Since the record's origin is a collection and not a data source, **RecordInfo** will

return an error.

Refresh function

Article • 04/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions

Refreshes the records of a data source.

Description

The **Refresh** function retrieves a fresh copy of a data source. You'll see changes that other users made.

Refresh has no return value, and you can use it only in behavior formulas.

Syntax

Refresh(*DataSource*)

- *DataSource* – Required. The data source that you want to refresh.

Example

In this example, you'll refresh the data source named **IceCream**, which starts with this data:

ID	Flavor	Quantity
1	"Chocolate"	100
2	"Vanilla"	200
3	"Strawberry"	300

A user on another device changes the **Quantity** in the **Strawberry** record to **400**. You won't see this change until this formula executes:

Refresh(IceCream)

After that formula executes, galleries that are bound to the **IceCream** data source will show the updated value for **Strawberry**:

ID	Flavor	Quantity
1	"Chocolate"	100
2	"Vanilla"	200
3	"Strawberry"	400

Relate and Unrelate functions

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

Relate and unrelate records of two tables through a one-to-many or many-to-many relationship.

Description

The **Relate** function links two records through a one-to-many or many-to-many relationship in Microsoft Dataverse. The **Unrelate** function reverses the process and removes the link.

For one-to-many relationships, the Many table has a foreign-key field that points to a record of the One table. **Relate** sets this field to point to a specific record of the One table, while **Unrelate** sets this field to *blank*. If the field is already set when **Relate** is called, the existing link is lost in favor of the new link. You can also set this field by using the **Patch** function or an **Edit form** control; you need not use the **Relate** function.

For many-to-many relationships, the system that links the records maintains a hidden join table. You can't access this join table directly; it can be read only through a one-to-many projection and set through the **Relate** and **Unrelate** functions. Neither related table has a foreign key.

The data for the table that you specify in the first argument will be refreshed to reflect the change, but the data for the table that you specify in the second argument won't. That data must be manually refreshed with the **Refresh** function to show the result of the operation.

These functions never create or delete a record. They only relate or unrelate two records that already exist.

You can use these functions only in behavior formulas.

> **Note**
>
> These functions are part of a preview feature, and their behavior is available only when the **Relational data, option sets, and other new features for CDS** feature is enabled. This is an app-level setting that's enabled by default for new apps. To find this feature switch, select **Settings**, and then select **Upcoming features**. Your

feedback is very valuable to us - please let us know what you think in the Power Apps community forums.

Syntax

Relate(*Table1RelatedTable*, *Table2Record*)

- *Table1RelatedTable* - Required. For a record of *Table1*, the table of *Table2* records related through a one-to-many or many-to-many relationship.
- *Table2Record* - Required. The *Table2* record to add to the relationship.

Unrelate(*Table1RelatedTable*, *Table2Record*)

- *Table1RelatedTable* - Required. For a record of *Table1*, the table of *Table2* records related through a one-to-many or many-to-many relationship.
- *Table2Record* - Required. The *Table2* record to remove from the relationship.

Examples

Consider a **Products** table with the following relationships as seen in the Power Apps portal's table viewer:

Expand table

Relationship display name	Related table	Relationship type
Product Reservation	Reservation	One-to-many
Product ↔ Contact	Contact	Many-to-many

Products and **Reservations** are related through a One-to-Many relationship. To relate the first record of the **Reservations** table with the first record of the **Products** table:

```
Relate( First( Products ).Reservations, First( Reservations ) )
```

To remove the relationship between these records:

```
Unrelate( First( Products ).Reservations, First( Reservations ) )
```

At no time did we create or remove or a record, only the relationship between records was modified.

Products and **Contacts** are related through a Many-to-Many relationship. To relate the first record of the **Contacts** table with the first record of the **Products** table:

```
Relate( First( Products ).Contacts, First( Contacts ) )
```

As Many-to-Many relationships are symmetric, we could also have done this in the opposite direction:

```
Relate( First( Contacts ).Products, First( Products ) )
```

To remove the relationship between these records:

```
Unrelate( First( Products ).Contacts, First( Contacts ) )
```

or:

```
Unrelate( First( Contacts ).Products, First( Products ) )
```

The walk through that follows does exactly these operations on these tables using an app with **Gallery** and **Combo box** controls for selecting the records involved.

These examples depend on the sample data being installed in your environment. Either create a trial environment including sample data or add sample data to an existing environment.

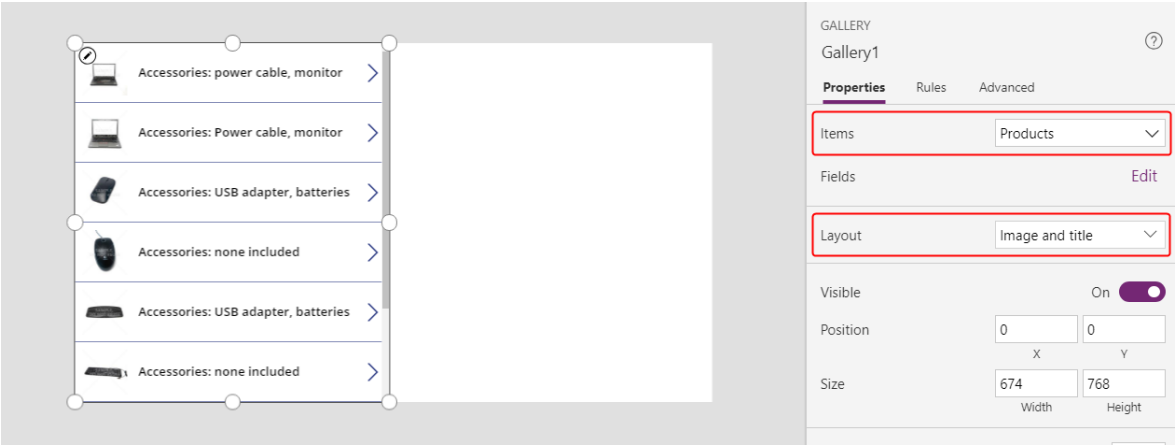
One-to-many

Relate function

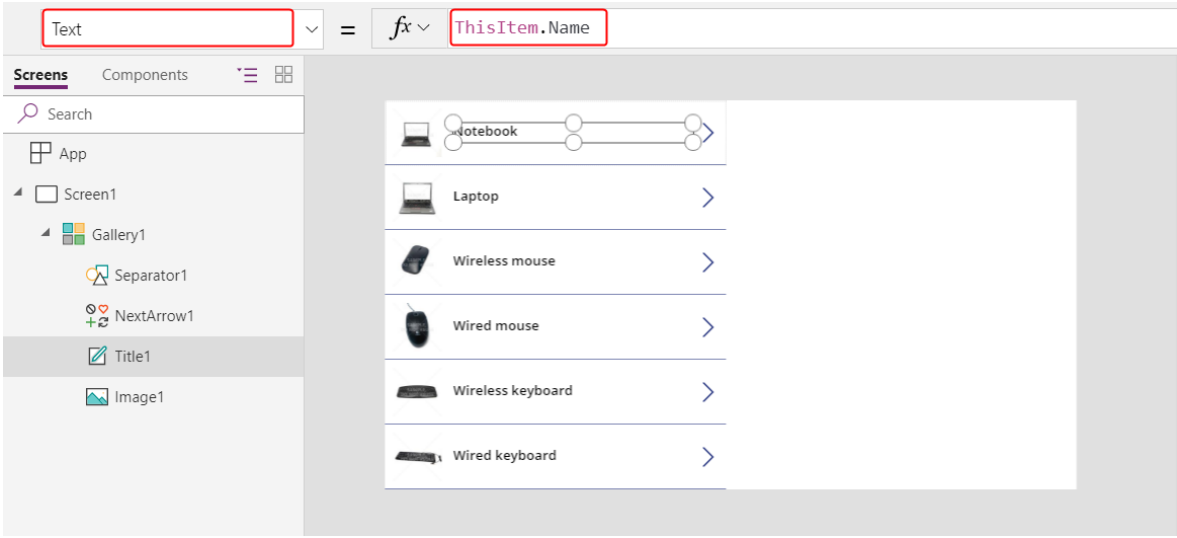
You'll first create a simple app to view and reassign the reservations that are associated with a product.

1. Create a tablet app from blank.
2. On the **View** tab, select **Data sources**.
3. In the **Data** pane, select **Add data** > select **Products**.
   The Products table is part of the sample data loaded above.
4. On the **Insert** tab, add a blank vertical **Gallery** control.
5. Ensure that the control that you just added is named **Gallery1**, and then move and resize it to fill the left-hand side of the screen.

6. On the **Properties** tab, set **Gallery1**'s **Items** property to **Products** and its **Layout** to **Image and title**.



7. In **Gallery1**, ensure that the **Label** control is named **Title1**, and then set its **Text** property to **ThisItem.Name**.



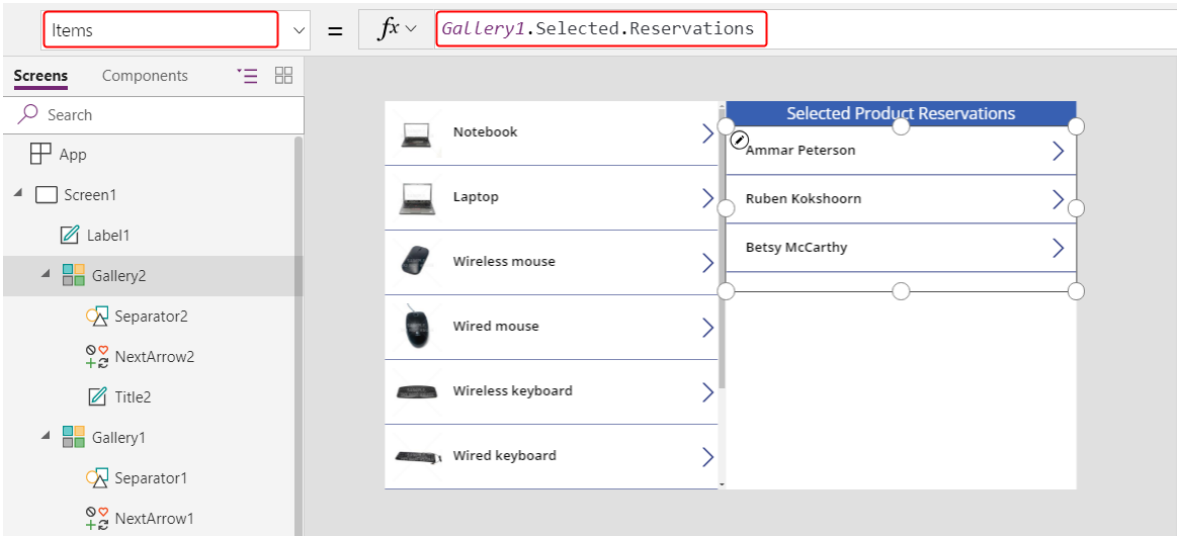
8. Select the screen to avoid inserting the next item into **Gallery1**. Add a second blank vertical **Gallery** control, and ensure that it's named **Gallery2**.

   Gallery2 will show the reservations for whatever product the user selects in **Gallery1**.

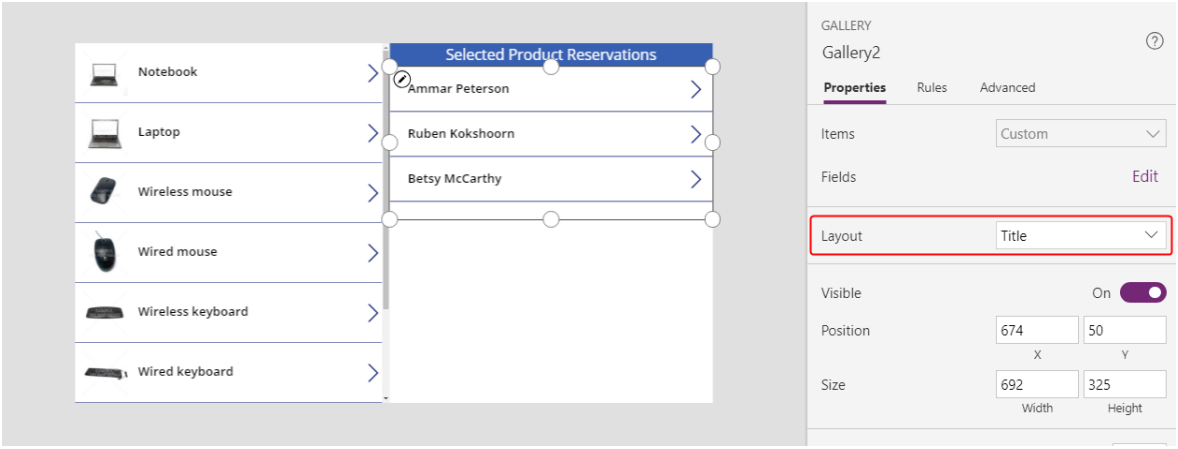
9. Move and resize **Gallery2** to fill the upper-right quadrant of the screen.

10. (optional) Add the blue **Label** control above **Gallery2**, as the next graphic shows.

11. In the formula bar, set the **Items** property of **Gallery2** to **Gallery1.Selected.Reservations**.



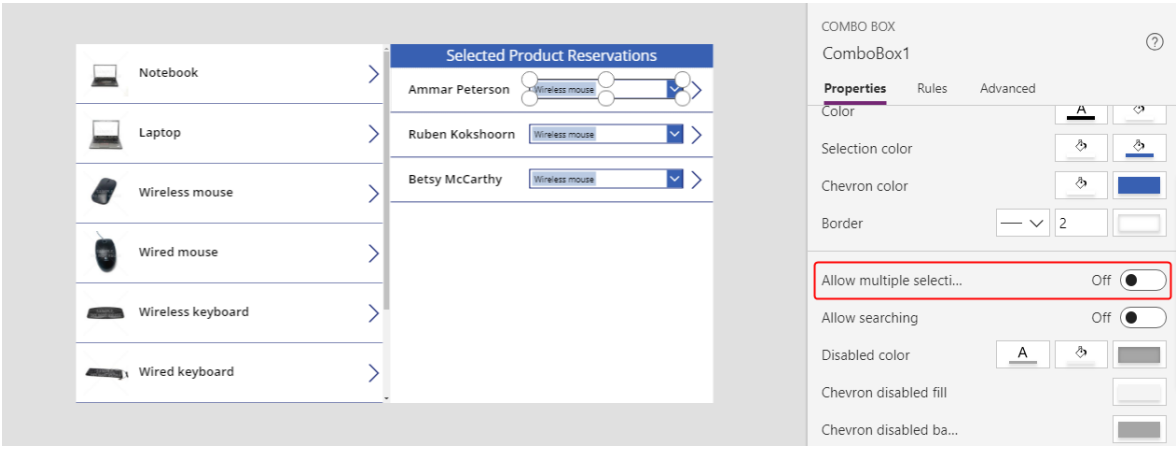
12. In the properties pane, set **Gallery2**'s **Layout** to **Title**.



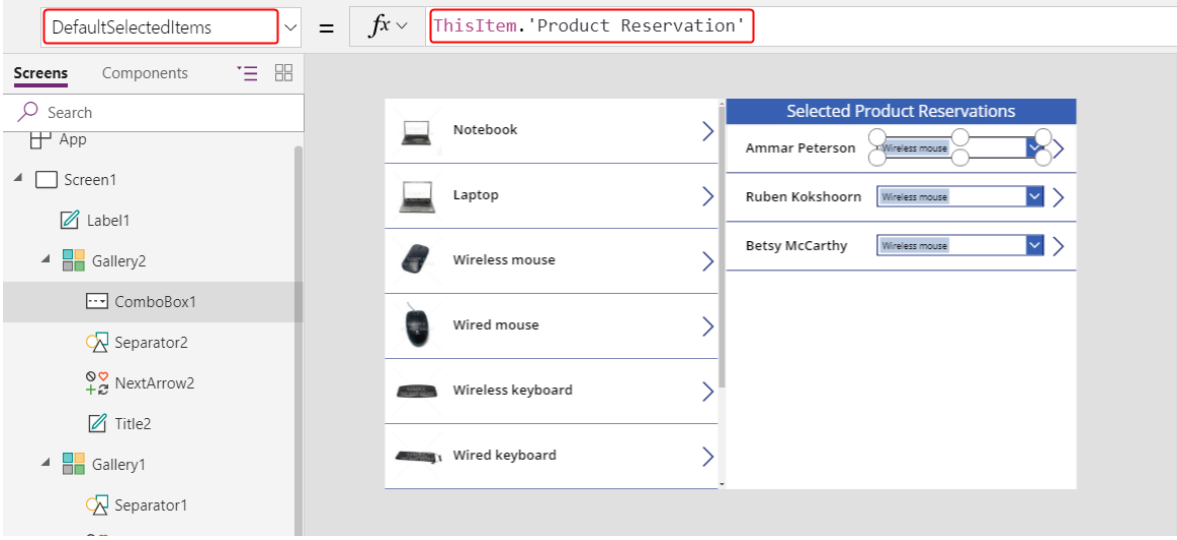
13. In **Gallery2**, add a Combo box control, ensure that it's named **ComboBox1**, and then move and resize it to avoid blocking the other controls in **Gallery2**.

14. On the **Properties** tab, set **ComboBox1**'s **Items** property to **Products**.

15. Scroll down in the **Properties** tab and set **ComboBox1**'s **Allow multiple selection** property to **Off**.



16. In the formula bar, set **ComboBox1**'s **DefaultSelectedItems** property to **ThisItem.'Product Reservation'**.

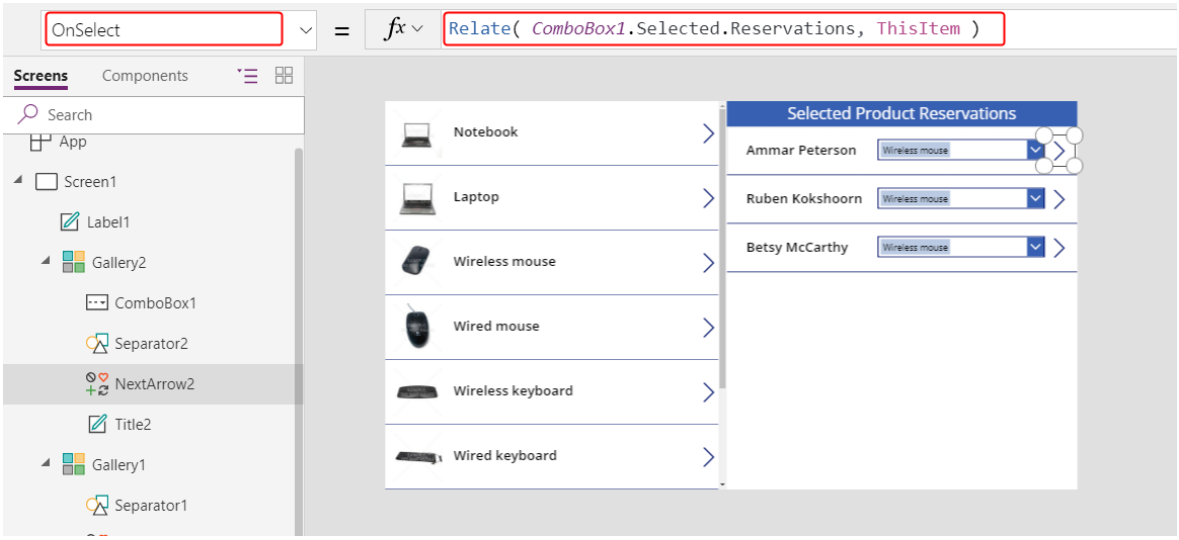


17. In **Gallery2**, set **NextArrow2**'s **OnSelect** property to this formula:

Power Apps

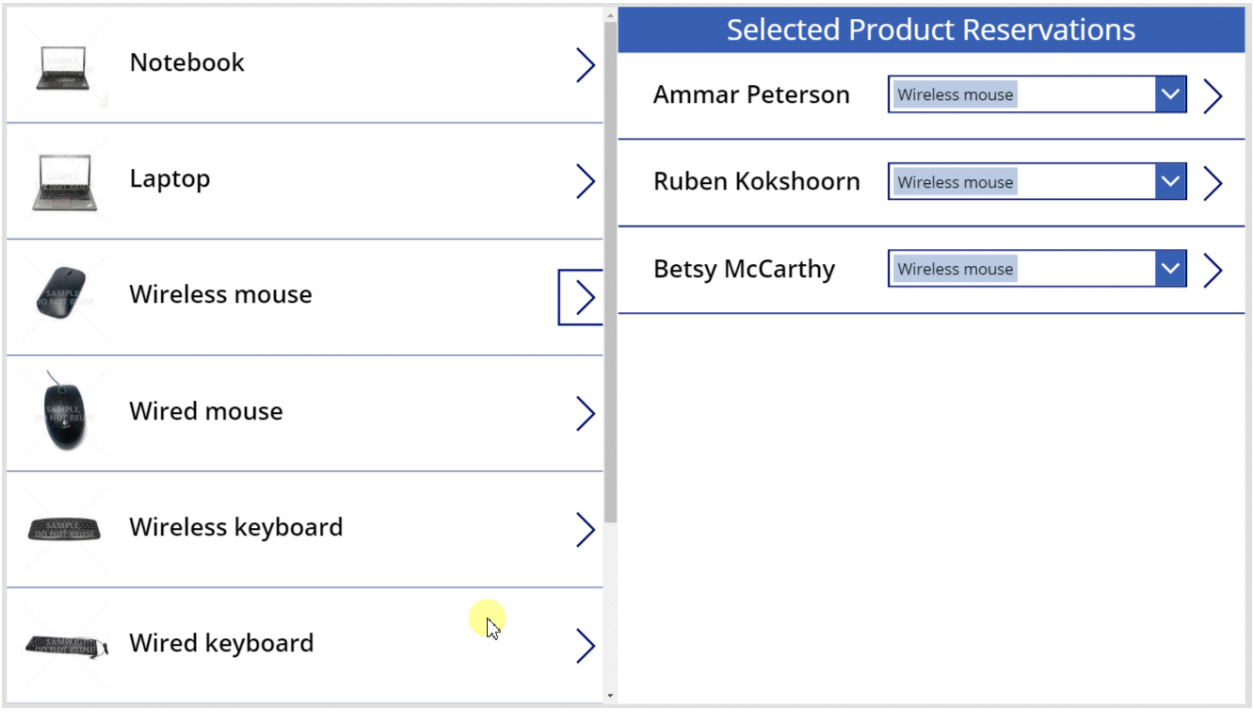
```
Relate( ComboBox1.Selected.Reservations, ThisItem )
```

When the user selects this icon, the current reservation changes to the product that the user selected in **ComboBox1**.



18. Press F5 to test the app in Preview mode.

With this app, the user can move a reservation from one product to another. For a reservation on one product, the user can select a different product in **ComboBox1** and then select **NextArrow2** to change that reservation.



Unrelate function

At this point, you can move the relationship from one record to another, but you can't remove the relationship altogether. You can use the **Unrelate** function to disconnect a reservation record from any product.

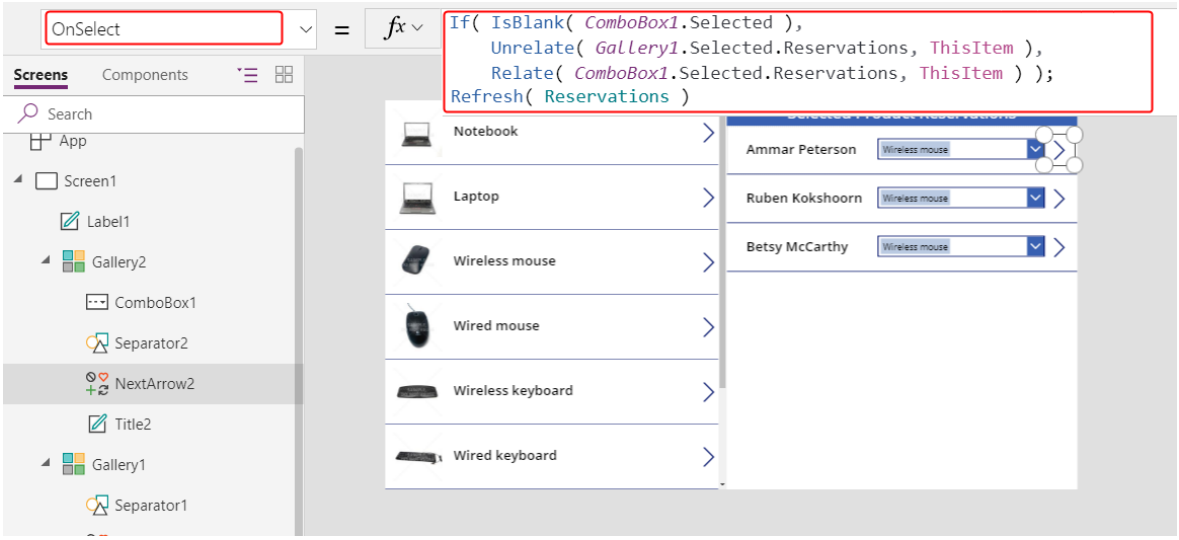
1. On the **View** tab, select **Data sources**.

2. In the **Data** pane, select **Add data source** > **Microsoft Dataverse** > **Reservations** > **Connect**.

3. In **Gallery2**, set the **OnSelect** formula for **NextArrow2** to this formula:

```
Power Apps

If( IsBlank( ComboBox1.Selected ),
    Unrelate( Gallery1.Selected.Reservations, ThisItem ),
    Relate( ComboBox1.Selected.Reservations, ThisItem )
);
Refresh( Reservations )
```



4. Copy **Gallery2** to the Clipboard by selecting it and then pressing Ctrl-C.

5. Paste a duplicate of **Gallery2** to the same screen by pressing Ctrl-V, and then move it to the lower-right quadrant of the screen.

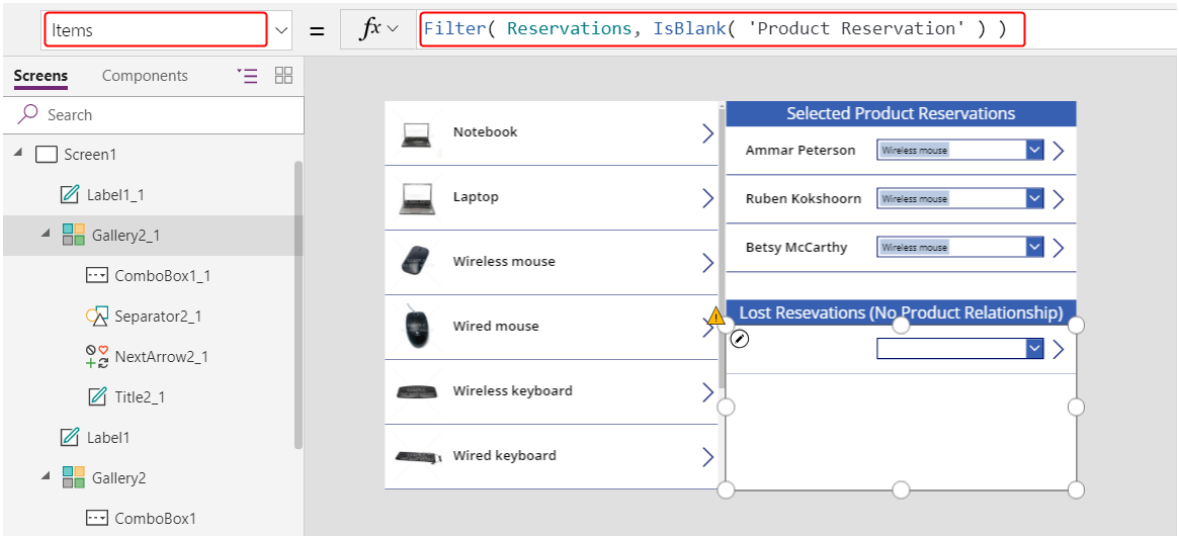
6. (optional) If you added a label above **Gallery2**, repeat the previous two steps for that label.

7. Ensure that the duplicate of **Gallery2** is named **Gallery2_1**, and then set its **Items** property to this formula:

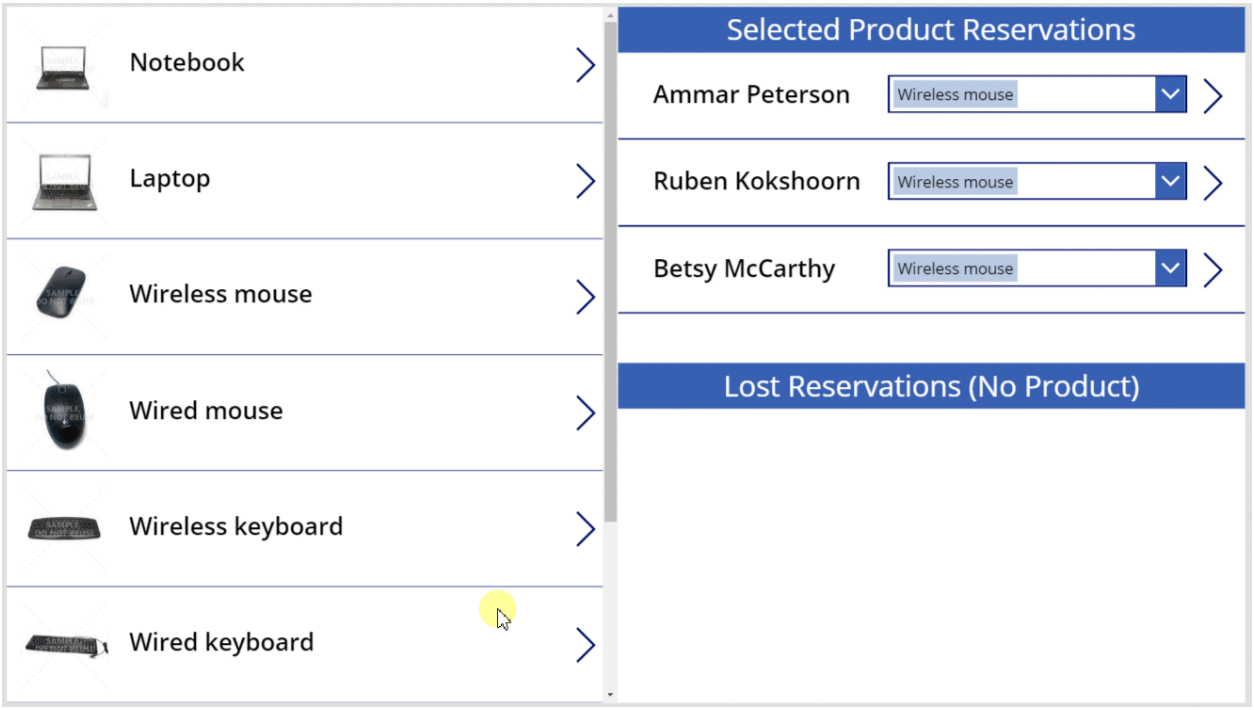
```
Power Apps

Filter( Reservations, IsBlank( 'Product Reservation' ) )
```

   A delegation warning appears, but it won't matter with the small amount of data in this example.



With these changes, users can clear the selection in **ComboBox1** for a contact if that person hasn't reserved a product. Contacts who haven't reserved a product appear in **Gallery2_1** where users can assign each contact to a product.

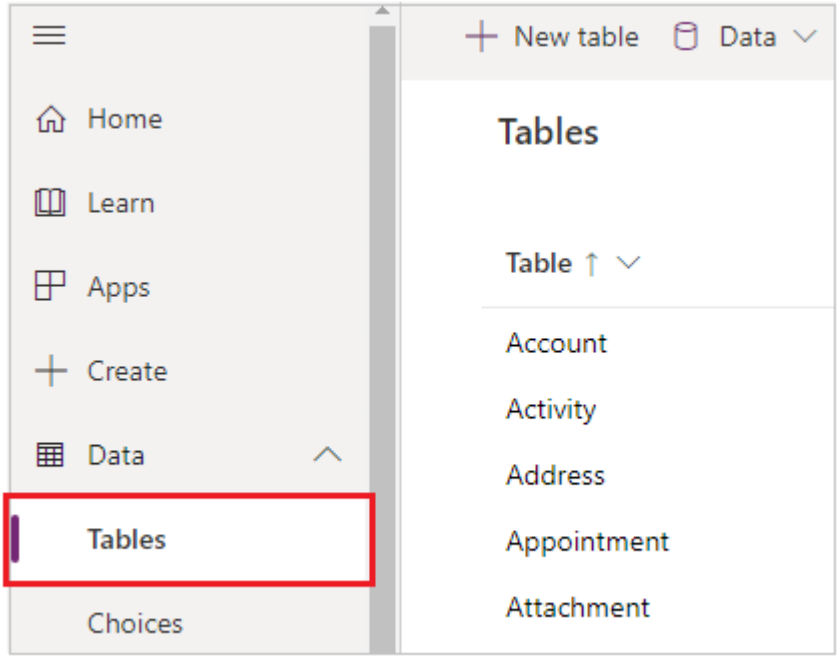


Many-to-many

Create a many-to-many relationship

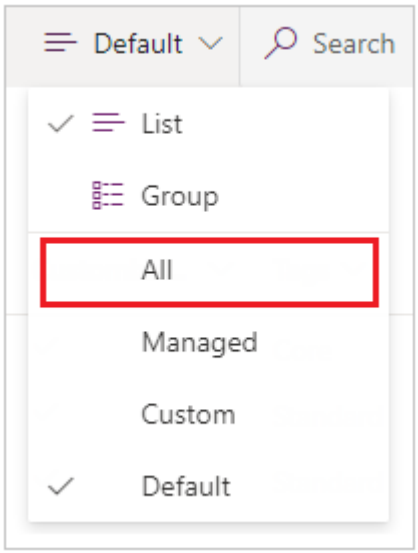
The sample data doesn't include a many-to-many relationship, but you'll create one between the Products table and the Contacts table. Users can relate each product to more than one contact and each contact to more than one product.

1. From this page, select **Data** in the left navigation bar, and then select **Tables**.



2. Change the table filter to include all tables.

   By default, sample tables don't appear.



3. Scroll down, open the **Product** table, and select **Relationships**.

4. Select **Add relationship** > **Many-to-many**.

5. Select the **Contact** table for the relationship.

6. Select **Done** > **Save table**.

Relate and unrelate contacts with one or more products

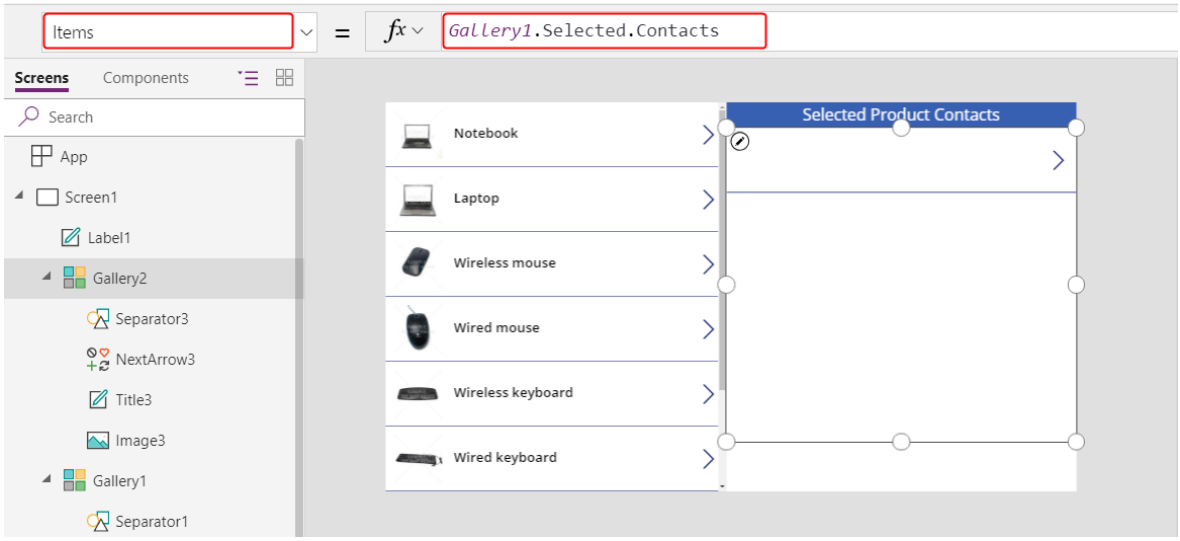
You'll create another app that resembles the one you created earlier in this topic, but the new app will offer a many-to-many relationship. Each contact will be able to reserve multiple products instead of only one.

1. In a blank app for tablets, create **Gallery1** as the first procedure in this topic describes.

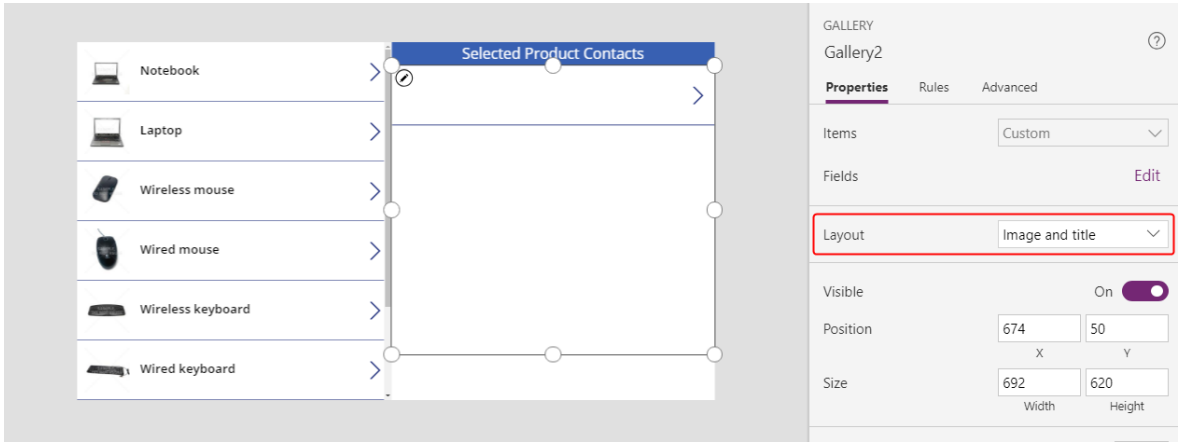
2. Add another blank vertical **Gallery** control, ensure that it's named **Gallery2**, and then move it into the upper-right corner of the screen.

   Later in this topic, you'll add a **Combo box** control under **Gallery2**.

3. In the formula bar, set **Gallery2**'s **Items** property to **Gallery1.Selected.Contacts**.

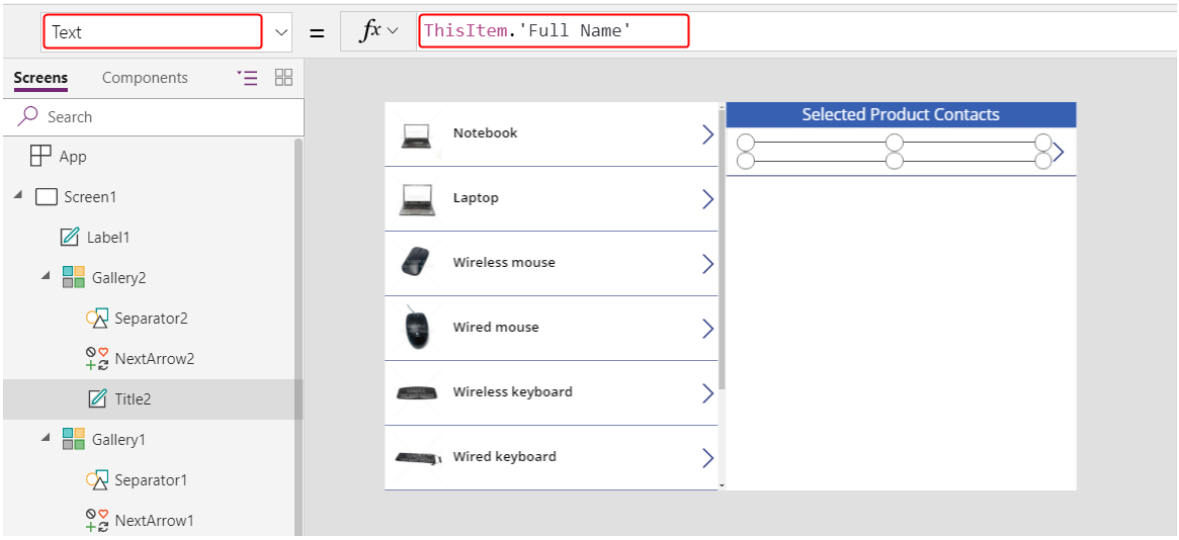


4. On the **Properties** tab, set **Layout** to **Image and title**.



5. In **Gallery2**, ensure that the **Label** control is named **Title2**, and then set its **Text** property to **ThisItem.'Full Name'**.

   No text will appear in that control until you finish this procedure and assign a contact to a product.

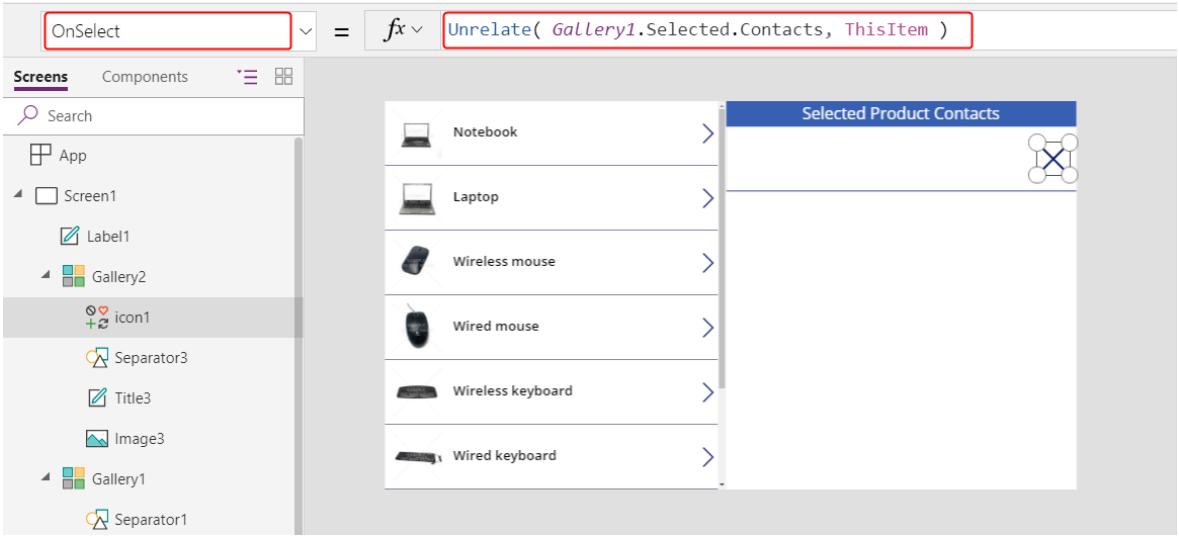


6. Delete **NextArrow2**, insert a **Cancel** icon, and ensure that it's named **icon1**.

7. Set the **Cancel** icon's **OnSelect** property to this formula:

```
Power Apps

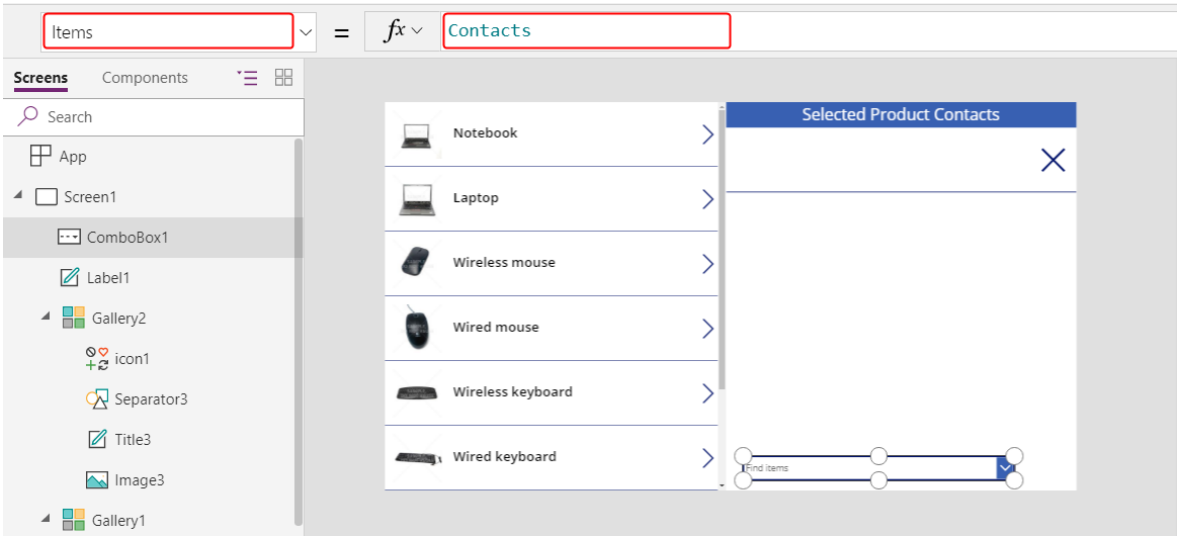
Unrelate( Gallery1.Selected.Contacts, ThisItem )
```



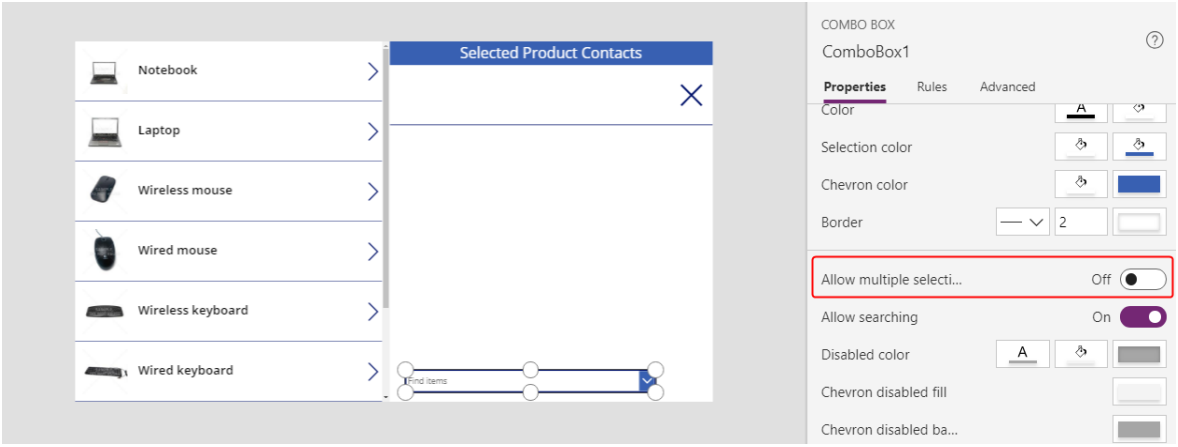
8. On the **View** tab, select **Data sources**.

9. In the **Data** pane, select **Add data source** > **Microsoft Dataverse** > **Contacts** > **Connect**.

10. Under **Gallery2**, add a **Combo box** control, ensure that it's named **ComboBox1**, and then set its **Items** property to **Contacts**.



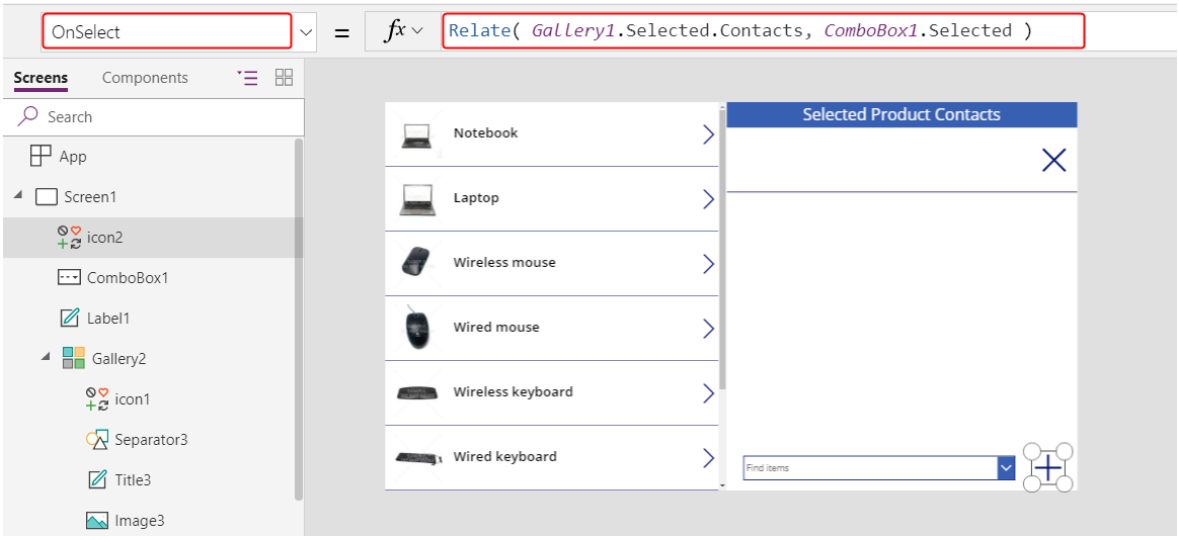
11. On the **Properties** tab, set **Allow multiple selection** to **Off**.



12. Insert an **Add** icon, and set its **OnSelect** property to this formula:

Power Apps

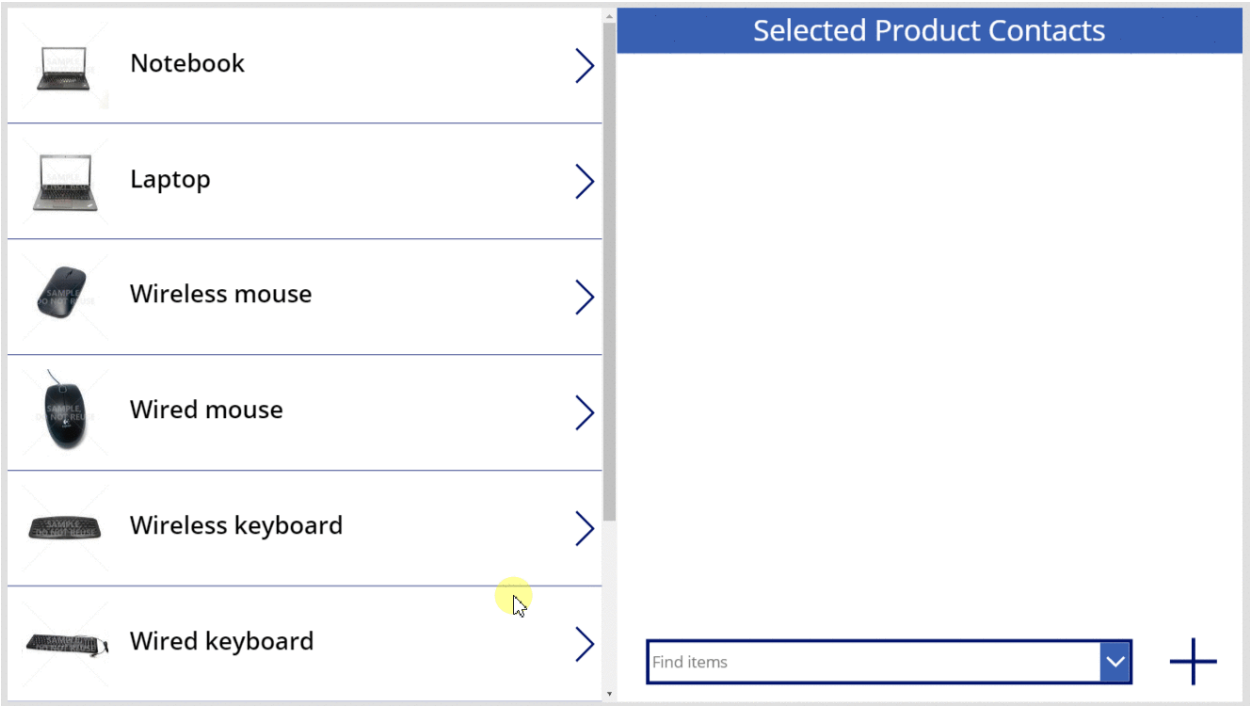
```
Relate( Gallery1.Selected.Contacts, ComboBox1.Selected )
```



With this app, users can now freely relate and unrelate a set of contacts to each product.

- To add a contact to a product, select the contact in the combo box at the bottom of the screen, and then select the **Add** icon.
- To remove a contact from a product, select the **Cancel** icon for that contact.

  Unlike one-to-many, a many-to-many relationship allows users to associate the same contact with multiple products.

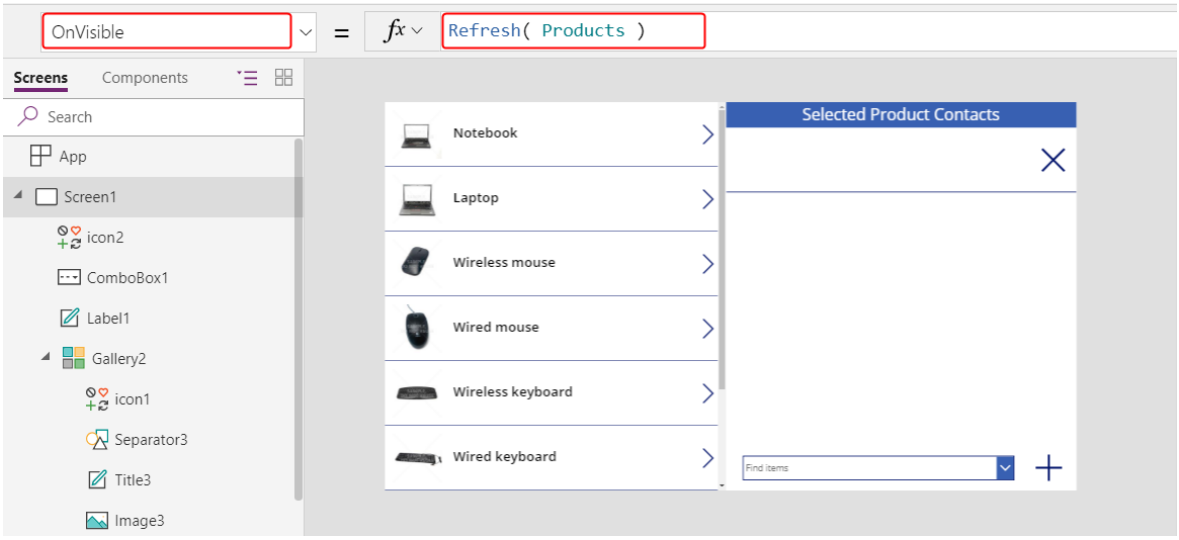


In reverse: relate and unrelate products with multiple contacts

Many-to-many relationships are symmetric. You can extend the example to add products to a contact and then flip between the two screens to show how the relationship appears from either direction.

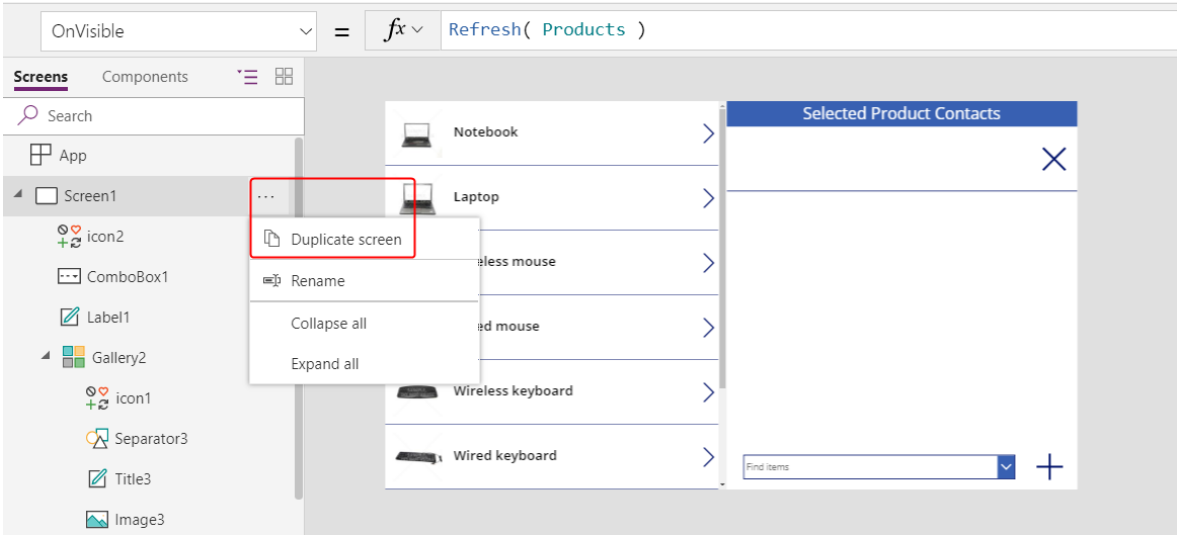
1. Set the **OnVisible** property of **Screen1** to **Refresh(Products)**.

   When you update a one-to-many or many-to-many relationship, only the data of the first argument table of the **Relate** or **Unrelate** call is refreshed. The second must be refreshed manually if you want to flip between the screens of this app.



2. Duplicate **Screen1**.

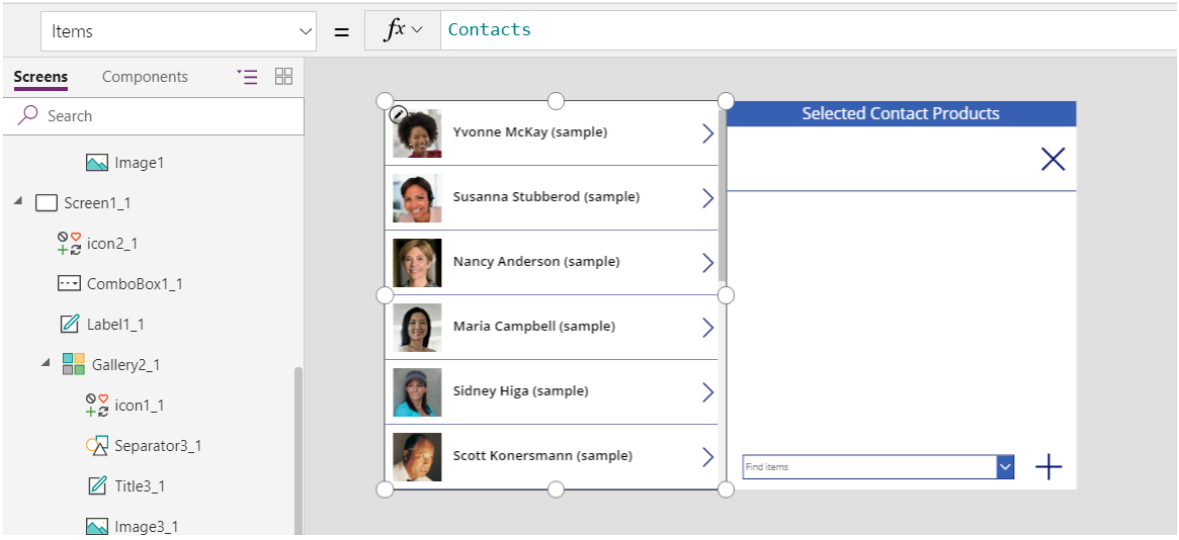
   The duplicate will be named **Screen1_1** and form the basis for looking at the relationships from the contacts side.



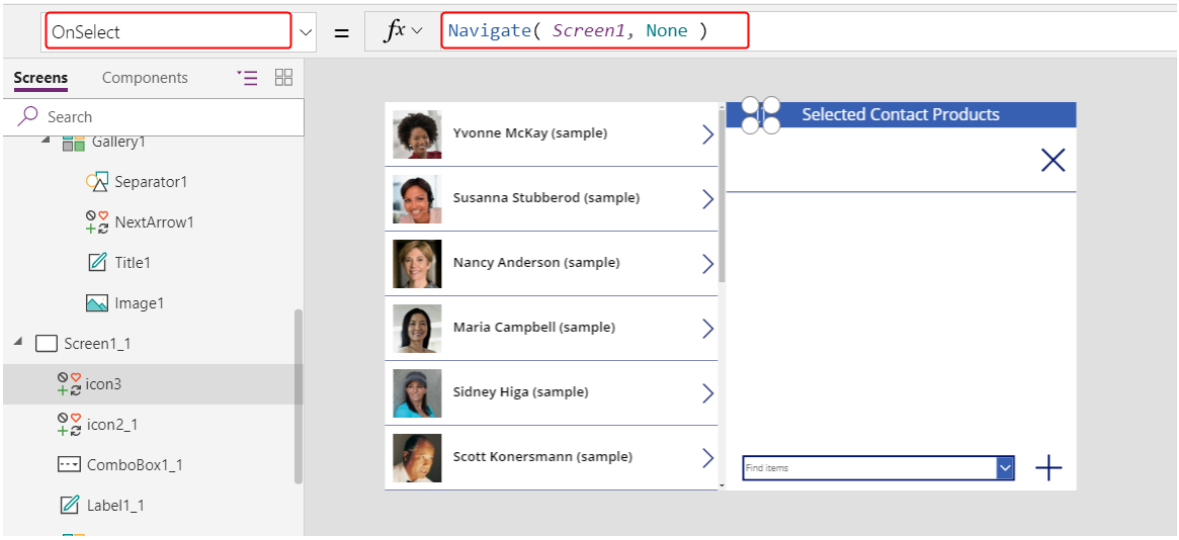
3. To create the reverse view, change these formulas on the controls of **Screen1_1**:

   - Screen1_1.OnVisible = `Refresh( Contacts )`
   - Gallery1_1.Items = `Contacts`
   - Title1_1.Text = `ThisItem.'Full Name'`
   - Label1_1.Text = `"Selected Contact Products"`
   - Gallery2_1.Items = `Gallery1_1.Selected.Products`
   - Title2_1.Text = `ThisItem.Name`
   - Icon1_1.OnSelect = `Unrelate( Gallery1_1.Selected.Products, ThisItem )`
   - ComboBox1_1.Items = `Products`
   - Icon2_1.OnSelect = `Relate( Gallery1_1.Selected.Products, ComboBox1_1.Selected )`

The result will look very similar to the previous screen but comes at the relationship from the **Contacts** side.



4. Insert an **Arrows up down** icon and set its **OnSelect** property to **Navigate(Screen1, None)**. Do the same thing on **Screen1** with the formula **Navigate(Screen1_1, None)**.



With this new screen, users can add a contact to a product and then flip to a view of contacts and see the associated product. The relationships are symmetric and shared between the two screens.

Remove and RemoveIf functions

Article • 10/31/2024

Applies to: Canvas apps Model-driven apps Power Platform CLI

Removes records from a data source.

> **Note**
>
> PAC CLI pac power-fx commands do not support the **RemoveIf** function.

Description

Remove function

Use the **Remove** function to remove a specific record or records from a data source.

For collections, the entire record must match. You can use the **RemoveFlags.All** argument to remove all copies of a record; otherwise, only one copy of the record is removed.

RemoveIf function

Use the **RemoveIf** function to remove a record or records based on a condition or a set of conditions. Each condition can be any formula that results in a **true** or **false** and can reference columns of the data source by name. Each condition is evaluated individually for each record, and the record is removed if all conditions evaluate to **true**.

Remove and **RemoveIf** return the modified data source as a table. You can use both functions only in behavior formulas.

You can also use the **Clear** function to remove all of the records in a collection.

Delegation

RemoveIf is supported by only a few data sources. For data sources that don't upport this feature, Power Apps will query the server and retrieve all data matching the filter expression, up to a maximum of either 500 or 2000 records or the data page size. Subsequently, it will delete each of those records individually by making separate calls to the server.

Syntax

Remove(*DataSource*, *Record1* [, *Record2*, ...] [, **RemoveFlags.All**])

- *DataSource* – Required. The data source that contains the record or records that you want to remove.
- *Record(s)* – Required. The record or records to remove.
- **RemoveFlags.All** – Optional. In a collection, the same record may appear more than once. You can add the **RemoveFlags.All** argument to remove all copies of the record.

Remove(*DataSource*, *Table* [, **RemoveFlags.All**])

- *DataSource* – Required. The data source that contains the records that you want to remove.
- *Table* – Required. A table of records to remove.
- **RemoveFlags.All** – Optional. In a collection, the same record may appear more than once. You can add the **RemoveFlags.All** argument to remove all copies of the record.

RemoveIf(*DataSource*, *Condition* [, ...])

- *DataSource* – Required. The data source that contains the record or records that you want to remove.
- *Condition(s)* – Required. A formula that evaluates to **true** for the record or records to remove. You can use column names from the *DataSource* in the formula. If you specify multiple *Conditions*, all must evaluate to **true** for the record or records to be removed.

Examples - single formulas

In these examples, you'll remove a record or records in a data source that's named **IceCream** and that starts with the data in this table:

ID	Flavor	Quantity
1	"Chocolate"	100
2	"Vanilla"	200
3	"Strawberry"	300

Create a collection with sample records

To create a collection with this data:

1. Insert a **Button** control.

2. Set button control's **OnSelect** property to the below formula:

```
Power Fx
```

```
ClearCollect( IceCream,
              { ID: 1, Flavor: "Chocolate",  Quantity: 100 },
              { ID: 2, Flavor: "Vanilla",    Quantity: 200 },
              { ID: 3, Flavor: "Strawberry", Quantity: 300 }
)
```

3. Select the button while holding down the Alt key:

Remove sample records from collection using a formula

Expand table

Formula	Description	Result
Remove(IceCream, LookUp(IceCream, Flavor="Chocolate"))	Removes the **Chocolate** record from the data source.	 The **IceCream** data source has been modified.
Remove(IceCream, LookUp(IceCream, Flavor="Chocolate"), LookUp(IceCream, Flavor="Strawberry"))	Removes two records from the data source.	 The **IceCream** data source has been modified.
RemoveIf(IceCream, Quantity > 150)	Removes records that have a **Quantity** that's greater than **150**.	 The **IceCream** data source has been modified.
RemoveIf(IceCream, Quantity > 150, Left(Flavor, 1) = "S")	Removes records that have a **Quantity** that's greater than 150 and **Flavor** starts with an **S**.	 The **IceCream** data source has been modified.

Formula	Description	Result
RemoveIf(IceCream, true)	Removes all records from the data source.	ID Flavor Quantity The **IceCream** data source has been modified.

Examples - remove button outside a gallery

In this example, you'll use a **Gallery** control to list the records in a table. And then use the **Remove** function to selectively remove an item.

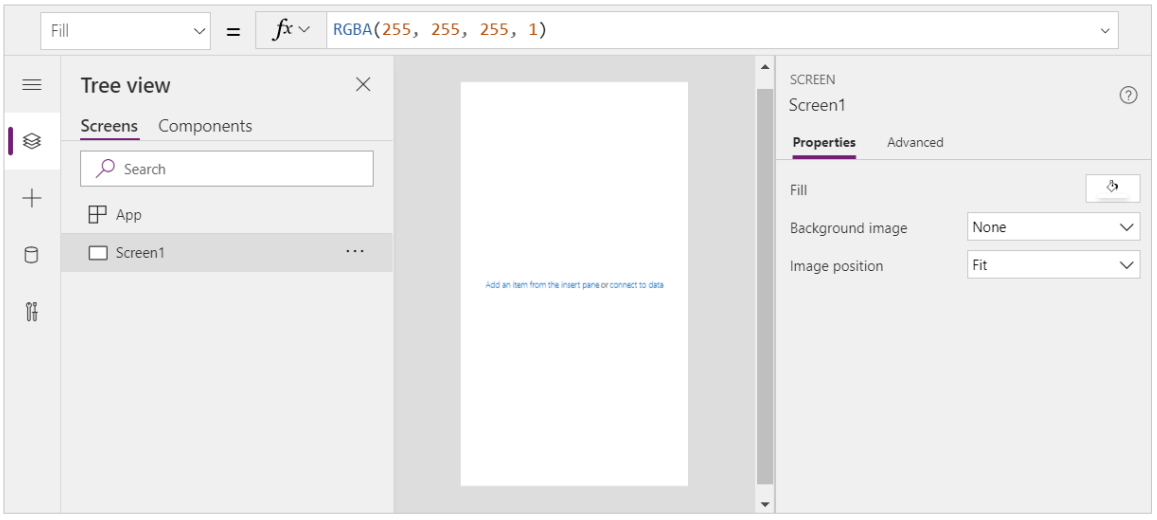
Prepare for sample data

This example uses the **Contacts** table in Microsoft Dataverse available with the *sample apps and data*. You can deploy *sample apps and data* when you create an environment. You can also use any other data source instead.

Remove button outside a gallery

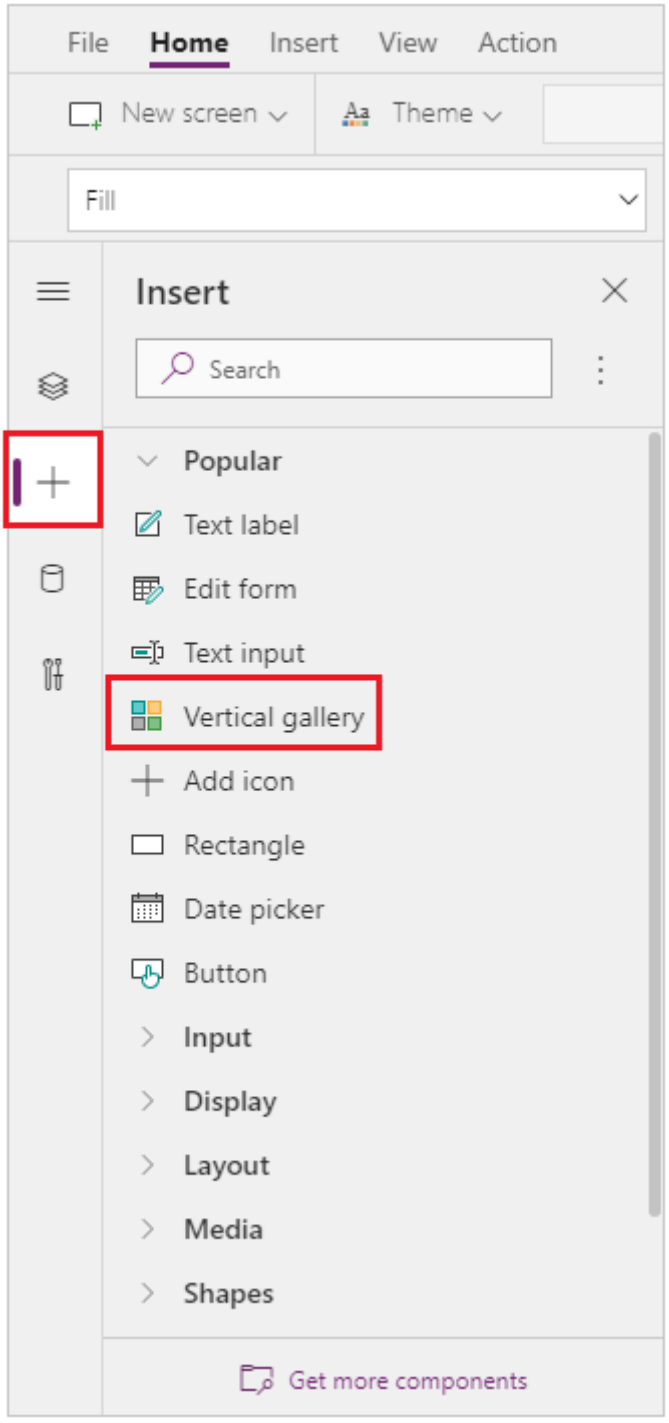
In this example, you'll remove an item by using a *button* that is outside the gallery.

1. Create a new blank canvas app using a Phone layout.

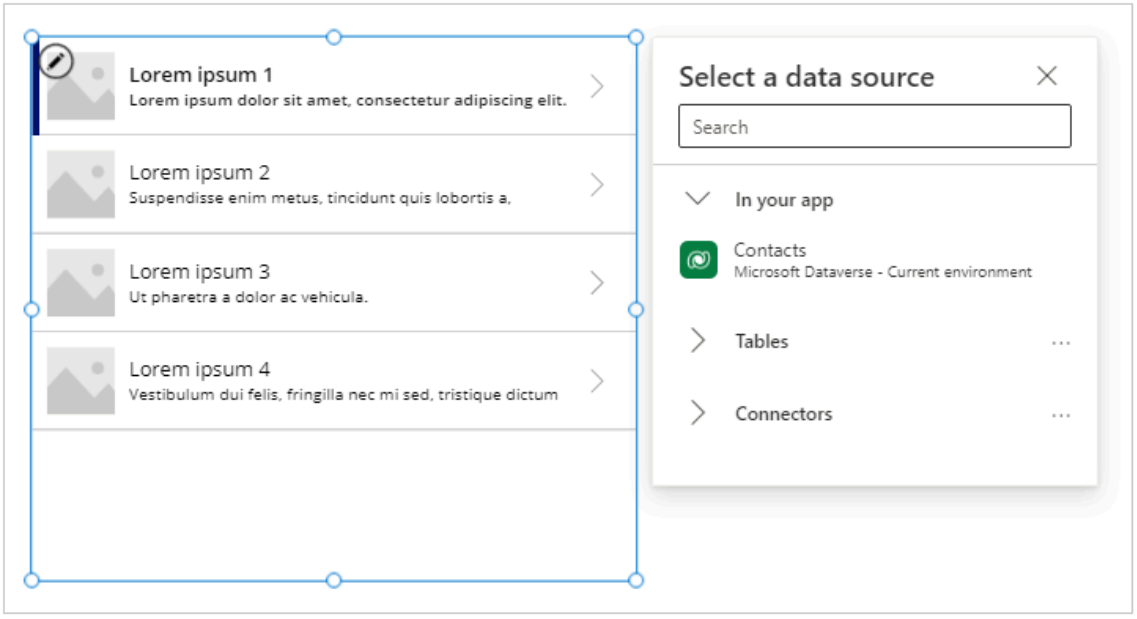


2. Select the **Insert** from the left pane.

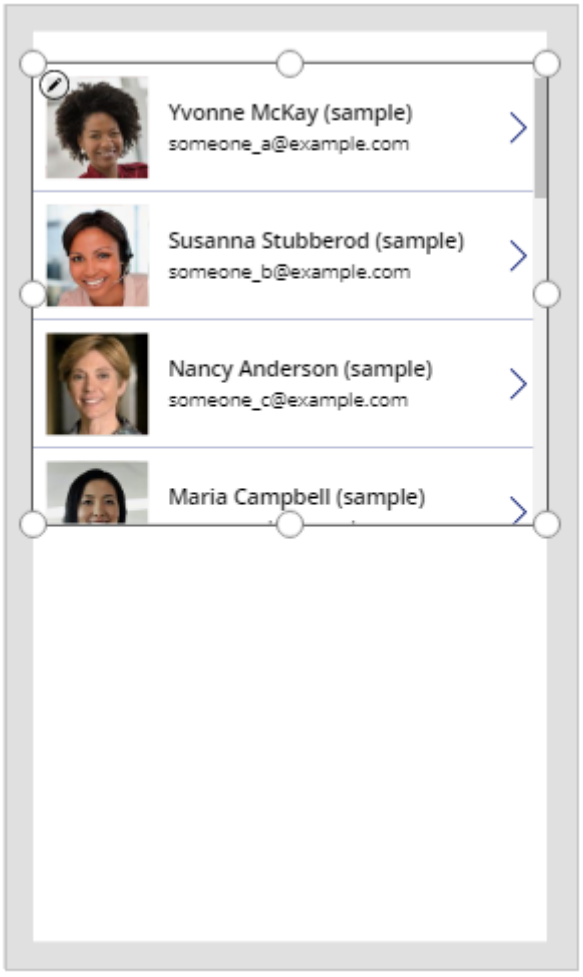
3. Select **Vertical gallery**.
   A **Gallery** control is be added to your screen.



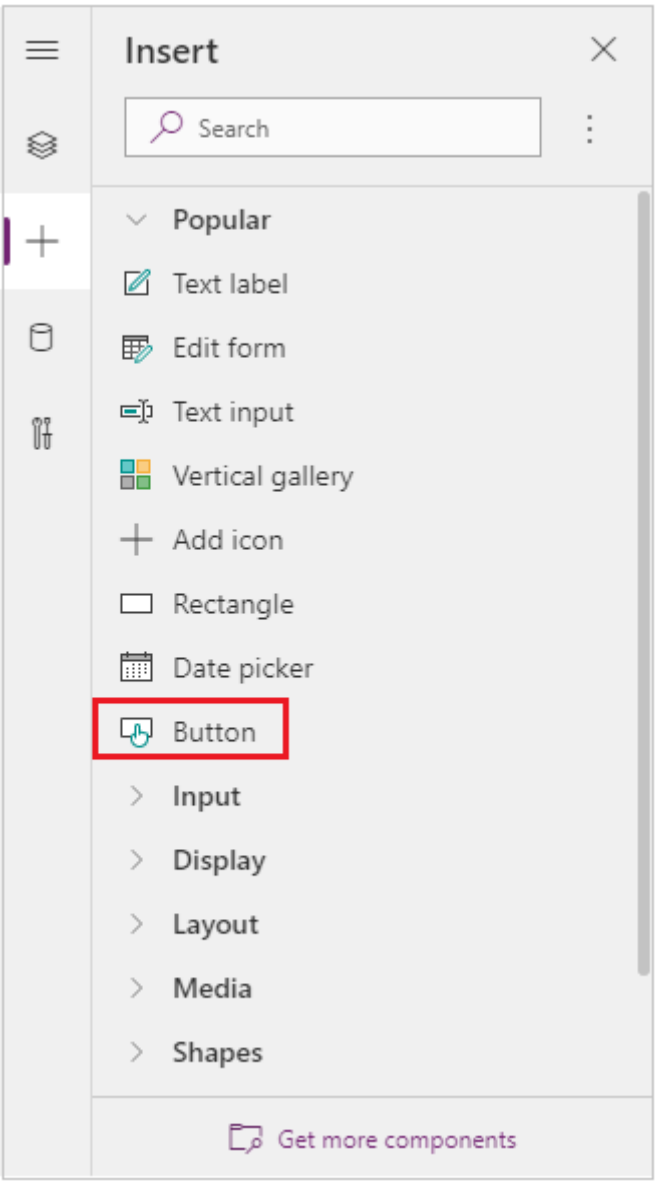
4. You're prompted to select a data source where you can select a data source from the available data sources.
   For example, select the **Contacts** table to use *sample data*:



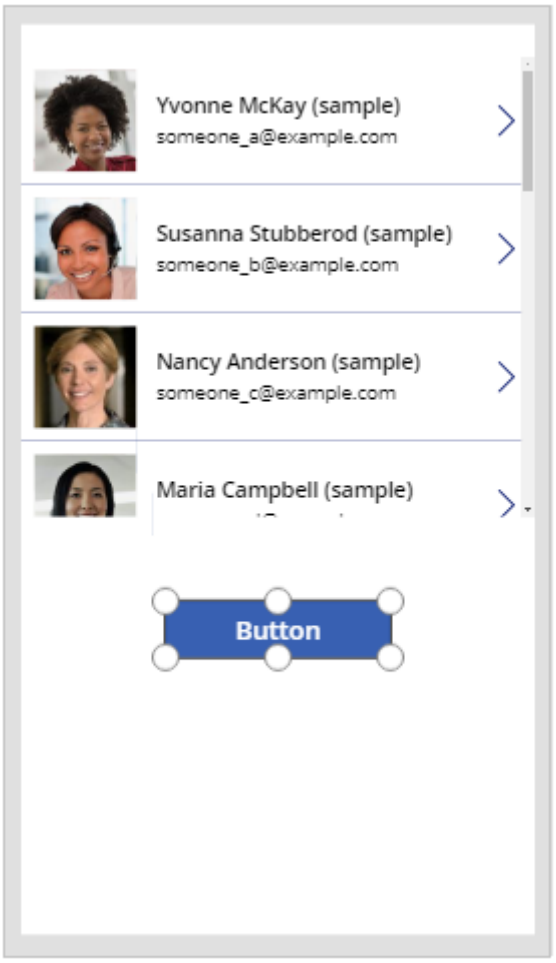
The gallery shows items from this table:



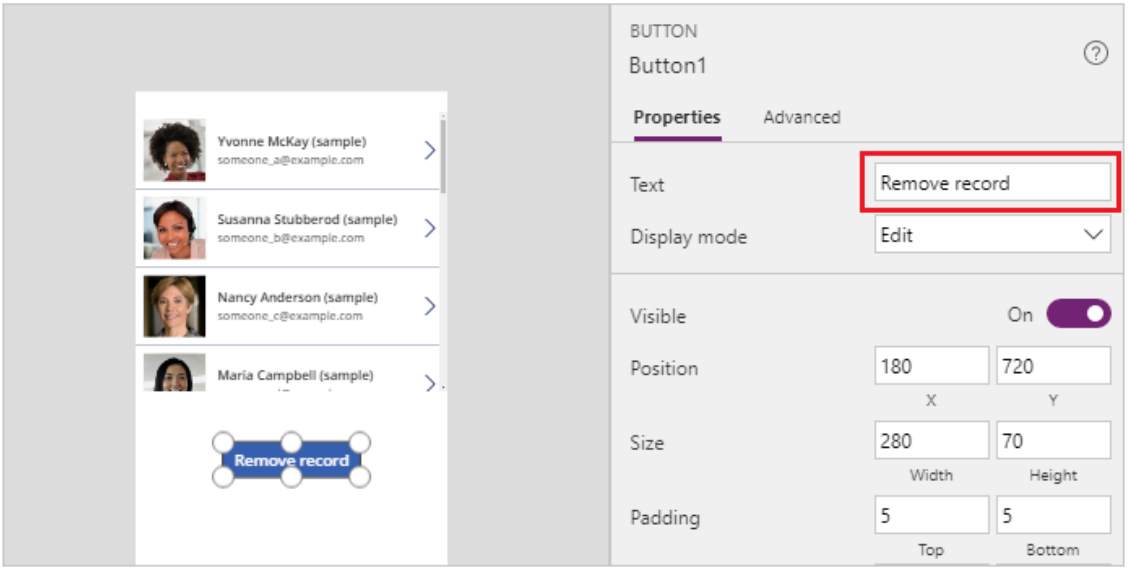
5. Insert a **Button** control from left pane:



6. Move the added button below the gallery items:



7. Update button text property to *Remove record*. You can also use text of your choice:



8. Set the **OnSelect** property for this button control to the following formula:

```
Power Fx

Remove( Contacts, Gallery1.Selected )
```

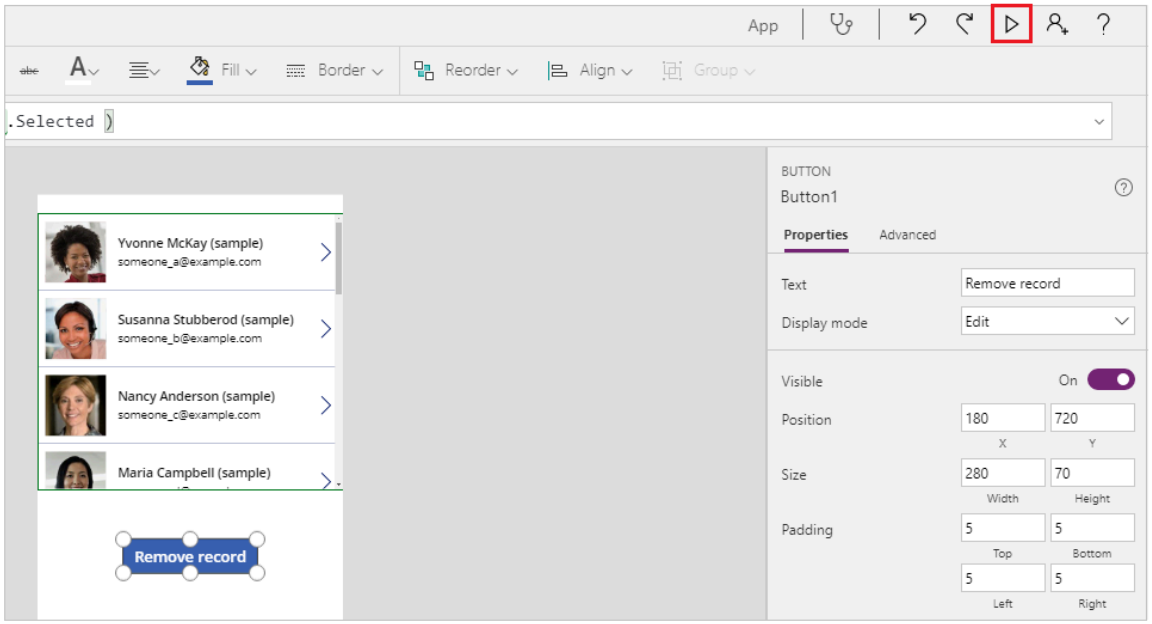
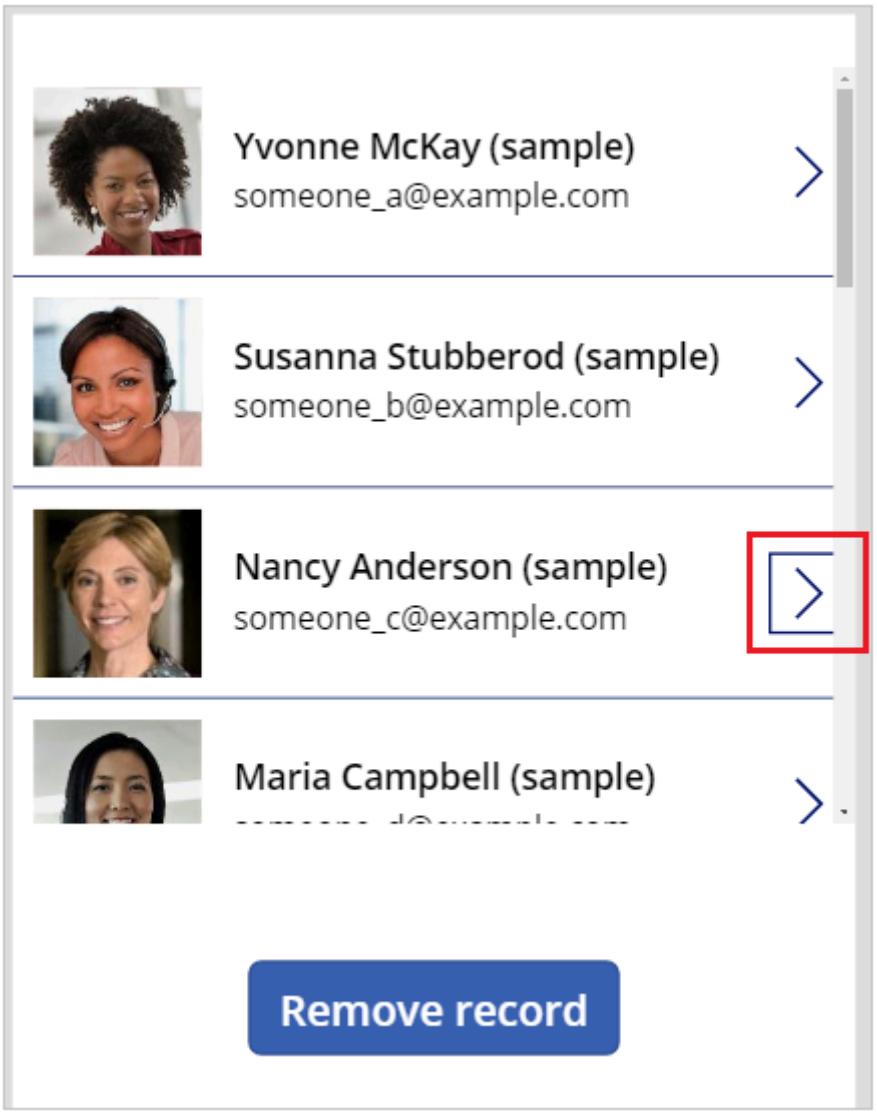
The gallery control makes the currently selected record available using **Selected** property. **Remove** function refers to this selected record to remove it.

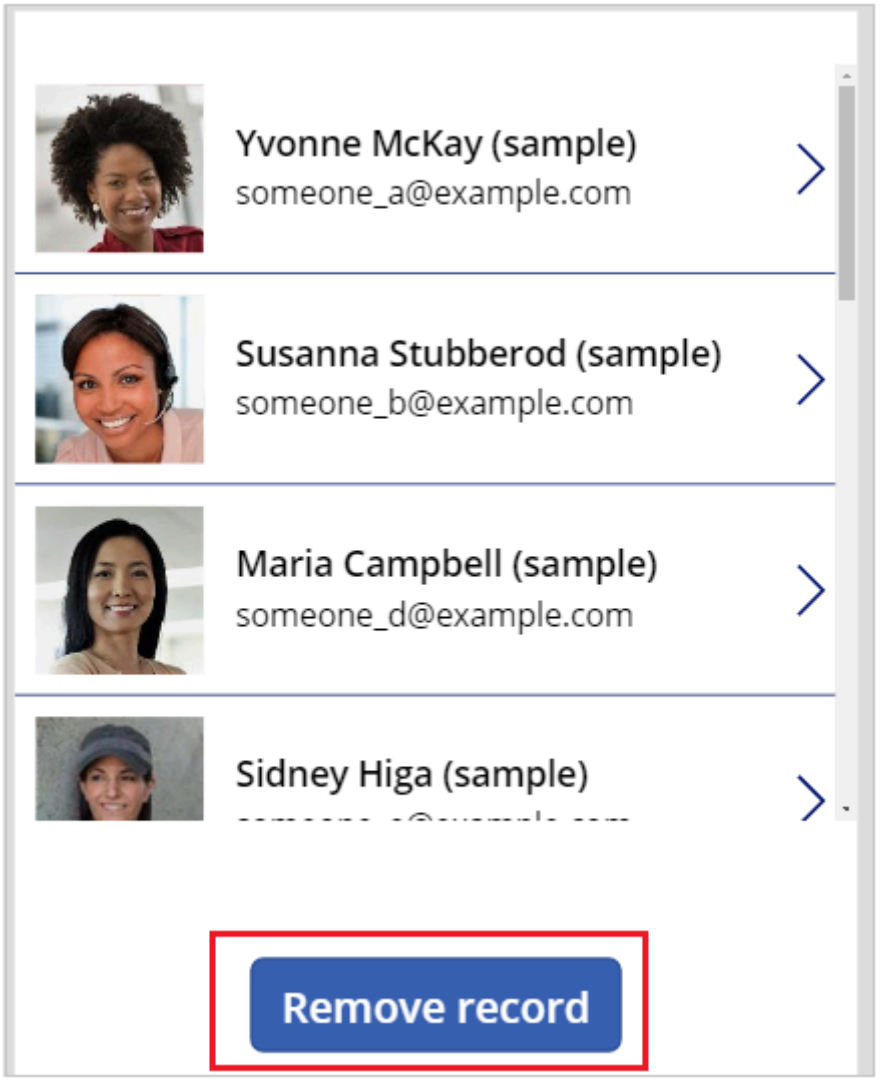
9. Preview the app using the *Play* button on the top right, or press *F5* on keyboard:



10. Select a record to remove, such as *Nancy*'s record in this example:



11. Select **Remove record**:



Selecting the button removes the selected record (in this example, Nancy's record).

12. Close the app preview.

> **Tip**
>
> You can also use alternate behavior with ***Alt key*** instead of using the app preview with *Play* button or *F5*.

Examples - trash can icon inside a gallery

In this example, you'll remove an item by using an *icon* placed inside the gallery.

Create a collection with sample data

If you already have prepared sample data, skip this step and move to Trash can icon inside a gallery.

1. Add a **Button** control to your screen.

2. Set the **OnSelect** property to the following formula:

```
Power Fx
```

```
ClearCollect( SampleContacts,
      { 'Full Name': "Yvonne McKay (sample)",      'Primary Email':
"someone_a@example.com" },
      { 'Full Name': "Susanna Stubberod (sample)", 'Primary Email':
"someone_b@example.com" },
      { 'Full Name': "Nancy Anderson (sample)",    'Primary Email':
"someone_c@example.com" },
      { 'Full Name': "Maria Campbell (sample)",    'Primary Email':
"someone_d@example.com" },
      { 'Full Name': "Robert Lyon (sample)",       'Primary Email':
"someone_e@example.com" },
      { 'Full Name': "Paul Cannon (sample)",       'Primary Email':
"someone_f@example.com" },
      { 'Full Name': "Rene Valdes (sample)",       'Primary Email':
"someone_g@example.com" }
)
```

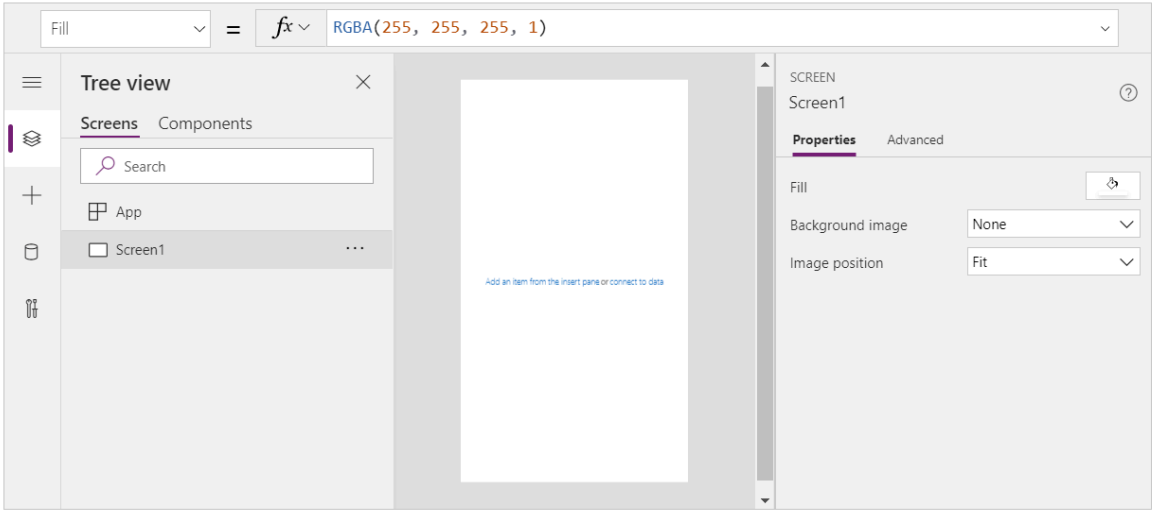
3. Select the button while holding down the Alt key.

Sample collection is created that you can use in the following example.

Trash can icon inside a gallery

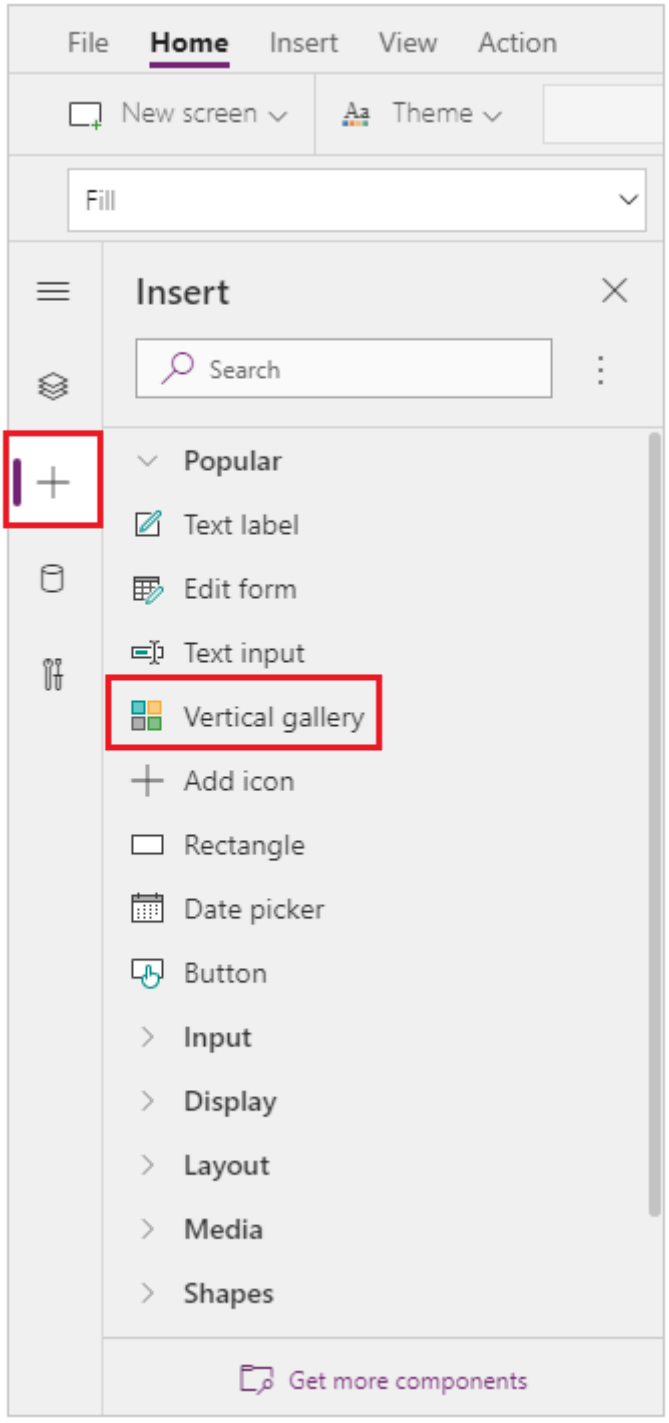
1. Create a new blank canvas app using a Phone layout.



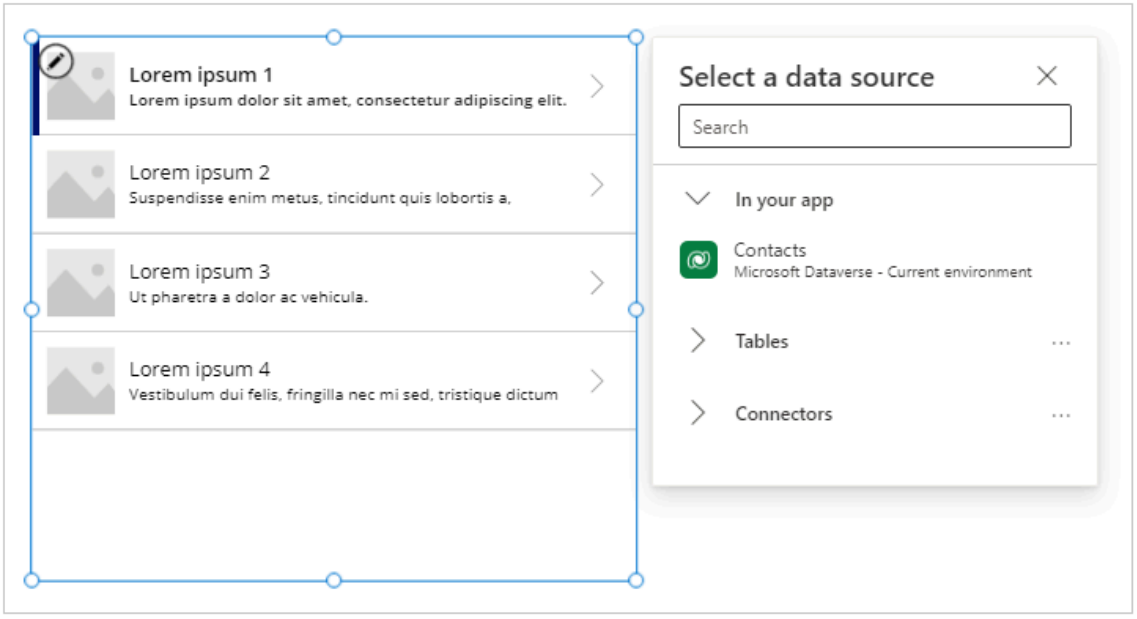
2. Select the **Insert** from the left pane.

3. Select **Vertical gallery**.

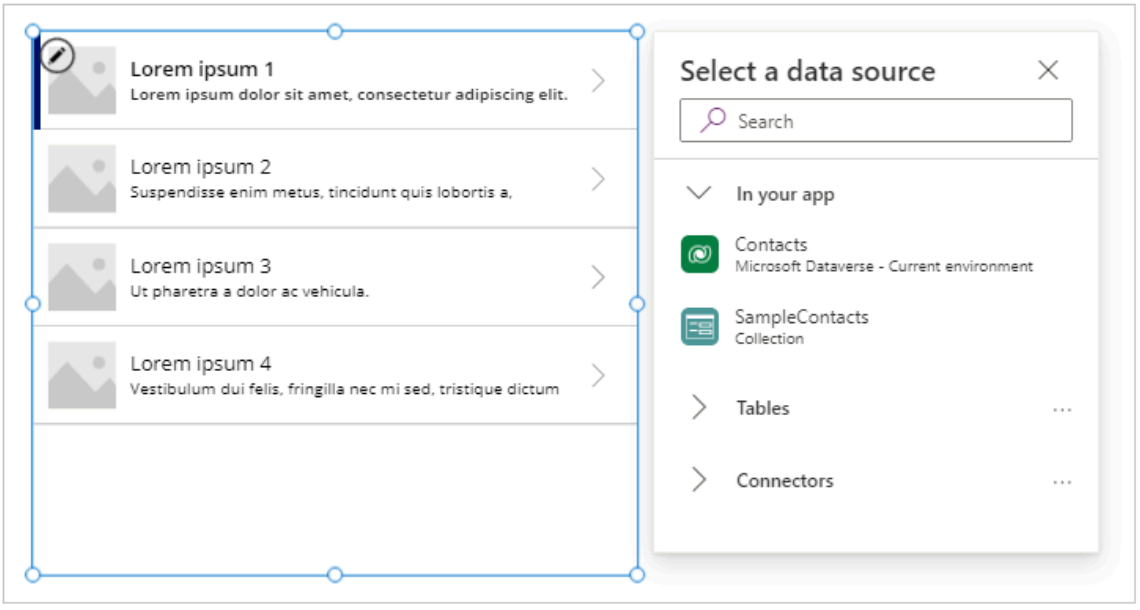
   A **Gallery** control is be added to your screen.



4. You're prompted to select a data source where you can select a data source from the available data sources.
   For example, select the **Contacts** table to use *sample data*:

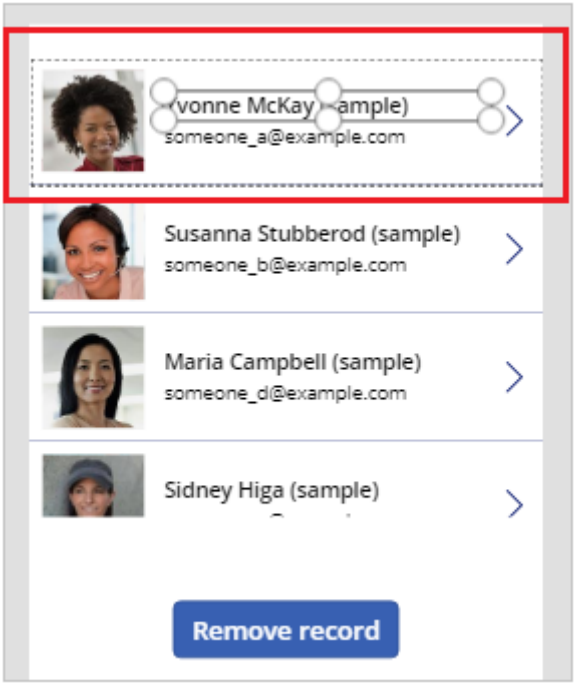


If you created a collection, select your collection instead:

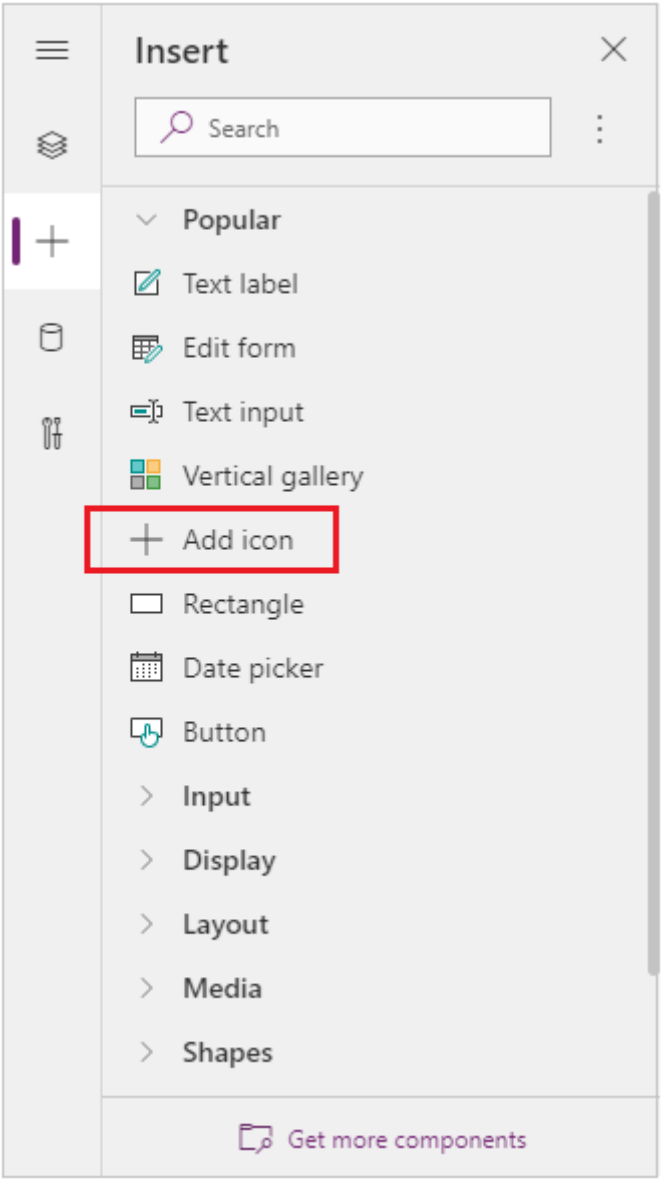


5. Select a control within the top item in the gallery.

   To ensure next step inserts item into gallery's template and not outside the gallery, ensure you follow this step before moving to the next step.

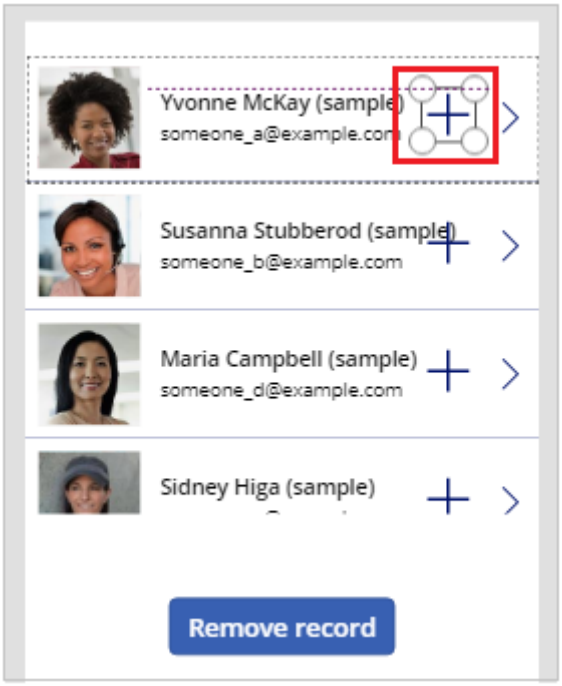


6. Select **Add icon** from left pane.



> ⓘ Note
>
> **Add icon** inserts a + icon on the left side of the gallery, replicated for each item in the gallery.

7. In the top item, move the icon to the right side of the screen.



8. Select the **Icon** property for icon and set it to the following formula to update the icon image as trash icon:

```
Power Fx

Icon.Trash
```

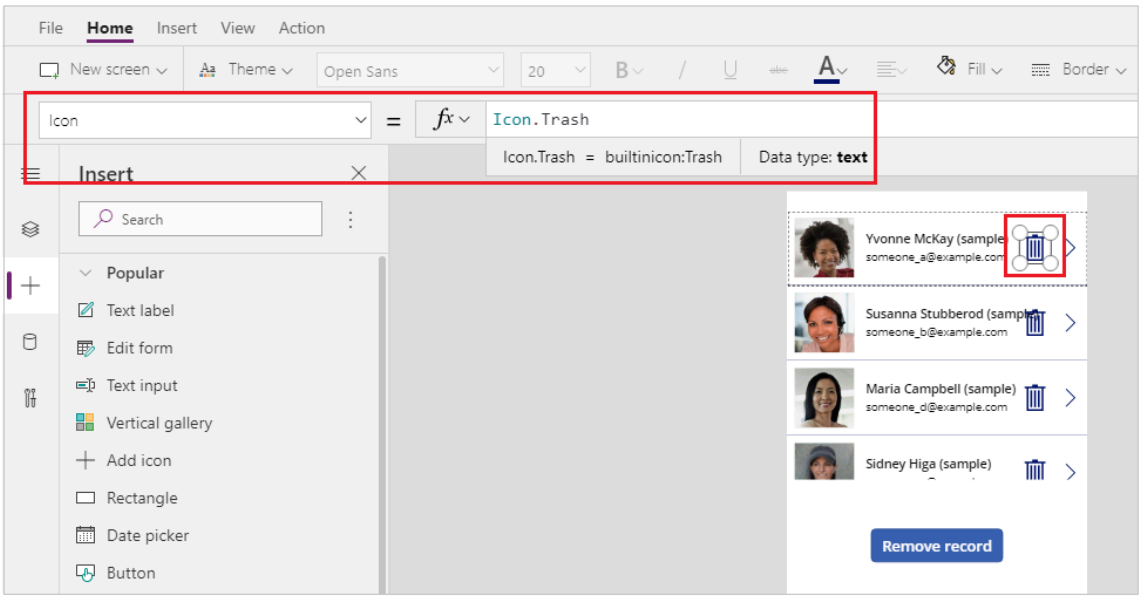
> ⓘ Note
>
> The **Icon.** prefix is only shown when you're actively editing the formula.



9. Set the **OnSelect** property to the following formula:

```
Power Fx

Remove( [@Contacts], ThisItem )
```

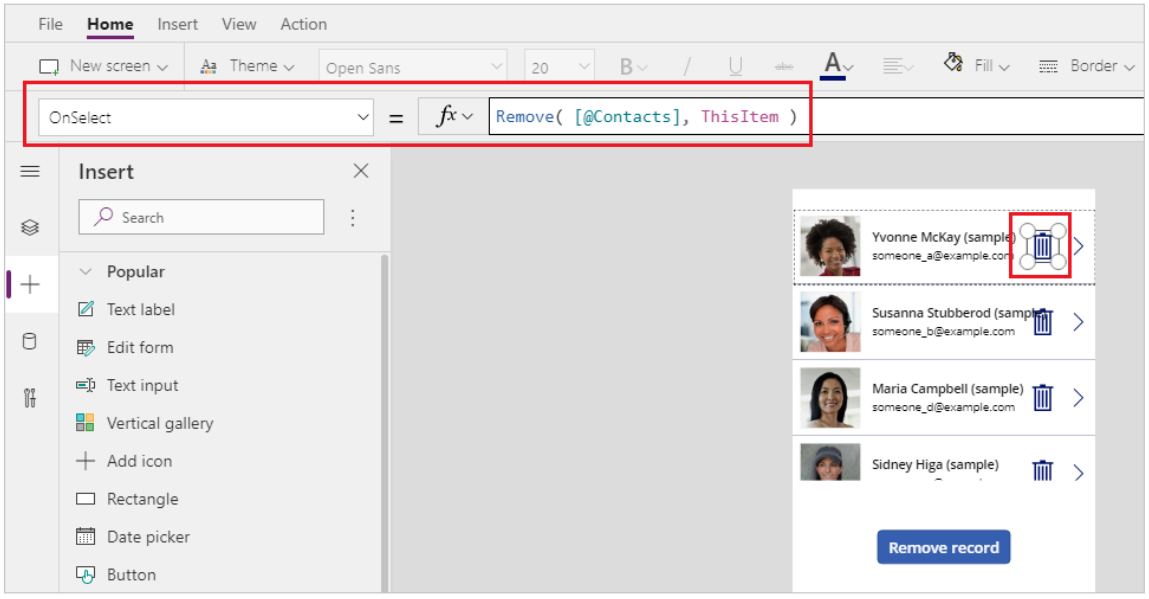
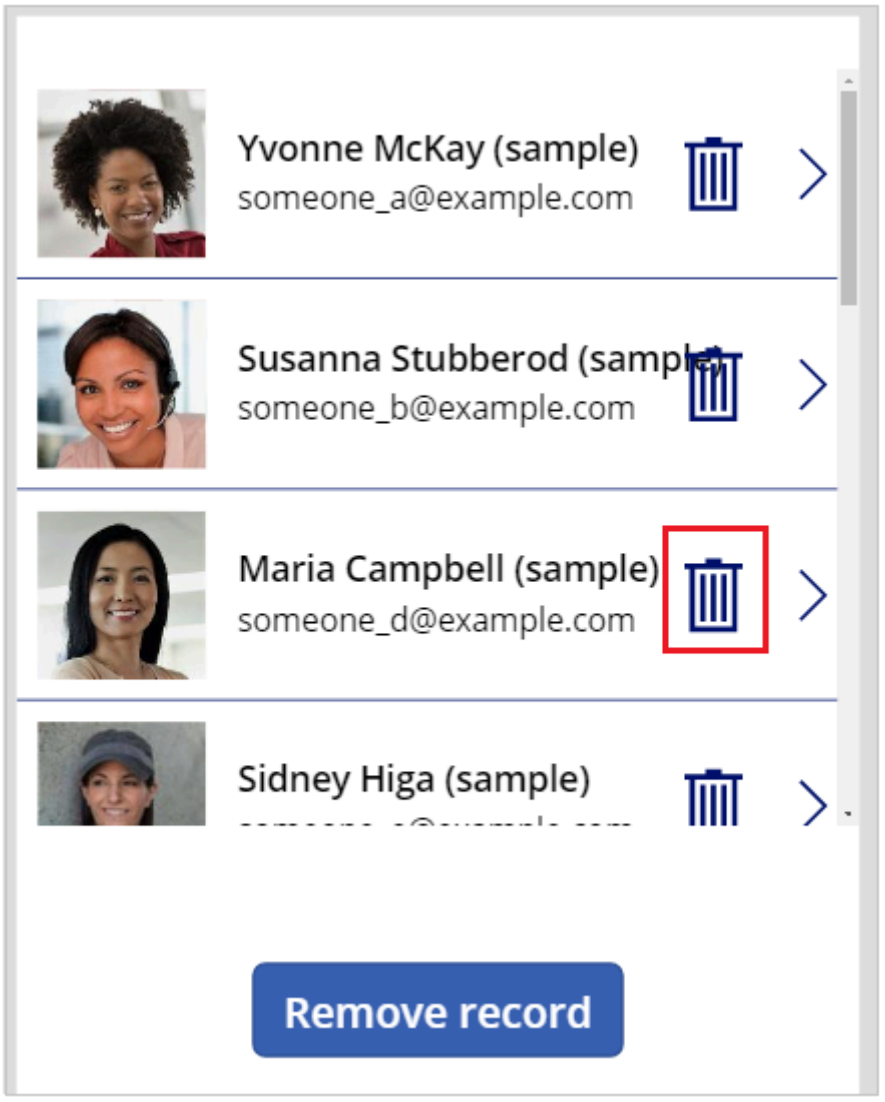
> **Note**
>
> You must use global disambiguation operator [@...] in this example with sample data that uses the *Contacts* table to avoid conflict with a *One-to-Many* relationship. If you use data sources such as a list or a SQL Server table, using *global disambiguation operator* is not required.

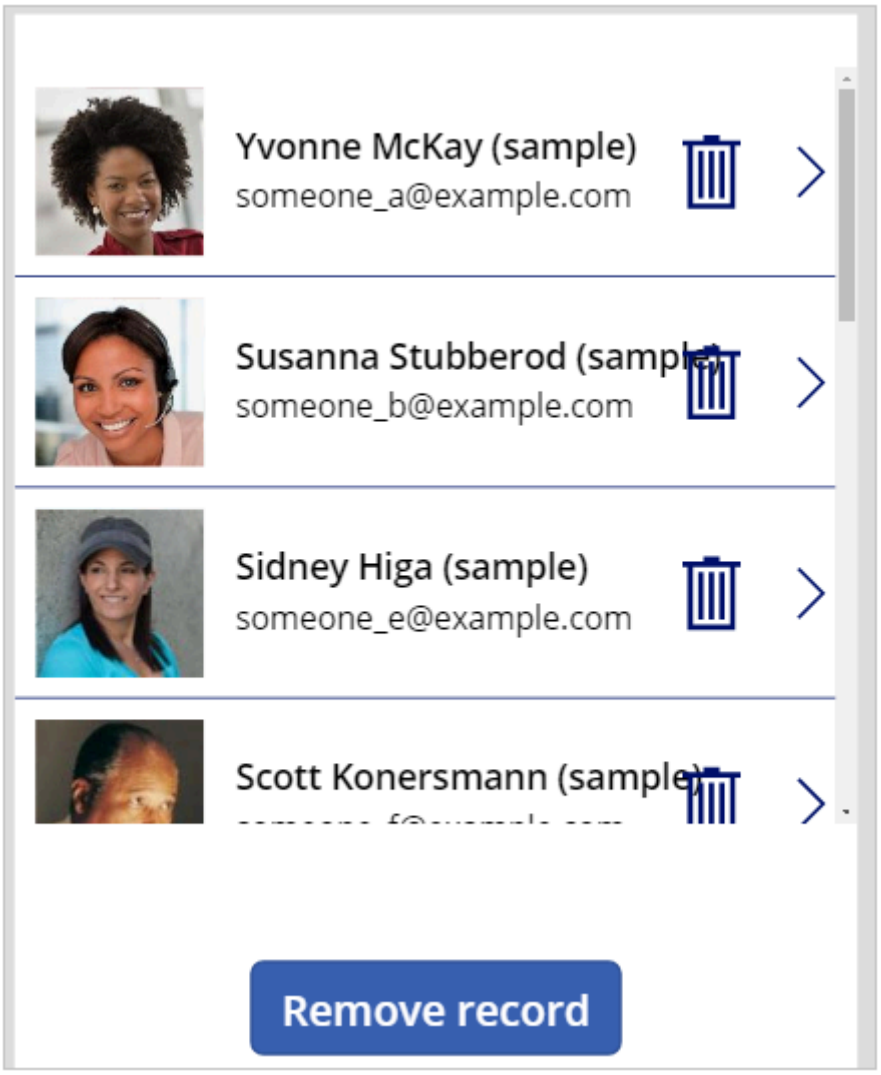


10. Preview the app using the *Play* button on the top right, or press *F5* on keyboard.

11. Select the trash icon next to a record, for example *Maria*'s:



The record is deleted:



12. Close the app preview.

Remove and RemoveIf functions

Article • 10/31/2024

Applies to: Canvas apps Model-driven apps Power Platform CLI

Removes records from a data source.

> **Note**
>
> PAC CLI pac power-fx commands do not support the **RemoveIf** function.

Description

Remove function

Use the **Remove** function to remove a specific record or records from a data source.

For collections, the entire record must match. You can use the **RemoveFlags.All** argument to remove all copies of a record; otherwise, only one copy of the record is removed.

RemoveIf function

Use the **RemoveIf** function to remove a record or records based on a condition or a set of conditions. Each condition can be any formula that results in a **true** or **false** and can reference columns of the data source by name. Each condition is evaluated individually for each record, and the record is removed if all conditions evaluate to **true**.

Remove and **RemoveIf** return the modified data source as a table. You can use both functions only in behavior formulas.

You can also use the **Clear** function to remove all of the records in a collection.

Delegation

RemoveIf is supported by only a few data sources. For data sources that don't upport this feature, Power Apps will query the server and retrieve all data matching the filter expression, up to a maximum of either 500 or 2000 records or the data page size. Subsequently, it will delete each of those records individually by making separate calls to the server.

Syntax

Remove(*DataSource*, *Record1* [, *Record2*, ...] [, **RemoveFlags.All**])

- *DataSource* – Required. The data source that contains the record or records that you want to remove.
- *Record(s)* – Required. The record or records to remove.
- **RemoveFlags.All** – Optional. In a collection, the same record may appear more than once. You can add the **RemoveFlags.All** argument to remove all copies of the record.

Remove(*DataSource*, *Table* [, **RemoveFlags.All**])

- *DataSource* – Required. The data source that contains the records that you want to remove.
- *Table* – Required. A table of records to remove.
- **RemoveFlags.All** – Optional. In a collection, the same record may appear more than once. You can add the **RemoveFlags.All** argument to remove all copies of the record.

RemoveIf(*DataSource*, *Condition* [, ...])

- *DataSource* – Required. The data source that contains the record or records that you want to remove.
- *Condition(s)* – Required. A formula that evaluates to **true** for the record or records to remove. You can use column names from the *DataSource* in the formula. If you specify multiple *Conditions*, all must evaluate to **true** for the record or records to be removed.

Examples - single formulas

In these examples, you'll remove a record or records in a data source that's named **IceCream** and that starts with the data in this table:

ID	Flavor	Quantity
1	"Chocolate"	100
2	"Vanilla"	200
3	"Strawberry"	300

Create a collection with sample records

To create a collection with this data:

1. Insert a **Button** control.

2. Set button control's **OnSelect** property to the below formula:

```
Power Fx
```

```
ClearCollect( IceCream,
              { ID: 1, Flavor: "Chocolate",  Quantity: 100 },
              { ID: 2, Flavor: "Vanilla",    Quantity: 200 },
              { ID: 3, Flavor: "Strawberry", Quantity: 300 }
)
```

3. Select the button while holding down the Alt key:

Remove sample records from collection using a formula

Expand table

Formula	Description	Result
Remove(IceCream, LookUp(IceCream, Flavor="Chocolate"))	Removes the **Chocolate** record from the data source.	 The **IceCream** data source has been modified.
Remove(IceCream, LookUp(IceCream, Flavor="Chocolate"), LookUp(IceCream, Flavor="Strawberry"))	Removes two records from the data source.	 The **IceCream** data source has been modified.
RemoveIf(IceCream, Quantity > 150)	Removes records that have a **Quantity** that's greater than **150**.	 The **IceCream** data source has been modified.
RemoveIf(IceCream, Quantity > 150, Left(Flavor, 1) = "S")	Removes records that have a **Quantity** that's greater than 150 and **Flavor** starts with an **S**.	 The **IceCream** data source has been modified.

Formula	Description	Result
RemoveIf(IceCream, true)	Removes all records from the data source.	ID Flavor Quantity The **IceCream** data source has been modified.

Examples - remove button outside a gallery

In this example, you'll use a **Gallery** control to list the records in a table. And then use the **Remove** function to selectively remove an item.

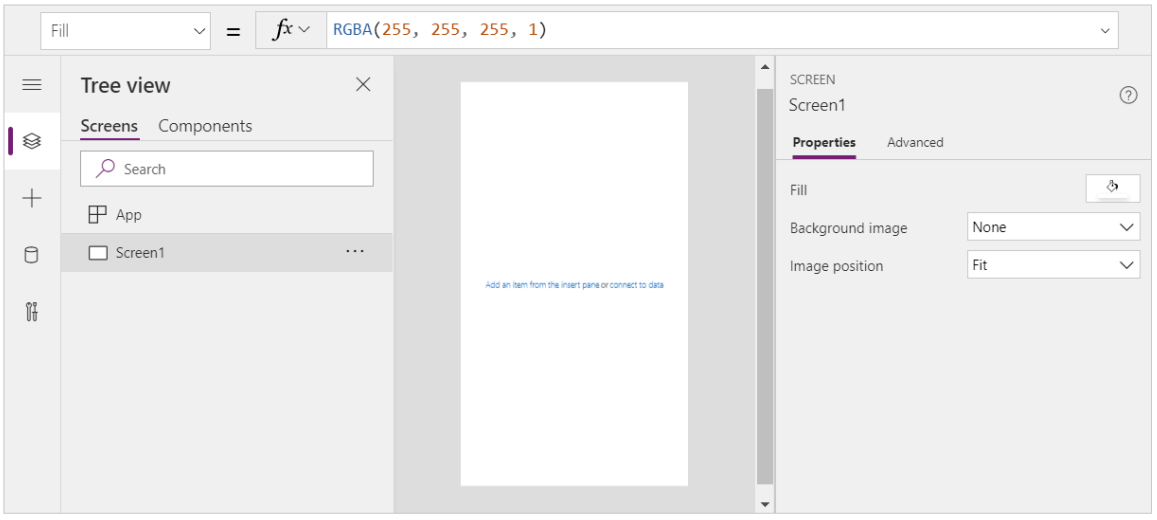
Prepare for sample data

This example uses the **Contacts** table in Microsoft Dataverse available with the *sample apps and data*. You can deploy *sample apps and data* when you create an environment. You can also use any other data source instead.

Remove button outside a gallery

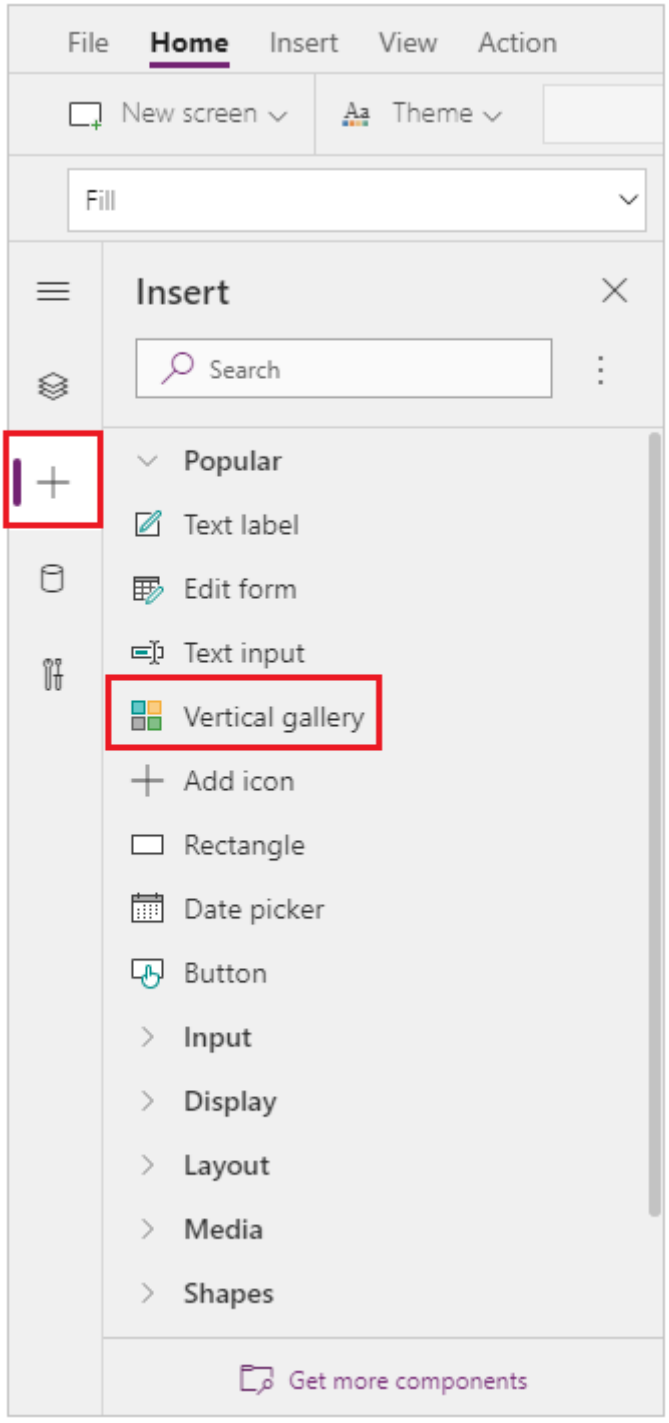
In this example, you'll remove an item by using a *button* that is outside the gallery.

1. Create a new blank canvas app using a Phone layout.

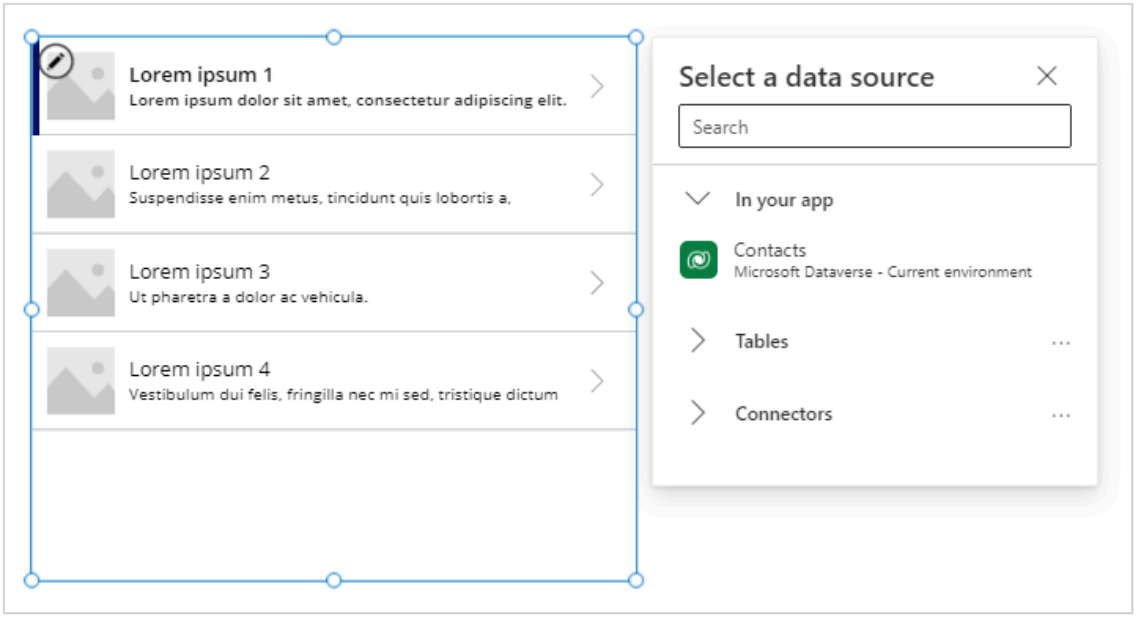


2. Select the **Insert** from the left pane.

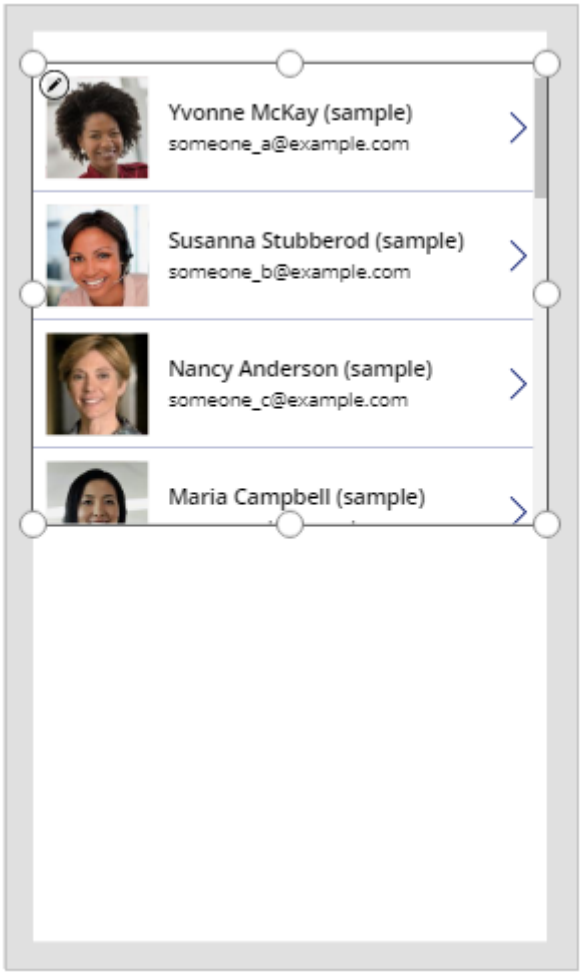
3. Select **Vertical gallery**.
   A **Gallery** control is be added to your screen.



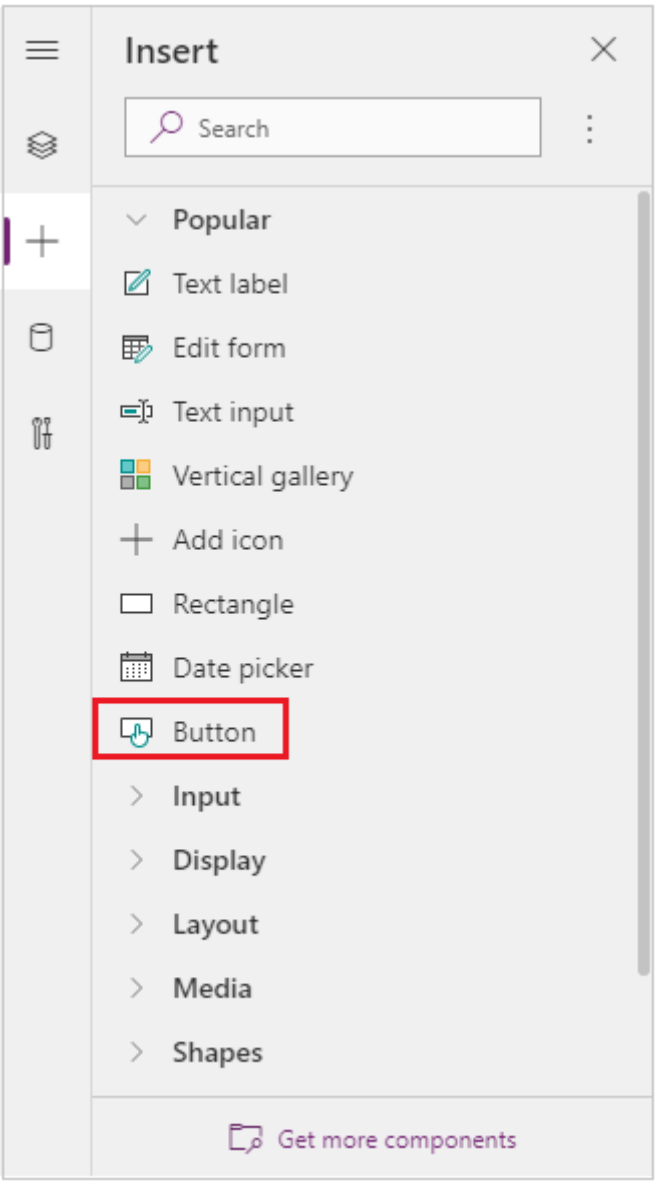
4. You're prompted to select a data source where you can select a data source from the available data sources.
   For example, select the **Contacts** table to use *sample data*:



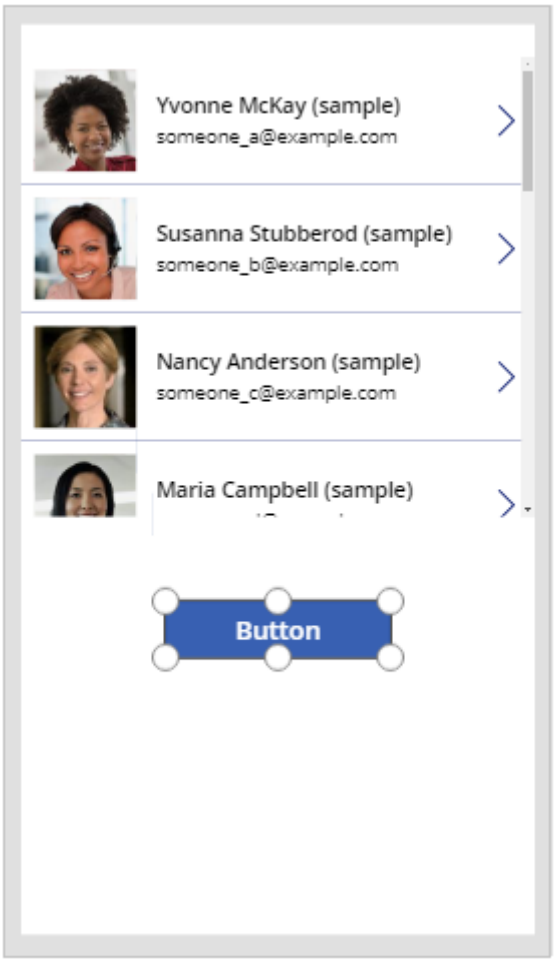
The gallery shows items from this table:



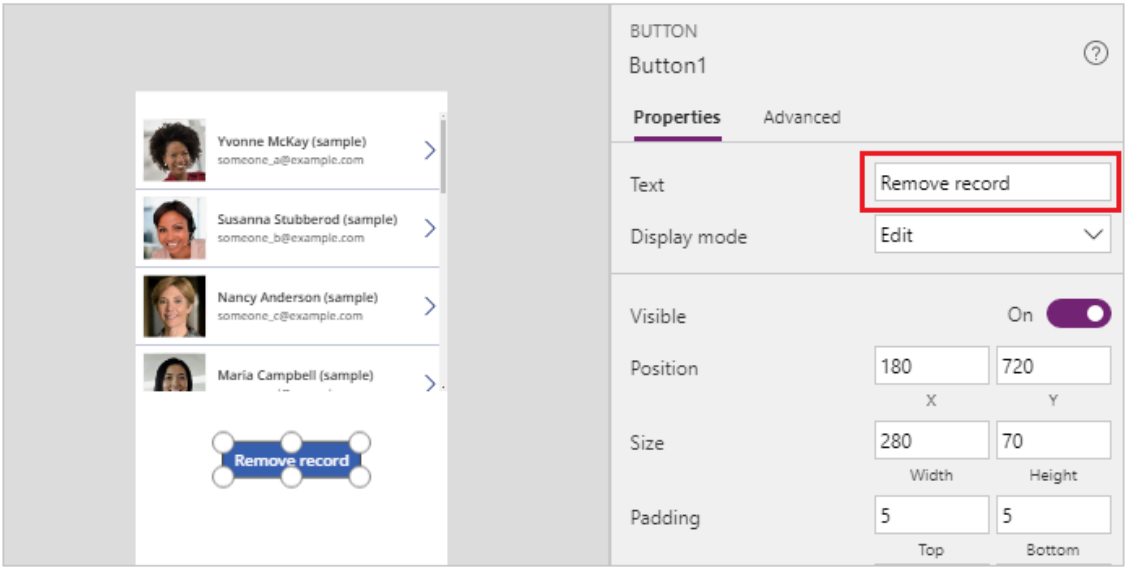
5. Insert a **Button** control from left pane:



6. Move the added button below the gallery items:



7. Update button text property to *Remove record*. You can also use text of your choice:



8. Set the **OnSelect** property for this button control to the following formula:

```
Power Fx

Remove( Contacts, Gallery1.Selected )
```

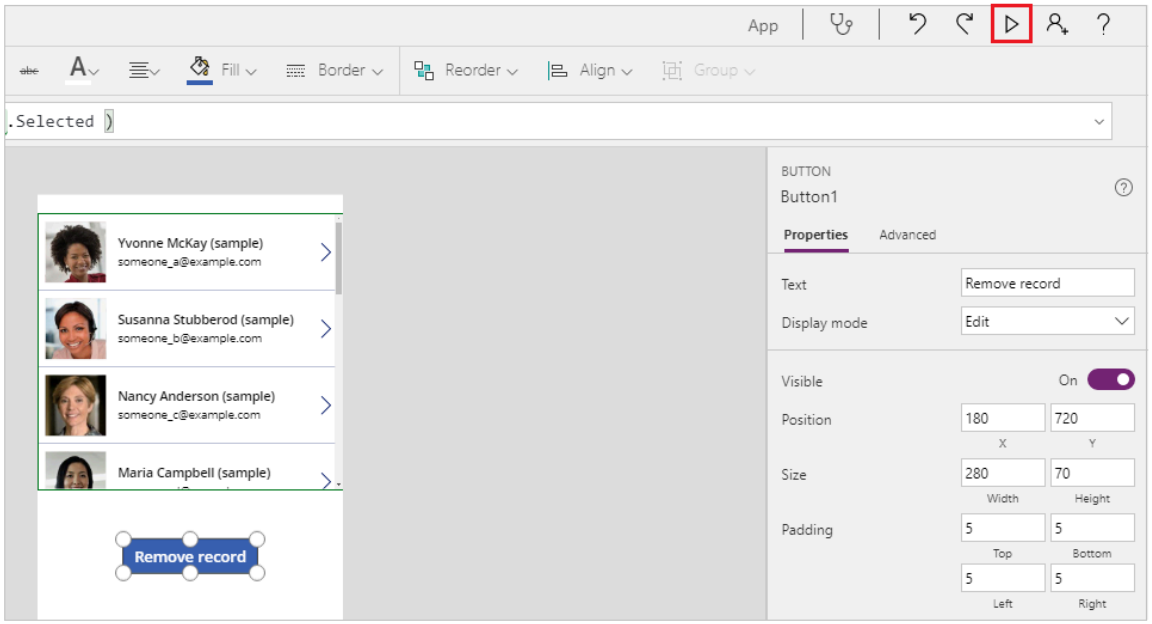
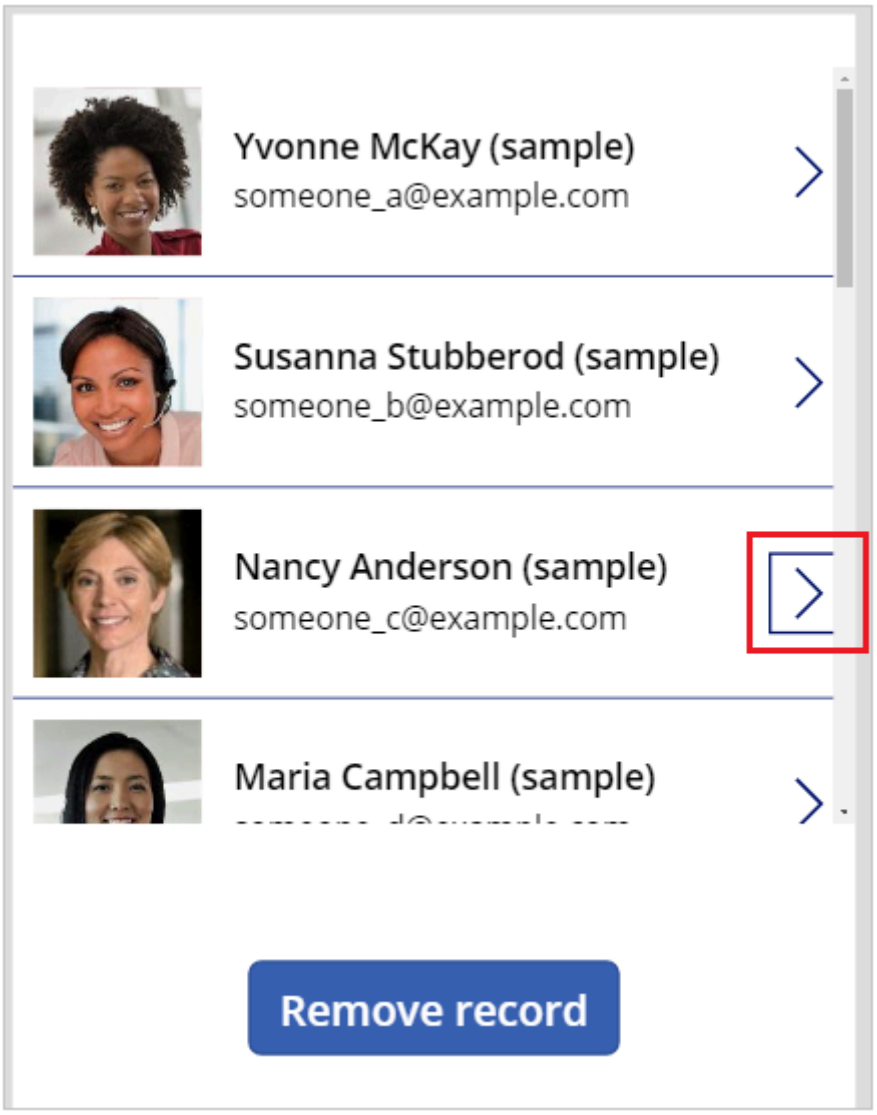
The gallery control makes the currently selected record available using **Selected** property. **Remove** function refers to this selected record to remove it.

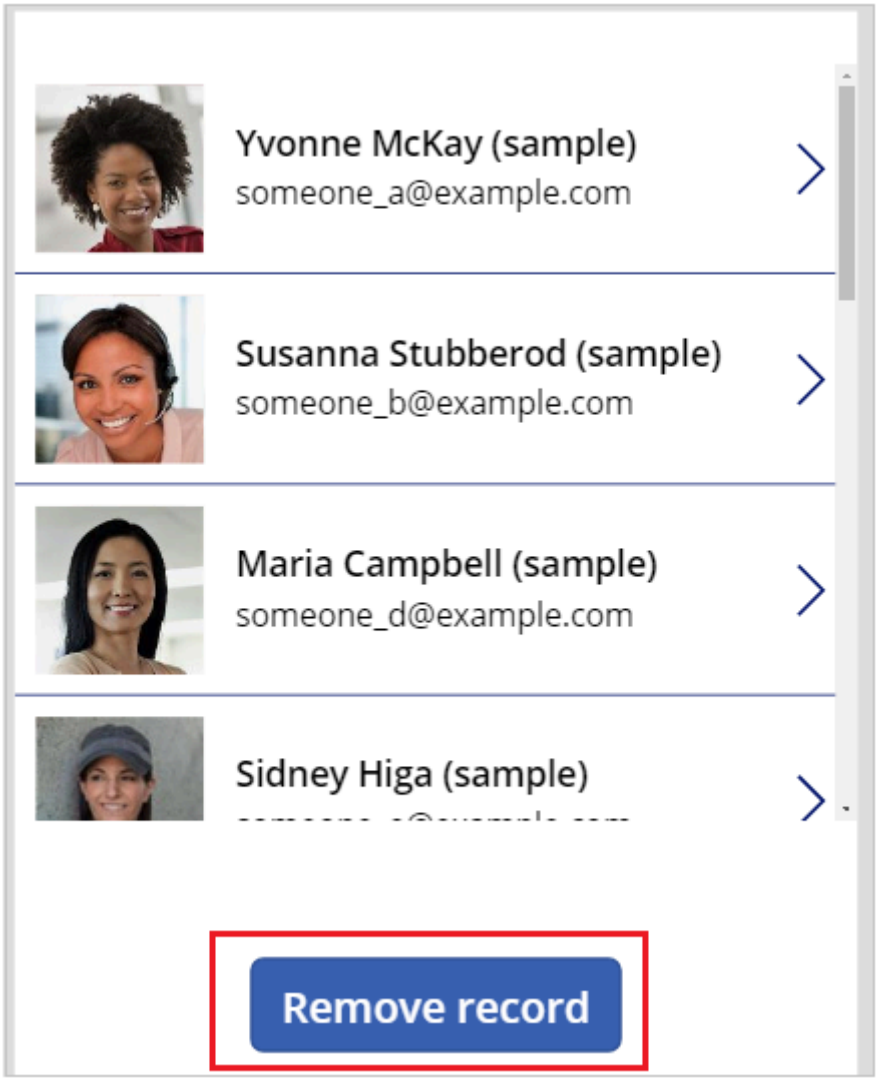
9. Preview the app using the *Play* button on the top right, or press *F5* on keyboard:



10. Select a record to remove, such as *Nancy*'s record in this example:



11. Select **Remove record**:



Selecting the button removes the selected record (in this example, Nancy's record).

12. Close the app preview.

> **Tip**
>
> You can also use alternate behavior with ***Alt key*** instead of using the app preview with *Play* button or *F5*.

Examples - trash can icon inside a gallery

In this example, you'll remove an item by using an *icon* placed inside the gallery.

Create a collection with sample data

If you already have prepared sample data, skip this step and move to Trash can icon inside a gallery.

1. Add a **Button** control to your screen.

2. Set the **OnSelect** property to the following formula:

```
Power Fx
```

```
ClearCollect( SampleContacts,
      { 'Full Name': "Yvonne McKay (sample)",      'Primary Email':
"someone_a@example.com" },
      { 'Full Name': "Susanna Stubberod (sample)", 'Primary Email':
"someone_b@example.com" },
      { 'Full Name': "Nancy Anderson (sample)",    'Primary Email':
"someone_c@example.com" },
      { 'Full Name': "Maria Campbell (sample)",    'Primary Email':
"someone_d@example.com" },
      { 'Full Name': "Robert Lyon (sample)",       'Primary Email':
"someone_e@example.com" },
      { 'Full Name': "Paul Cannon (sample)",       'Primary Email':
"someone_f@example.com" },
      { 'Full Name': "Rene Valdes (sample)",       'Primary Email':
"someone_g@example.com" }
)
```

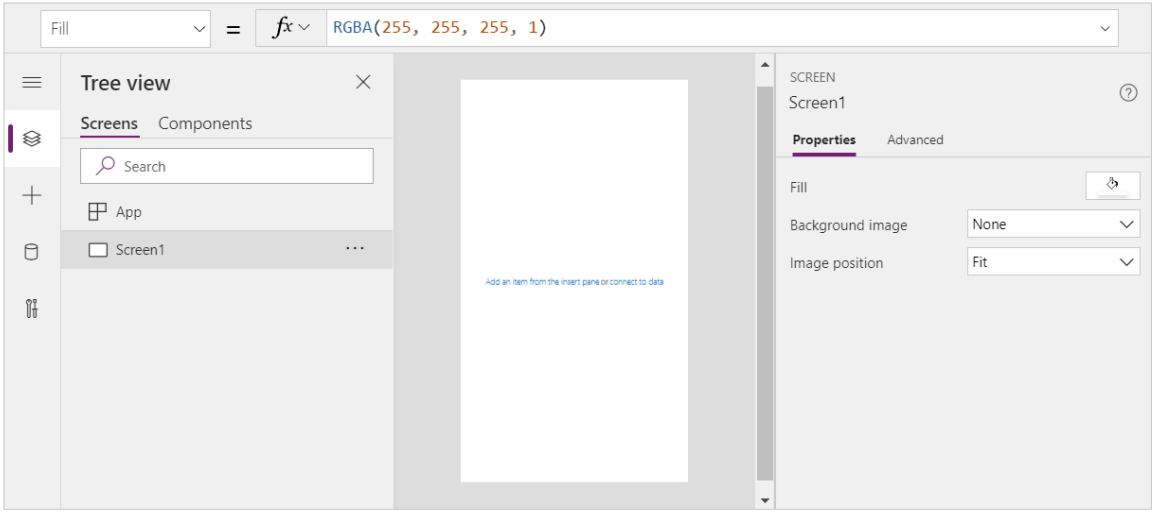
3. Select the button while holding down the Alt key.

Sample collection is created that you can use in the following example.

Trash can icon inside a gallery

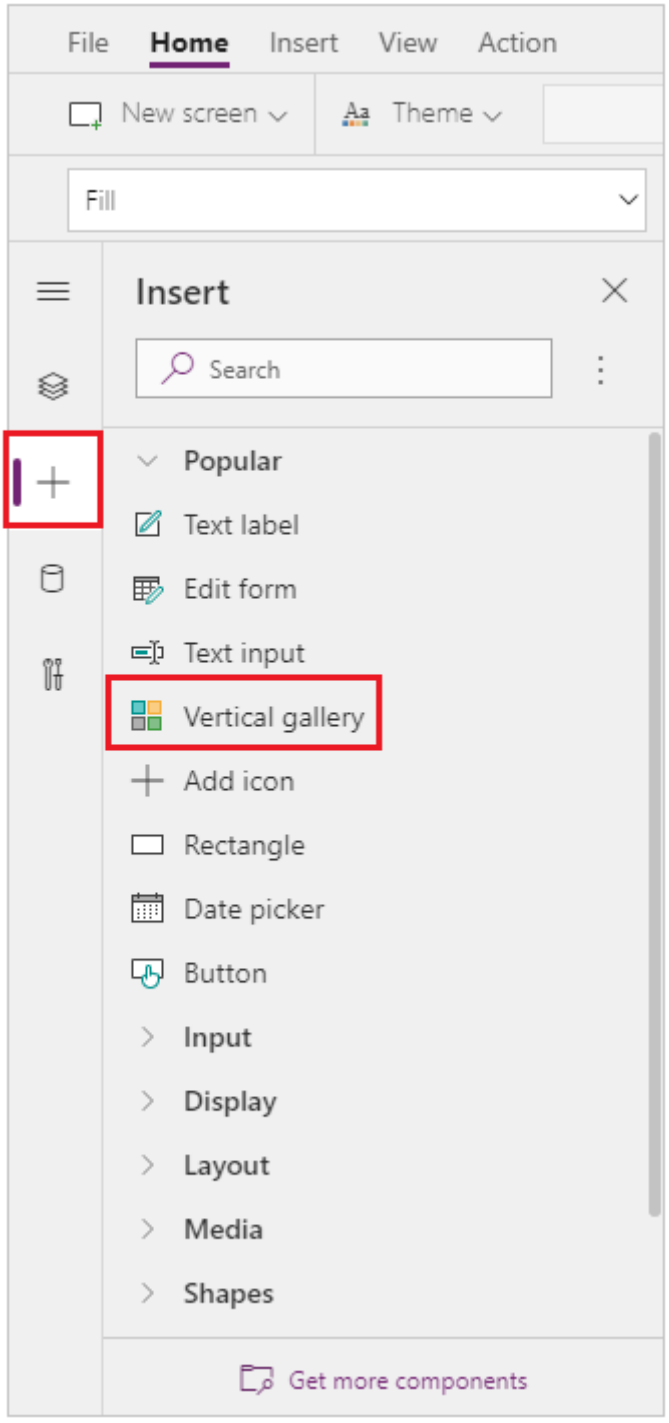
1. Create a new blank canvas app using a Phone layout.



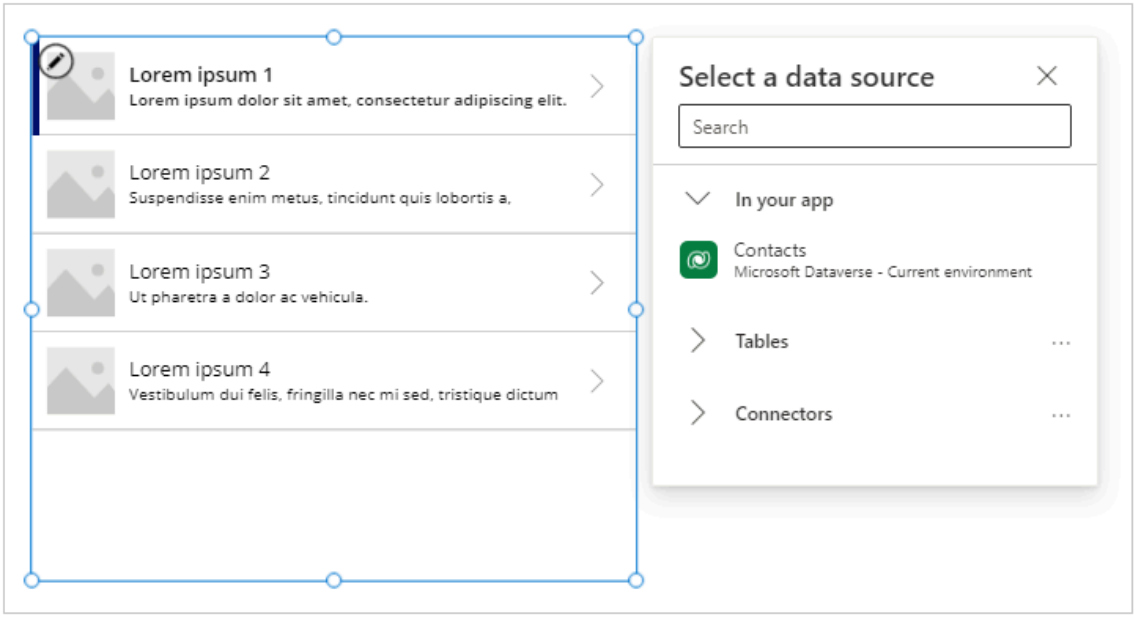
2. Select the **Insert** from the left pane.

3. Select **Vertical gallery**.

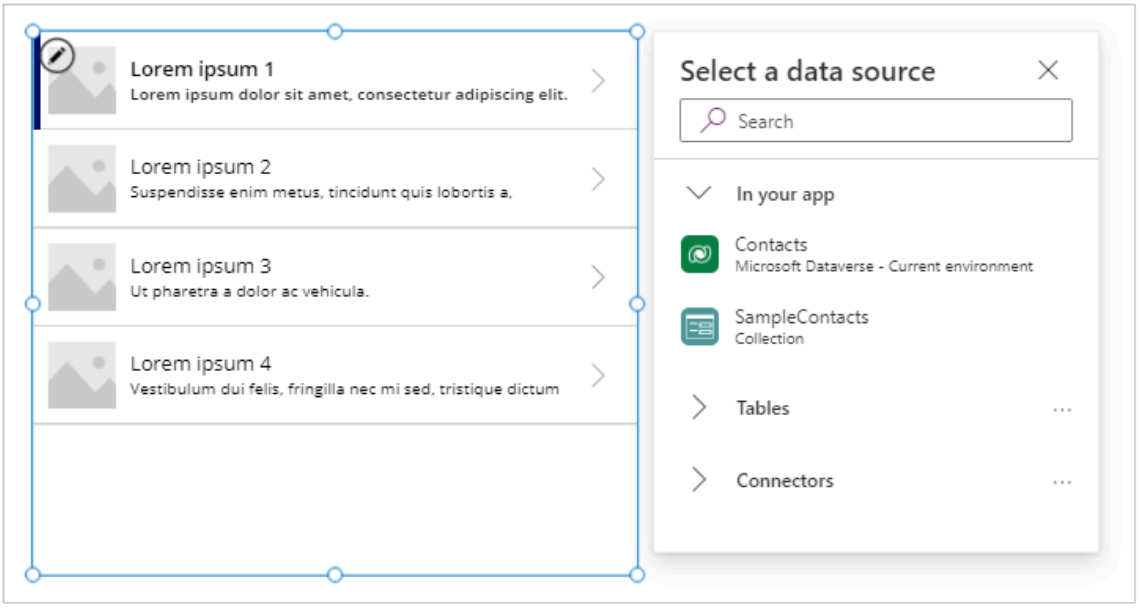
   A **Gallery** control is be added to your screen.



4. You're prompted to select a data source where you can select a data source from the available data sources.
   For example, select the **Contacts** table to use *sample data*:

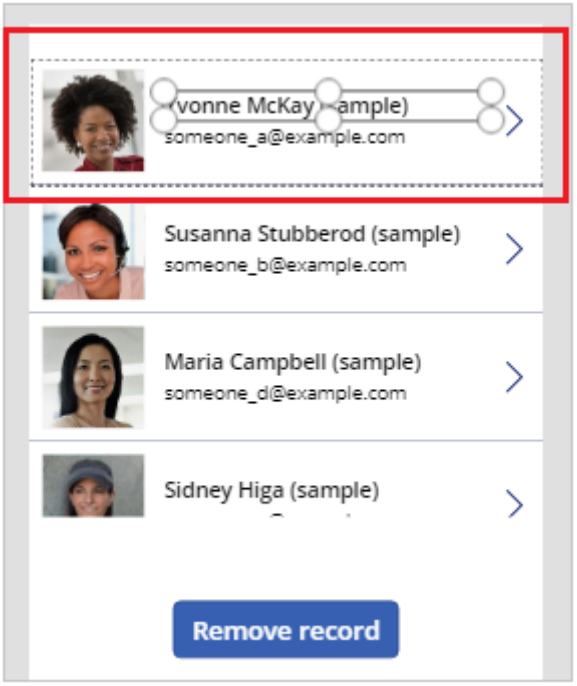


If you created a collection, select your collection instead:

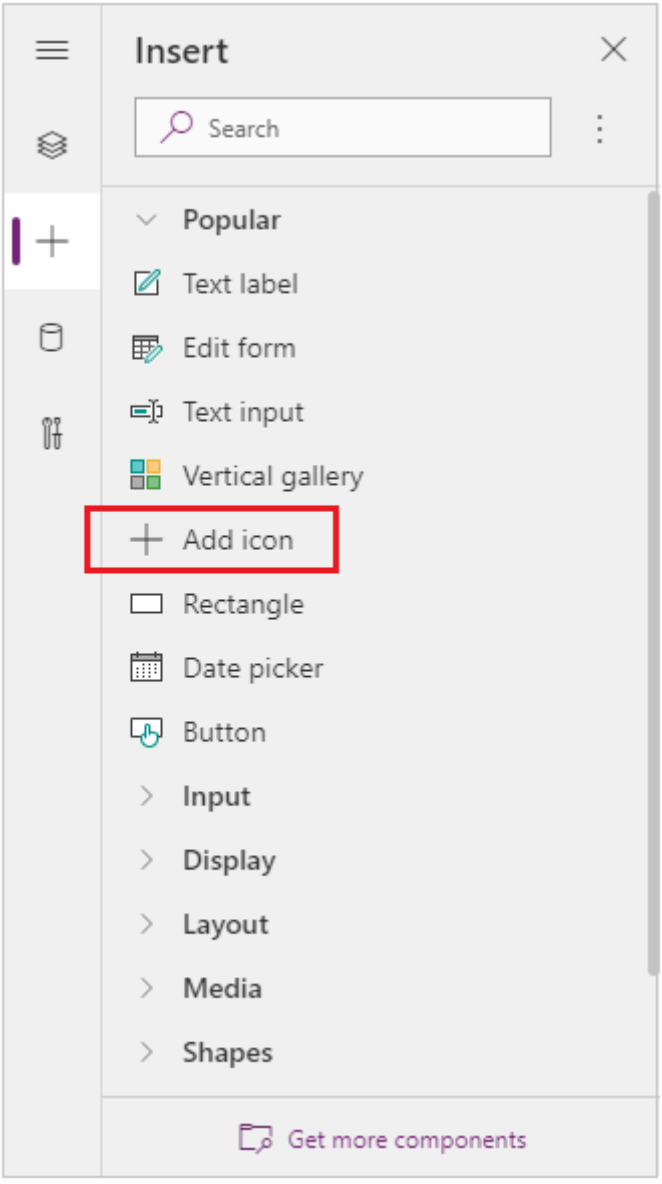


5. Select a control within the top item in the gallery.

   To ensure next step inserts item into gallery's template and not outside the gallery, ensure you follow this step before moving to the next step.

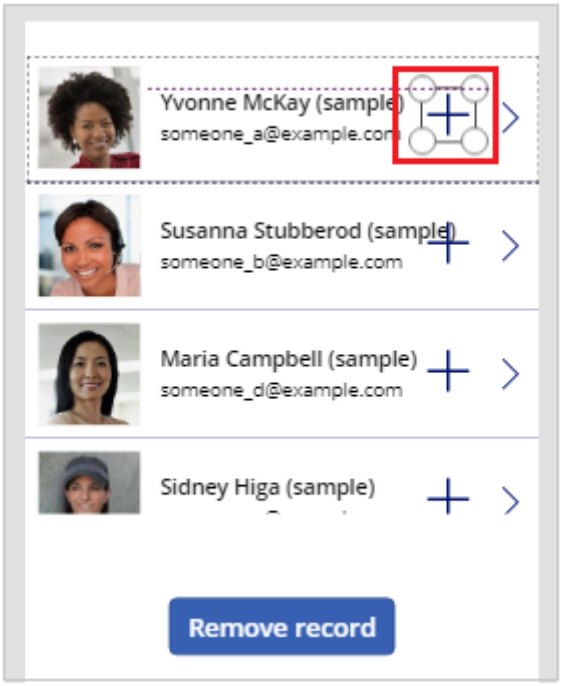


6. Select **Add icon** from left pane.



> ⓘ Note
>
> **Add icon** inserts a + icon on the left side of the gallery, replicated for each item in the gallery.

7. In the top item, move the icon to the right side of the screen.



8. Select the **Icon** property for icon and set it to the following formula to update the icon image as trash icon:

```
Power Fx

Icon.Trash
```

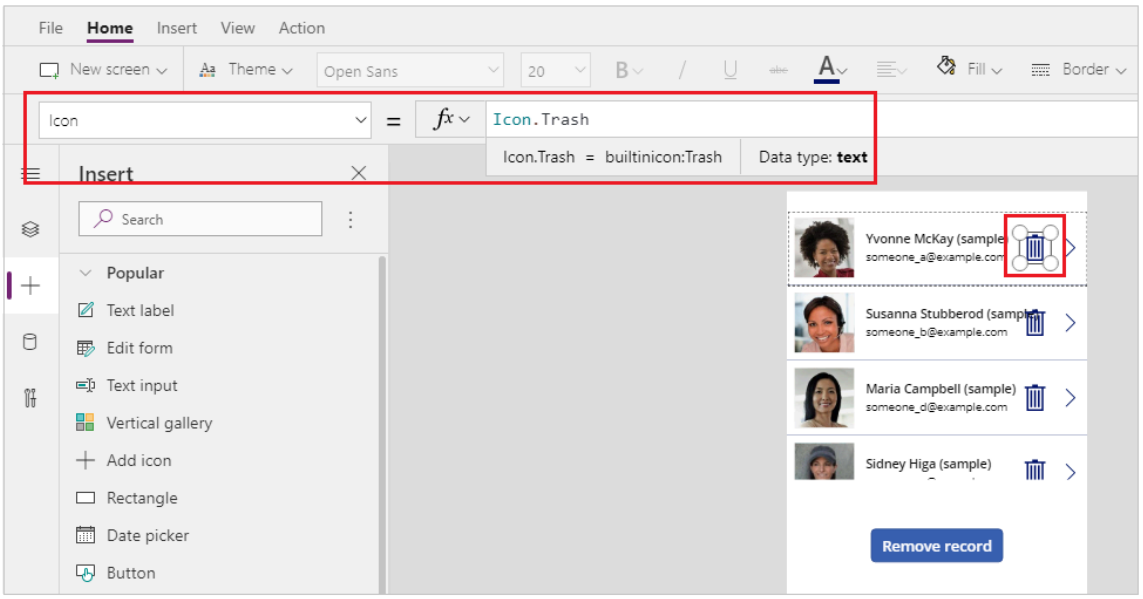
> ⓘ Note
>
> The **Icon.** prefix is only shown when you're actively editing the formula.



9. Set the **OnSelect** property to the following formula:

```
Power Fx

Remove( [@Contacts], ThisItem )
```

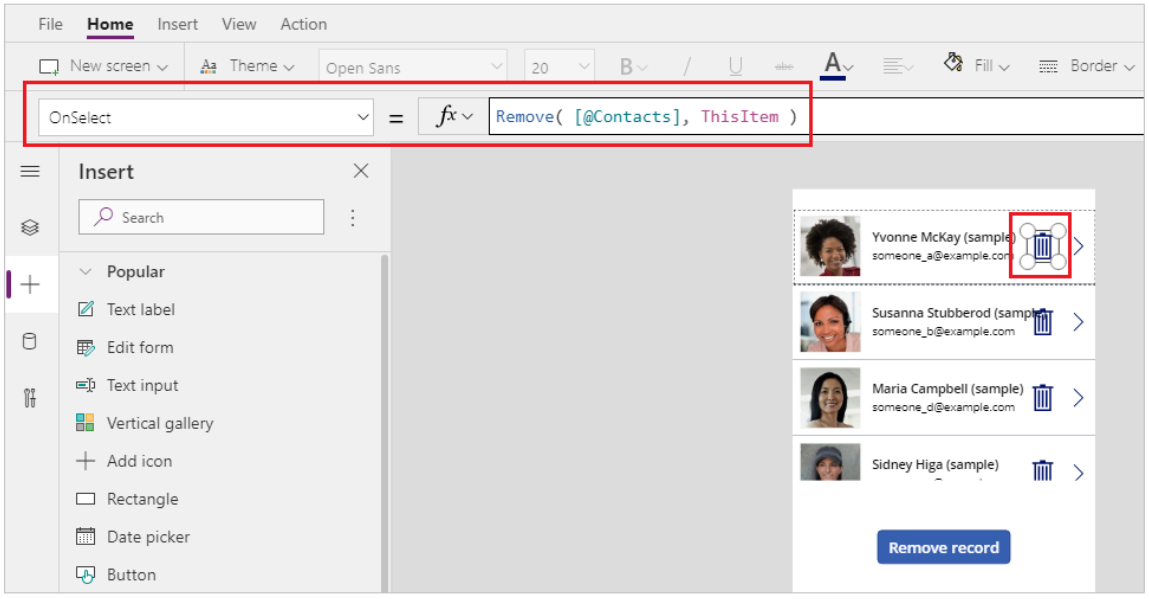
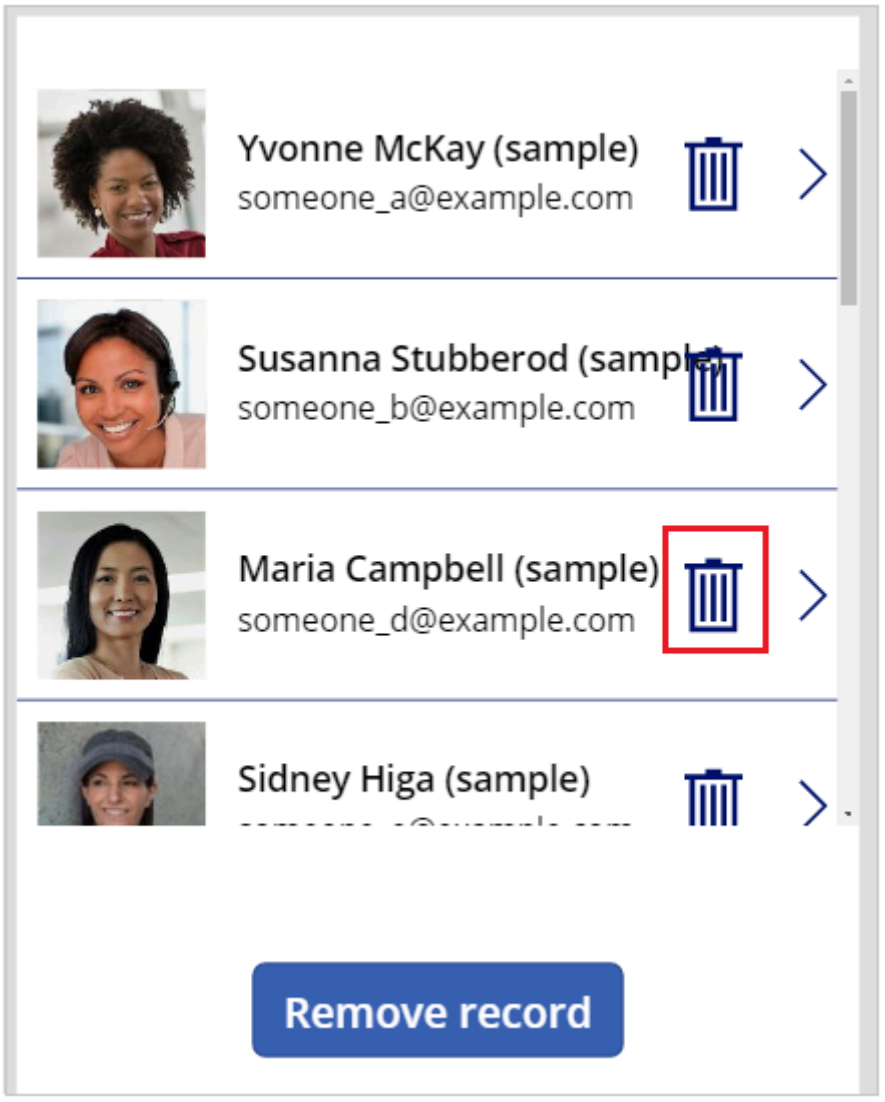
> **Note**
>
> You must use global disambiguation operator [@...] in this example with sample data that uses the *Contacts* table to avoid conflict with a *One-to-Many* relationship. If you use data sources such as a list or a SQL Server table, using *global disambiguation operator* is not required.

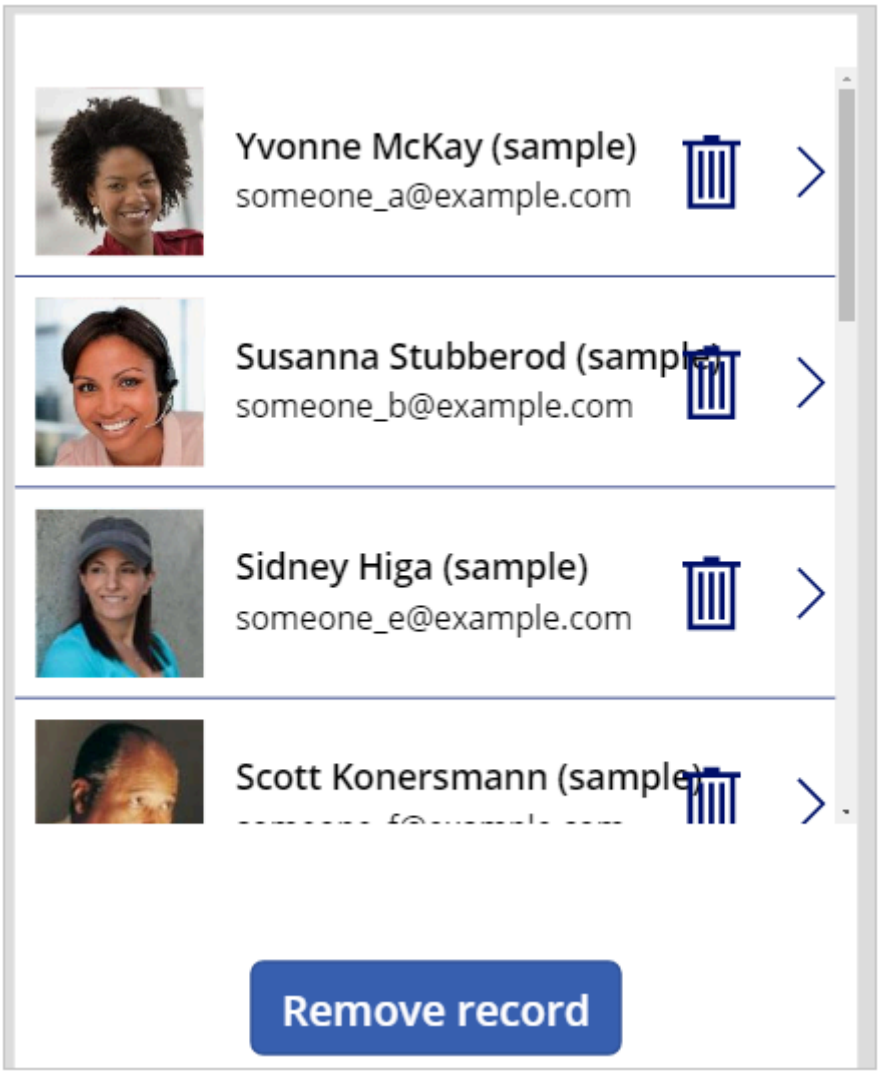


10. Preview the app using the *Play* button on the top right, or press *F5* on keyboard.

11. Select the trash icon next to a record, for example *Maria*'s:



The record is deleted:



12. Close the app preview.

AddColumns, DropColumns, RenameColumns, and ShowColumns functions

06/21/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions

Shapes a table or record by adding, dropping, renaming, and selecting its columns.

The ForAll function can also be used to shape a table, by returning a table of new records created from existing columns.

Overview

These functions shape a table or record by adjusting its columns:

- Reduce a table or record that contains multiple columns down to a single column for use with single-column functions, such as **Lower** or **Sqrt**.
- Add a calculated column to a table or record (for example, a **Total Price** column that shows the results of multiplying **Quantity** by **Unit Price**).
- Rename a column to something more meaningful, for display to users or for use in formulas.

A table is a value in Power Apps, just like a string or a number. You can specify a table as an argument in a formula, and functions can return a table as a result.

> **Note**
>
> The functions that this topic describes don't modify the original table. Instead, they take that table as an argument and return a new table with a transform applied. For more information, see working with tables.

You can't modify the columns of a data source by using these functions. You must modify the data at its source. You can add columns to a collection with the **Collect** function. For more information, see working with data sources.

Description

The **AddColumns** function adds a column to a table or record, and a formula defines the values in that column. Existing columns remain unmodified.

The formula is evaluated for the provided record, or for each record of the provided table.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

The **DropColumns** function excludes columns from a table or record. All other columns remain unmodified. **DropColumns** excludes columns, and **ShowColumns** includes columns.

Use the **RenameColumns** function to rename one or more columns of a table or record by providing at least one argument pair that specifies the name of a column that the table or record contains (the old name, which you want to replace) and the name of a column that the table or record doesn't contain (the new name, which you want to use). The old name must already exist in the table or record, and the new name must not exist. Each column name may appear only once in the argument list as either an old column name or a new column name. To rename a column to an existing column name, first drop the existing column with **DropColumns**, or rename the existing column out of the way by nesting one **RenameColumns** function within another.

The **ShowColumns** function includes columns of a table or record and drops all other columns. You can use **ShowColumns** to create a single-column table or record from a multi-column table or record. **ShowColumns** includes columns, and **DropColumns** excludes columns.

For all these functions, the result is a new table or record with the transform applied. The original table or record isn't modified. You can't modify an existing table or record with a formula. SharePoint, Microsoft Dataverse, SQL Server, and other data sources provide tools for modifying the columns of lists and tables, which are often referred to as the schema. The functions in this topic only transform an input table or record, without modifying the original, into an output table or record for further use.

The arguments to these functions support delegation. For example, a **Filter** function used as an argument to pull in related records searches through all listings, even if the '**[dbo].[AllListings]**' data source contains a million rows:

Power Fx

```
AddColumns( RealEstateAgents,
   Listings,
```

```
    Filter(  '[dbo].[AllListings]', ListingAgentName = AgentName )
)
```

However, the output of these functions is subject to the non-delegation record limit. In this example, only 500 records are returned even if the **RealEstateAgents** data source has 501 or more records.

If you use **AddColumns** in this manner, **Filter** must make separate calls to the data source for each of those first records in **RealEstateAgents**, which causes lots of network chatter. If **[dbo](.[AllListings]** is small enough and doesn't change often. You can call the **Collect** function in OnStart to cache the data source in your app when it starts. As an alternative, you could restructure your app so that you pull in the related records only when the user asks for them.

> **Note**
>
> In Power Apps prior to version 3.24042, column names were specified with a text string using double quotes, and if connected to a data source they also needed to be logical names. For example, the logical name **"cr43e_name"** with double quotes was used instead of the display name **Name** without quotes. For SharePoint and Excel data sources that contain column names with spaces, each space was specified with **"_x0020_"**, for example **"Column Name"** as **"Column_x0020_Name"**. After this version, all apps were automatically updated to the new syntax described in this article.

Syntax

AddColumns(*TableOrRecord*, *ColumnName1*, *Formula1* [, *ColumnName2*, *Formula2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.
- *ColumnName(s)* - Required. Names of the columns to add.
- *Formula(s)* - Required. Formulas to evaluate for each record. The result is added as the value of the corresponding new column. You can reference other columns of the table or record in this formula.

DropColumns(*TableOrRecord*, *ColumnName1* [, *ColumnName2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.
- *ColumnName(s)* - Required. Names of the columns to drop.

RenameColumns(*TableOrRecord*, *OldColumnName1*, *NewColumnName1* [, *OldColumnName2*, *NewColumnName2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.

- *OldColumnName(s)* - Required. Names of the columns to rename from the original table or record. This element appears first in the argument pair (or first in each argument pair if the formula includes more than one pair).
- *NewColumnName(s)* - Required. Replacement names. This element appears last in the argument pair (or last in each argument pair if the formula includes more than one pair).

ShowColumns(*TableOrRecord*, *ColumnName1* [, *ColumnName2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.
- *ColumnName(s)* - Required. Names of the columns to include.

Examples

The examples in this section use the **IceCreamSales** data source, which contains the data in this table:

Flavor	UnitPrice	QuantitySold
"Strawberry"	1.99	20
"Chocolate"	2.99	45
"Vanilla"	1.50	35

None of these examples modify the **IceCreamSales** data source. Each function transforms the value of the data source as a table and returns that value as the result.

Expand table

Formula	Description	Result
AddColumns(IceCreamSales, Revenue, UnitPrice * QuantitySold)	Adds a **Revenue** column to the result. For each record, **UnitPrice * QuantitySold** is evaluated, and the result is placed in the new column.	
DropColumns(IceCreamSales, UnitPrice)	Excludes the **UnitPrice** column from the result. Use this function to exclude columns, and use **ShowColumns** to include them.	ShowColumns(IceCreamSales, Flavor)	Includes only the **Flavor** column in the result. Use this function include columns, and use **DropColumns** to exclude them.	
RenameColumns(IceCreamSales, UnitPrice, Price)	Renames the **UnitPrice** column in the result.	

Formula	Description	Result
RenameColumns(IceCreamSales, UnitPrice, Price, QuantitySold, Number)	Renames the **UnitPrice** and **QuantitySold** columns in the result.	<table><tr><th>Flavor</th><th>Price</th><th>Number</th></tr><tr><td>"Strawberry"</td><td>1.99</td><td>20</td></tr><tr><td>"Chocolate"</td><td>2.99</td><td>45</td></tr><tr><td>"Vanilla"</td><td>1.50</td><td>35</td></tr></table>
DropColumns(RenameColumns(AddColumns(IceCreamSales, Revenue, UnitPrice * QuantitySold), UnitPrice, Price), Quantity)	Performs the following table transforms in order, starting from the inside of the formula: 1. Adds a **Revenue** column based on the per record calculation of **UnitPrice * Quantity**. 2. Renames **UnitPrice** to **Price**. 3. Excludes the **Quantity** column. Order is important, for example we can't calculate with **UnitPrice** after it's renamed.	<table><tr><th>Flavor</th><th>Price</th><th>Revenue</th></tr><tr><td>"Strawberry"</td><td>1.99</td><td>39.80</td></tr><tr><td>"Chocolate"</td><td>2.99</td><td>134.55</td></tr><tr><td>"Vanilla"</td><td>1.49</td><td>52.15</td></tr></table>

Step by step

Let's try some of the examples from earlier in this article.

1. Create a collection by adding a **Button** control and setting its **OnSelect** property to this formula:

   Power Fx

   ```
   ClearCollect( IceCreamSales,
      Table(
          { Flavor: "Strawberry", UnitPrice: 1.99, QuantitySold: 20 },
          { Flavor: "Chocolate", UnitPrice: 2.99, QuantitySold: 45 },
          { Flavor: "Vanilla", UnitPrice: 1.50, QuantitySold: 35 }
      )
   )
   ```

2. Run the formula by selecting the button while holding down the Alt key.

3. Add a second **Button** control, set its **OnSelect** property to this formula, and then run it:

   Power Fx

   ```
   ClearCollect( FirstExample,
      AddColumns( IceCreamSales, Revenue, UnitPrice * QuantitySold )
   )
   ```

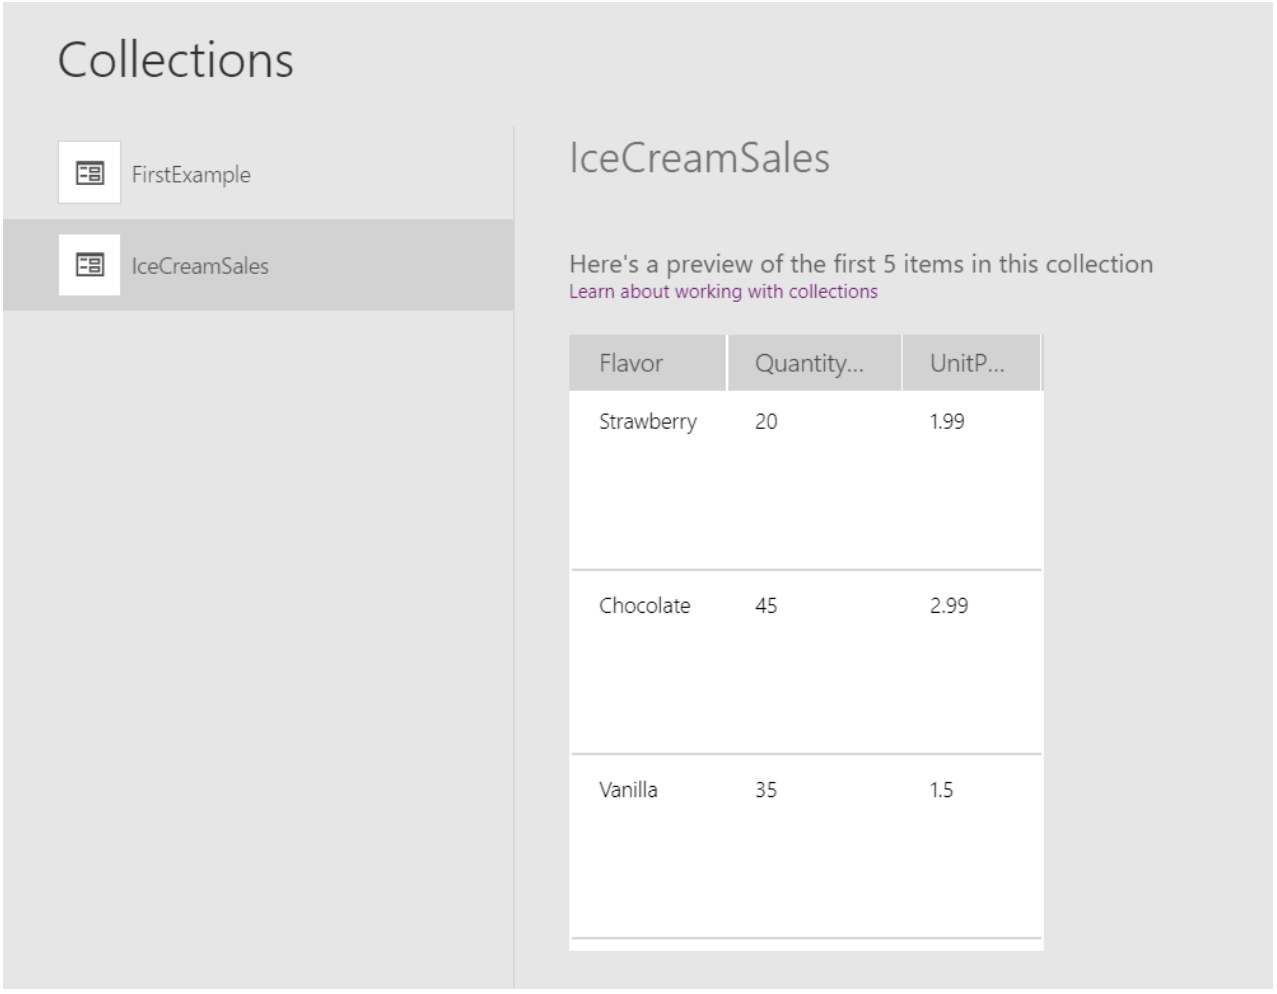
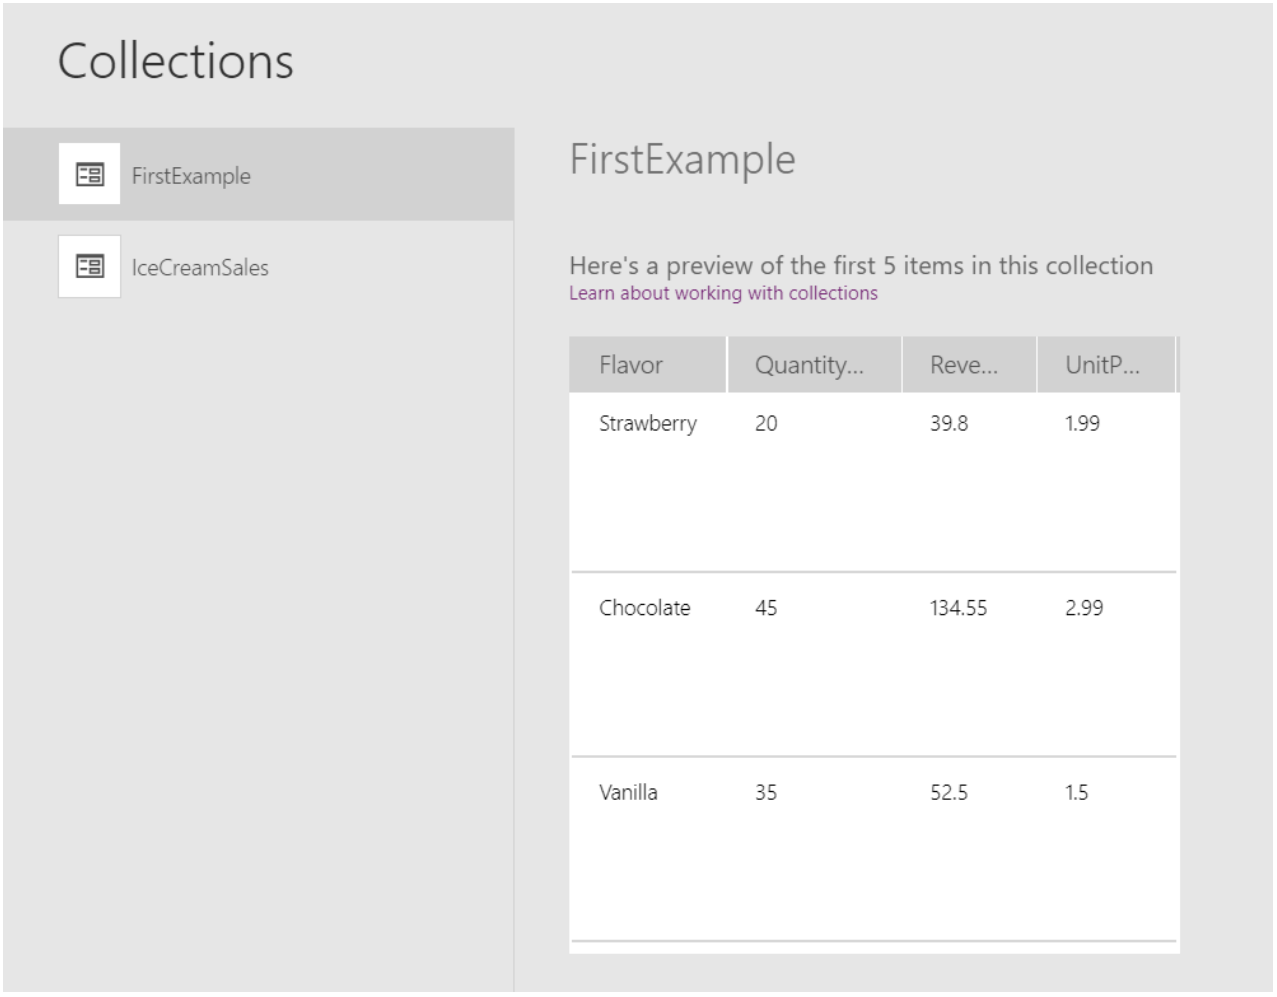
4. On the **File** menu, select **Collections**, and then select **IceCreamSales** to show that collection.

As this graphic shows, the second formula didn't modify this collection. The **AddColumns** function used **IceCreamSales** as a read-only argument; the function didn't modify the table to which that argument refers.



5. Select **FirstExample**.

   As this graphic shows, the second formula returned a new table with the added column. The **ClearCollect** function captured the new table in the **FirstExample** collection, adding something to the original table as it flowed through the function without modifying the source:



Map columns in a component

See Map columns.

Replace and Substitute functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Dataverse formula columns ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Replace a portion of a string of text with another string.

Description

The **Replace** function identifies the text to replace by starting position and length.

The **Substitute** function identifies the text to replace by matching a string. If more than one match is found, you can replace all of them or specify one to replace.

If you pass a single string, the return value is the modified string. If you pass a single-column table that contains strings, the return value is a single-column table with a **Value** column of modified strings. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

Syntax

Replace(*String*, *StartingPosition*, *NumberOfCharacters*, *NewString*)

- *String* - Required. The string to operate on.
- *StartingPosition* - Required. Character position to start the replacement. The first character of *String* is at position 1.
- *NumberOfCharacters* - Required. The number of characters to replace in *String*.
- *NewString* - Required. The replacement string. The number of characters in this argument can differ from the *NumberOfCharacters* argument.

Substitute(*String*, *OldString*, *NewString* [, *InstanceNumber*])

- *String* - Required. The string to operate on.
- *OldString* - Required. The string to replace.
- *NewString* - Required. The replacement string. *OldString* and *NewString* can have different lengths.
- *InstanceNumber* - Optional. Use this argument to specify which instance of *OldString* to replace if *String* contains more than one instance. If you don't specify this argument, all instances will be replaced.

Replace(*SingleColumnTable*, *StartingPosition*, *NumberOfCharacters*, *NewString*)

- *SingleColumnTable* - Required. A single-column table of strings to operate on.
- *StartingPosition* - Required. Character position to start the replacement. The first character of each string in the table is at position 1.
- *NumberOfCharacters* - Required. The number of characters to replace in each string.
- *NewString* - Required. The replacement string. The number of characters in this argument can differ from the *NumberOfCharacters* argument.

Substitute(*SingleColumnTable*, *OldString*, *NewString* [, *InstanceNumber*])

- *SingleColumnTable* - Required. A single-column table of strings to operate on.
- *OldString* - Required. The string to replace.
- *NewString* - Required. The replacement string. *OldString* and *NewString* can have different lengths.
- *InstanceNumber* - Optional. Use this argument to specify which instance of *OldString* to replace if *String* contains more than one instance. If you don't specify this argument, all instances will be replaced.

Examples

Expand table

Formula	Description	Result
Replace("abcdefghijk", 6, 5, "*")	Replaces five characters in "abcdefghijk" with a single "*" character, starting with the sixth character ("f").	"abcde*k"
Replace("2019", 3, 2, "20")	Replaces the last two characters of "2019" with "20".	"2020"
Replace("123456", 1, 3, "_")	Replaces the first three characters of "123456" with a single "_" character.	"_456"
Substitute("Sales Data", "Sales", "Cost")	Substitutes the string "Cost" for "Sales".	"Cost Data"
Substitute("Quarter 1, 2018", "1", "2", 1)	Substitutes only the first instance of "1" with "2" because the fourth argument	"Quarter 2, 2018"

Formula	Description	Result
	(*InstanceNumber*) is provided with a 1.	
Substitute("Quarter 1, 2011", "1", "2", 3)	Substitutes only the third instance of "1" with "2" because the fourth argument (*InstanceNumber*) is provided with a 3.	"Quarter 1, 2012"
Substitute("Quarter 1, 2011", "1", "2")	Substitutes all instances of "1" with "2" because the fourth argument (*InstanceNumber*) isn't provided.	"Quarter 2, 2022"
Replace(["Quarter 1, 2018", "Quarter 2, 2011", "Quarter 4, 2019"], 9, 1, "3")	Replaces the ninth character in each record of the single-column table with "3".	A single-column table with a `Value` column containing the following values: ["Quarter 3, 2018", "Quarter 3, 2011", "Quarter 3, 2019"]
Substitute(["Qtr 1, 2018", "Quarter 1, 2011", "Q1, 2019"], "1", "3", 1)	Because the fourth argument (*InstanceNumber*) is provided with a value of 1, substitutes only the first instance of "1" in each record of the single-column table with "3".	A single-column table with a `Value` column containing the following values: ["Qtr 3, 2018", "Quarter 3, 2011", "Q3, 2019"]
Substitute(["Qtr 1, 2018", "Quarter 1, 2011", "Q1, 2019"], "1", "3")	Because the fourth argument (*InstanceNumber*) isn't provided, substitutes all instances of "1" in each record of the single-column table with "3".	A single-column table with a `Value` column containing the following values: ["Qtr 3, 2038", "Quarter 3, 2033", "Q3, 2039"]

Reset function

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

Resets a control to its default value, discarding any user changes.

Description

The **Reset** function resets a control to its **Default** property value. Any user changes are discarded.

You cannot reset controls that are within a **Gallery** or **Edit form** control from outside those controls. You can reset controls from formulas on controls within the same gallery or form. You can also reset all the controls within a form with the **ResetForm** function.

Using the **Reset** function is an alternative to toggling the **Reset** property of input controls and is generally preferred. The **Reset** property may be a better choice if many controls need to be reset together from multiple formulas. Toggling the **Reset** property can be done from a **Button** control with the formula **Reset** = **Button.Pressed** or from a variable with **Reset** = **MyVar** and toggling **MyVar** with the formula **Button.OnSelect** = **Set(MyVar, true); Set(MyVar, false)**.

Input controls are also reset when their **Default** property changes.

Reset has no return value, and you can use it only in behavior formulas.

Syntax

Reset(*Control*)

- *Control* – Required. The control to reset.

Example

1. Insert a **Text input** control on a screen. By default, its name will be **TextInput1** and its **Default** property will be set to **"Text input"**.
2. Type a new value in the text box.
3. Insert a **Button** control on the screen.
4. Set the button's **OnSelect** property to **Reset(TextInput1)**.

5. Select the button. This can be done even when authoring by selecting toward the ends of the control.
6. The contents of the text box will return to the value of the **Default** property.

EditForm, NewForm, SubmitForm, ResetForm, and ViewForm functions

Article • 03/22/2024

Applies to: Canvas apps

View, edit, or create an item, save the contents, and reset the controls in an **Edit form** control.

Overview

These functions change the state of the **Edit form** control. The form control can be in one of these modes:

Expand table

Mode	Description
FormMode.Edit	The form is populated with an existing record and the user can modify the values of the fields. Once complete, the user can save the changes to the record.
FormMode.New	The form is populated with default values and the user can modify the values of the fields. Once complete, the user can add the record to the data source.
FormMode.View	The form is populated with an existing record but the user cannot modify the values of the fields.

Description

These functions are often invoked from the **OnSelect** formula of a **Button** or **Image** control so that the user can save edits, abandon edits, or create a record. You can use controls and these functions together to create a complete solution.

These functions return no values.

You can use these functions only in behavior formulas.

SubmitForm

Use the **SubmitForm** function in the **OnSelect** property of a Button control to save any changes in a Form control to the data source.

Before submitting any changes, this function checks for validation issues with any field that's marked as required or that has one or more constraints on its value. This behavior matches that of the **Validate** function.

SubmitForm also checks the **Valid** property of the Form, which is an aggregation of all the **Valid** properties of the **Card** controls that the Form control contains. If a problem occurs, the data isn't submitted, and the **Error** and **ErrorKind** properties of the Form control are set accordingly.

If validation passes, **SubmitForm** submits the change to the data source.

- If successful, the Form's **OnSuccess** behavior runs, and the **Error** and **ErrorKind** properties are cleared. If the form was in **FormMode.New** mode, it is returned to **FormMode.Edit** mode.
- If unsuccessful, the Form's **OnFailure** behavior runs, and the **Error** and **ErrorKind** properties are set accordingly. The mode of the form is unchanged.

EditForm

The **EditForm** function changes the Form control's mode to **FormMode.Edit**. In this mode, the contents of the Form control's **Item** property are used to populate the form. If the **SubmitForm** function runs when the form is in this mode, a record is changed, not created. **FormMode.Edit** is the default for the Form control.

> ⓘ **Note**
>
> When the form is in edit mode and Item is null, data card properties are not evaluated and will return default values.

NewForm

The **NewForm** function changes the Form control's mode to **FormMode.New**. In this mode, the contents of the Form control's **Item** property are ignored, and the default values of the Form's **DataSource** property populate the form. If the **SubmitForm** function runs when the form is in this mode, a record is created, not changed.

ResetForm

The **ResetForm** function resets the contents of a form to their initial values, before the user made any changes. If the form is in **FormMode.New** mode, the form is reset to **FormMode.Edit** mode. The **OnReset** behavior of the form control also runs. You can also reset individual controls with the **Reset** function but only from within the form.

ViewForm

The **ViewForm** function changes the Form control's mode to **FormMode.View**. In this mode, the contents of the Form control's **Item** property are used to populate the form. The **SubmitForm** and **ResetForm** functions have no effect when in this mode.

DisplayMode Property

The current mode can be read through the **Mode** property. The mode also determines the value of the **DisplayMode** property, which can be used by data cards and controls within the form control. Often, the data card's **DisplayMode** property will be set to **Parent.DisplayMode** (referencing the form) as will the control's **DisplayMode** property (referencing the data card):

Expand table

Mode	DisplayMode	Description
FormMode.Edit	**DisplayMode.Edit**	Data cards and controls are editable, ready to accept changes to a record.
FormMode.New	**DisplayMode.Edit**	Data cards and controls are editable, ready to accept a new record.
FormMode.View	**DisplayMode.View**	Data cards and controls are not editable and optimized for viewing.

Syntax

SubmitForm(*FormName*)

- *FormName* - Required. Form control to submit to the data source.

EditForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.Edit** mode.

NewForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.New** mode.

ResetForm(*FormName*)

- *FormName* - Required. Form control to reset to initial values. Also switches the form from **FormMode.New** mode to **FormMode.Edit** mode.

ViewForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.View** mode.

Examples

See Understand data forms for complete examples.

1. Add a Button control, set its **Text** property to show **Save**, and set its **OnSelect** property to this formula:

   SubmitForm(EditForm)

2. Set the **OnFailure** property of a Form control to blank and its **OnSuccess** property to this formula:

   Back()

3. Name a **Label** control **ErrorText**, and set its **Text** property to this formula:

   EditForm.Error

   When the user selects the **Save** button, any changes in the Form control are submitted to the underlying data source.

   - If the submission succeeds, any changes are saved or, if the Form control is in **New** mode, a record is created. **ErrorText** is *blank* and the previous screen reappears.
   - If the submission fails, **ErrorText** shows a user-friendly error message, and the current screen remains visible so that the user can correct the problem and try again.

4. Add a Button control, set its **Text** property to show **Cancel**, and set its **OnSelect** property to this formula:

   ResetForm(EditForm); Back()

   When the user selects the **Cancel** button, the values in the Form control are reset to what they were before the user started to edit it, the previous screen reappears,

and the Form control is returned to **Edit** mode if it was in **New** mode.

5. Add a Button control, set its Text property to show **New**, and set its OnSelect property to this formula:

   NewForm(EditForm); Navigate(EditScreen, None)

   When the user selects the **New** button, the Form control switches to **New** mode, the default values for the Form control's data source populate that control, and the screen that contains the Form control appears. When the **SubmitForm** function runs, a record is created instead of updated.

Revert function

Article • 03/22/2024

Applies to: Canvas apps

Refreshes and clears errors for the records of a data source.

Description

The **Revert** function refreshes an entire data source or a single record in that data source. You'll see changes that other users made.

For the records reverted, **Revert** also clears any errors from the table that the **Errors** function returned.

If the **Errors** function reports a conflict after a **Patch** or other data operation, **Revert** the record to start with the conflicting version and reapply the change.

Revert has no return value. You can use it only in a behavior formula.

Syntax

Revert(*DataSource* [, *Record*])

- *DataSource* – Required. The data source that you want to revert.
- *Record* - Optional. The record that you want to revert. If you don't specify a record, the entire data source is reverted.

Example

In this example, you'll revert the data source named **IceCream**, which starts with the data in this table:

ID	Flavor	Quantity
1	"Chocolate"	100
2	"Vanilla"	200
3	"Strawberry"	300

A user on another device changes the **Quantity** property of the **Strawberry** record to **400**. At about the same time, you change the same property of the same record to **500**, not knowing about the other change.

You use the Patch function to update the record:
Patch(IceCream, LookUp(IceCream, Flavor = "Strawberry"), { Quantity: 500 })

You check the Errors table and find an error:

Expand table

Record	Column	Message	Error
{ ID: 1, Flavor: "Strawberry", Quantity: 300 }	*blank*	"The record you are trying to modify has been modified by another user. Please revert the record and try again."	ErrorKind.Conflict

Based on the **Error** column, you have a **Reload** button for which the OnSelect property to set to this formula:
Revert(IceCream, LookUp(IceCream, Flavor = "Strawberry"))

After you select the **Reload** button, the Errors table is empty, and the new value for **Strawberry** has been loaded:

ID	Flavor	Quantity
1	"Chocolate"	100
2	"Vanilla"	200
3	"Strawberry"	400

You reapply your change on top of the previous change, and your change succeed because the conflict has been resolved.

ID	Flavor	Quantity
1	"Chocolate"	100
2	"Vanilla"	200
3	"Strawberry"	500

RequestHide function

Article • 03/22/2024

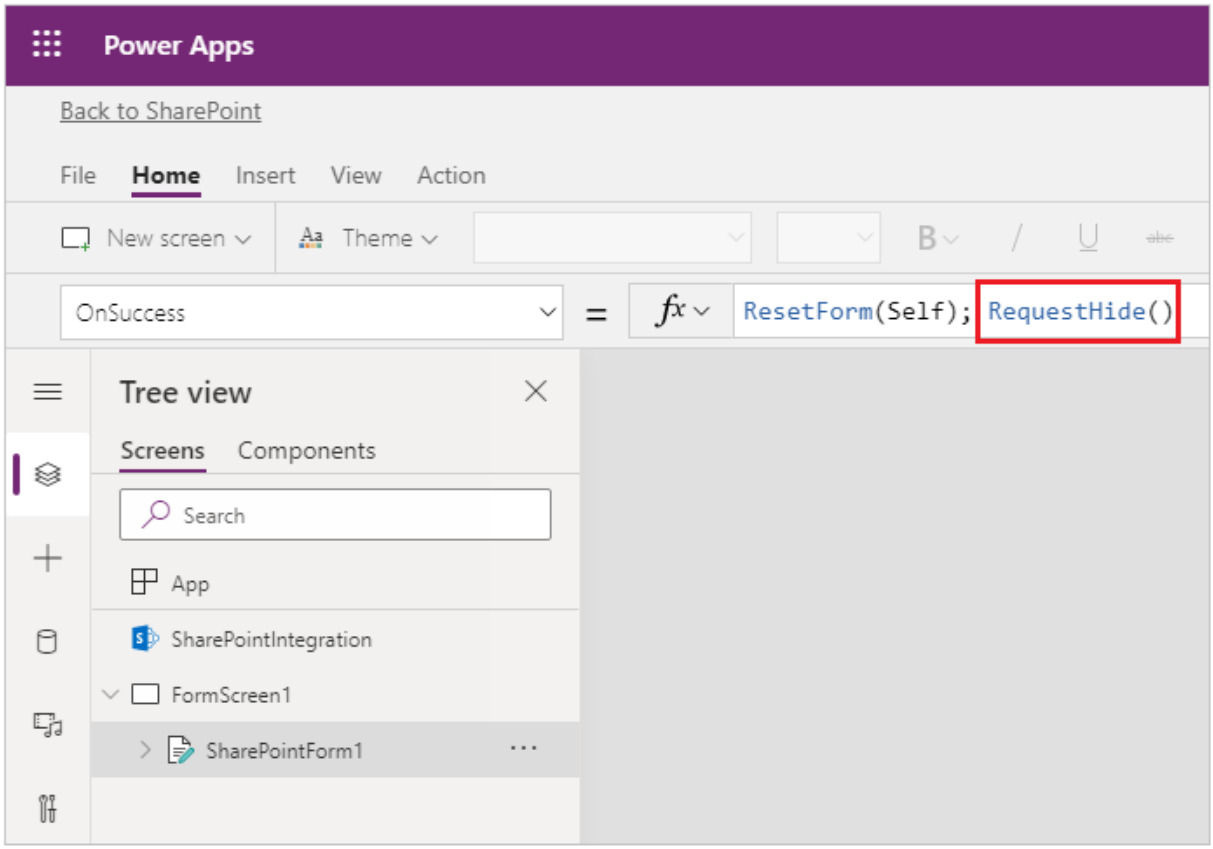
Applies to: Canvas apps

Hides the SharePoint form.

> **Note**
>
> Only works with SharePoint forms.

Description

Use the **RequestHide** function to hide the SharePoint form. By default, RequestHide() is used for the *OnSuccess* property of a SharePoint form being customized.



This function is not required for the **SharePointIntegration** control's **OnCancel** event as SharePoint by default hides the form when a user selects **Cancel**, and the function only reacts to a SharePoint form.

Syntax

RequestHide ( )

- No parameters.

Examples

Expand table

Formula	Description
RequestHide()	Hides the form.

Color enumeration and ColorFade, ColorValue, and RGBA functions

06/19/2025

Expand table

Functions	Applies to
Color	✅ Model-driven apps
ColorFade **ColorValue**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions
RGBA	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Use built-in color values, define custom colors, and use the alpha channel to control transparency.

> ⓘ Note
>
> PAC CLI pac power-fx commands don't support the **Color** enumeration.

Description

Use the **Color** enumeration to access colors defined by HTML's Cascading Style Sheets (CSS). For example, **Color.Red** returns pure red. A list of these colors appears at the end of this article.

The **ColorValue** function returns a color based on a CSS color string. The string can be in any of these forms:

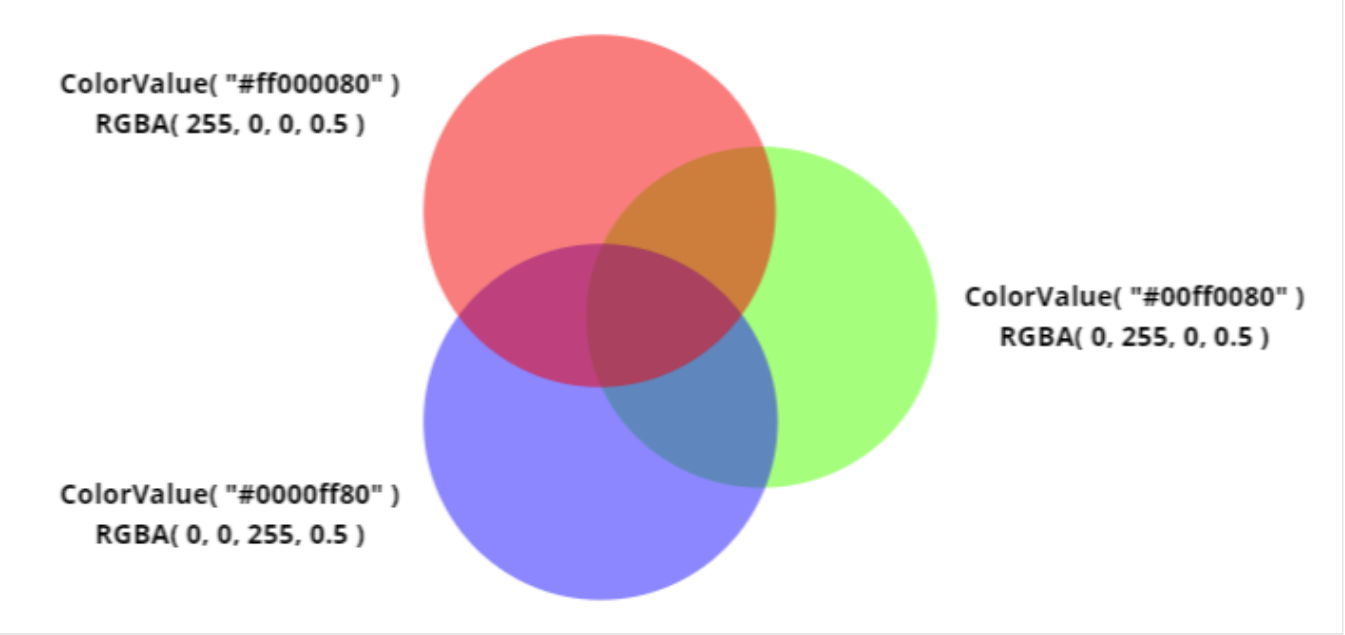
- **CSS color name:** **"RoxyBrown"** and **"OliveDrab"** are examples. These names don't include spaces. The list of supported colors appears later in this article.
- **6-digit hex value:** For example, **"#ffd700"** is the same as **"Gold"**. The string uses the format "*#rrggbb*", where *rr* is the red portion in two hexadecimal digits, *gg* is the green, and *bb* is the blue.
- **8-digit hex value:** For example, **"#ff7f5080"** is the same as **"Coral"** with a 50% alpha channel. The string uses the format "*#rrggbbaa*", where *rr*, *gg*, and *bb* are identical to the 6-digit form. The alpha channel is represented by *aa*: **00** means fully transparent, and **ff** means fully opaque.

The **RGBA** function returns a color based on red, green, and blue components. The function also includes an alpha channel for mixing colors of controls layered in front of each other. The alpha channel ranges from 0% or 0% (fully transparent and invisible) to 1% or 100% (fully opaque and completely blocks any layers behind a control).

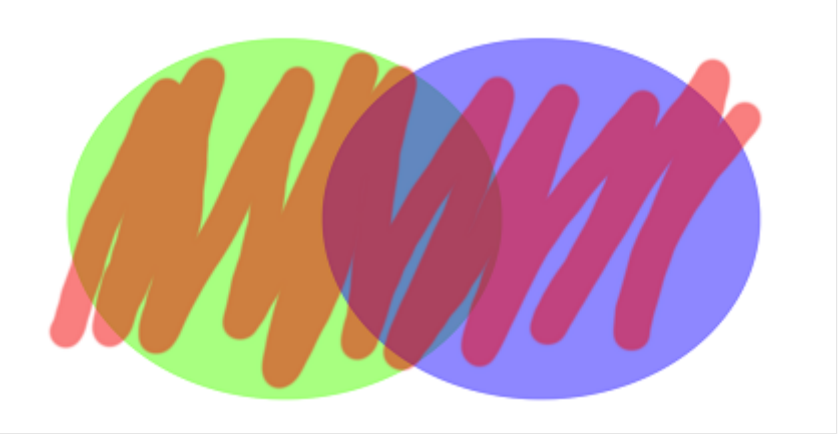
The **ColorFade** function returns a brighter or darker version of a color. The amount of fade ranges from -1 (fully darkens a color to black), to 0 (doesn't affect the color), to 1 (fully brightens a color to white).

Alpha channel

In a canvas app, you layer controls in front of one another and set the transparency of a control to any controls behind it. As a result, colors blend through the layers. For example, this diagram shows how the three primary colors mix with an alpha setting of 50 percent:



You can also blend images in file formats that support alpha channels. For example, you can't blend .jpeg files, but you can blend .png files. The next graphic shows the same red, green, and blue colors from the previous example, but the red color appears as a squiggle (instead of a circle) in a .png file with a 50 percent alpha channel:



If you specify a **Color** enumeration value or build a **ColorValue** formula with a color name or a 6-digit hexadecimal value, the alpha setting is 100 percent, which is fully opaque.

Syntax

Color.*ColorName*

- *ColorName* - Required. A Cascading Style Sheet (CSS) color name. The list of possible enumeration values is at the end of this article.

ColorValue(*CSSColor*)

- *CSSColor* - Required. A Cascading Style Sheet (CSS) color definition. S name, OliveDralike a hex value, like **#6b8e23** olikeffd420**. Hex values can use either #_rrggbb__usgormat. format

ColorValue(*Dynamic*)

- *Dynamic* - Required. A **Dynamic** value with a string that represents a Cascading Style Sheet (CSS) color definition.

RGBA(*Red*, *Green*, *Blue*, *Alpha*)

- *Red*, *Green*, *Blue* - Required. Color component values that range from 0 (no saturation) to 255 (full saturation).
- *Alpha* - Required. Alpha component that ranges from 0 (fully transparent) to 1 (fully opaque). You can also use a percentage, 0% to 100%.

ColorFade(*Color*, *FadeAmount*)

- *Color* - Required. A color value like **Color.Red** or the output from **ColorValue** or **RGBA**.
- *FadeAmount* - Required. A number between -1 and 1. -1 fully darkens a color to black, 0 doesn't affect the color, and 1 fully brightens a color to white. You can also use a percentage, from -100% to 100%.

Built-in colors

Left, Mid, and Right functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Dataverse formula columns ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Extracts the left, middle, or right portion of a string of text.

Description

The **Left**, **Mid**, and **Right** functions return a portion of a string.

- **Left** returns the beginning characters of a string.
- **Mid** returns the middle characters of a string.
- **Right** returns the ending characters of a string.

If you specify a single string as an argument, the function returns the portion that you requested of the string. If you specify a single-column table that contains strings, the function returns a single-column table with a **Value** column containing the portions that you requested of those strings. If you specify a multi-column table, you can shape it into a single-column table, as working with tables describes.

If the starting position is negative or beyond the end of the string, **Mid** returns *blank*. You can check the length of a string by using the **Len** function. If you request more characters than the string contains, the function returns as many characters as possible.

Syntax

Left(*String*, *NumberOfCharacters*)
Mid(*String*, *StartingPosition* [, *NumberOfCharacters*])
Right(*String*, *NumberOfCharacters*)

- *String* - Required. The string to from which to extract the result.
- *StartingPosition* - Required (**Mid** only). The starting position. The first character of the string is position 1.
- *NumberOfCharacters* - Required (**Left** and **Right** only). The number of characters to return. If omitted for the **Mid** function, the function returns the portion from the starting position until the end of the string.

Left(*SingleColumnTable*, *NumberOfCharacters*)
Mid(*SingleColumnTable*, *StartingPosition* [, *NumberOfCharacters*])

Right(*SingleColumnTable*, *NumberOfCharacters*)

- *SingleColumnTable* - Required. A single-column table of strings from which to extract the results.
- *StartingPosition* - Required (**Mid** only). The starting position. The first character of the string is position 1.
- *NumberOfCharacters* - Required (**Left** and **Right** only). The number of characters to return. If omitted for the **Mid** function, the function returns the portion from the starting position until the end of the string.

Examples

Single string

The examples in this section use a text-input control as their data source. The control is named **Author** and contains the string "E. E. Cummings".

Expand table

Formula	Description	Result
Left(Author.Text, 5)	Extracts up to five characters from the start of the string.	"E. E."
Mid(Author.Text, 7, 4)	Extracts up to four characters, starting with the seventh character, from the string.	"Cumm"
Mid(Author.Text, 7)	Extracts all characters, starting with the seventh character, from the string.	"Cummings"
Right(Author.Text, 5)	Extracts up to five characters from the end of the string.	"mings"

Single-column table

Each example in this section extracts strings from the **Address** column of this data source, named **People**, and returns a single-column table that contains the results:

Expand table

Name	Address
"Jean"	"123 Main St NE"

Name	Address
"Fred"	"789 SW 39th #3B"

Expand table

Formula	Description	Result
Left(ShowColumns(People, "Address"), 8)	Extracts the first eight characters of each string.	A single-column table with a `Value` column containing the following values: "123 Main", "789 SW 3"
Mid(ShowColumns(People, "Address"), 5, 7)	Extracts the middle seven characters of each string, starting with the fifth character.	A single-column table with a `Value` column containing the following values: "Main St", "SW 39th"
Right(ShowColumns(People, "Address"), 7)	Extracts the last seven characters of each string.	A single-column table with a `Value` column containing the following values: "n St NE", "9th #3B"

Step-by-step example

1. Import or create a collection named **Inventory**, and show it in a gallery, as the first procedure in Show images and text in a gallery describes.
2. Set the **Text** property of the lower label in the gallery to this function:

   Right(ThisItem.ProductName, 3)

   The label shows the last three characters of each product name.

Int, Round, RoundDown, RoundUp, and Trunc functions

Article • 04/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Rounds a number.

Round, RoundDown, and RoundUp

The **Round**, **RoundDown**, and **RoundUp** functions round a number to the specified number of decimal places:

- **Round** rounds up if the next digit is 5 or higher. Otherwise, this function rounds down.
- **RoundDown** always rounds down to the previous lower number, towards zero.
- **RoundUp** always rounds up to the next higher number, away from zero.

The number of decimal places can be specified for these functions:

Expand table

Decimal places	Description	Example
Greater than 0	The number is rounded to the right of the decimal separator.	`Round( 12.37, 1 )` returns 12.4.
0	The number is rounded to the nearest integer.	`Round( 12.37, 0 )` returns 12.
Less than 0	The number is rounded to the left of the decimal separator.	`Round( 12.37, -1 )` returns 10.

Int and Trunc

The **Int** and **Trunc** functions round a number to an integer (whole number without a decimal):

- **Int** rounds down to the nearest integer.
- **Trunc** truncates the number to just the integer portion by removing any decimal portion.

The difference between **Int** and **Trunc** is in the handling of negative numbers. For example, for an argument of `-4.3`, **Int** will return the integer further away from zero, `-5`, while **Trunc** will return the integer closer to zero, `-4`. **Int** returns values that are unique amongst the five rounding functions, while **Trunc** returns the same values as **RoundDown**.

Use **Trunc** to extract the decimal portion of a number by subtracting it from the original, for example `X - Trunc(X)`.

Decimal places cannot be specified with **Trunc** as it can with Microsoft Excel. Use **RoundDown** instead when this is needed.

Single-column tables

These functions support single-column tables. If you pass a single number, the return value is the rounded version of that number. If you pass a single-column table that contains numbers, the return value is a single-column table of rounded numbers. The *DecimalPlaces* parameter can be a single value or a single-column table. If the single-column table has less values that the *Number*, zero is used for the remaining values. Use **ShowColumns** and other table shaping functions to extract a single-column table from a larger table.

Syntax

Round(*Number*, *DecimalPlaces*)
RoundDown(*Number*, *DecimalPlaces*)
RoundUp(*Number*, *DecimalPlaces*)

- *Number* - Required. The number to round.
- *DecimalPlaces* - Required. Number of decimal places to round to. Use a positive value to indicate decimal places right of the decimal separator, a negative value to the left, and zero for a whole number.

Int(*Number*)
Trunc(*Number*)

- *Number* - Required. The number to be rounded to an integer.

Examples

Rounding to a whole number.

Expand table

X	Round(X, 0)	RoundUp(X, 0)	RoundDown(X, 0)	Int(X)	Trunc(X)
7.9	8	8	7	7	7
-7.9	-8	-8	-7	-8	-7
7.5	8	8	7	7	7
-7.5	-8	-8	-7	-8	-7
7.1	7	8	7	7	7
-7.1	-7	-8	-7	-8	-7

Rounding to two decimal places to the right of the decimal separator (0.01).

Expand table

X	Round(X, 2)	RoundUp(X, 2)	RoundDown(X, 2)
430.123	430.12	430.13	430.12
430.125	430.13	430.13	430.12
430.128	430.13	430.13	430.12

Rounding to two decimal places to the left of the decimal separator (100).

Expand table

X	Round(X, -2)	RoundUp(X, -2)	RoundDown(X, -2)
430.123	400	500	400
449.942	400	500	400
450.000	500	500	400
450.124	500	500	400
479.128	500	500	400

Rounding a single-column table of values.

Expand table

`X`	`Int( X )`	`Round( X, 2 )`	`RoundDown( X, [ 0, 1, 2 ] )`	`RoundUp( X, [ 2 ] )`
[123.456, 987.593, 542.639]	[123, 987, 542]	[123.46, 987.59, 542.64]	[123, 987.5, 542.63]	[123.46, 988, 543]

SaveData, LoadData, and ClearData functions

06/18/2025

Applies to: Canvas apps

Saves and reloads a collection from the app host's storage.

Description

The **SaveData** function stores a collection for later use under a name.

The **LoadData** function reloads a collection by name that was previously saved with **SaveData**. You can't use this function to load a collection from another source.

The **ClearData** function clears the storage under a specific name or clears all storage associated with the app if no name is provided.

> **Note**
>
> - The name shared between **SaveData**, **LoadData**, and **ClearData** is a key, not a file name. It need not be complex as names are unique to each app and there is no danger of name conflict. The name must not contain any of these characters: `*".?:\<>|/`.
> - SaveData is limited to 1 MB of data for Power Apps running in Teams and in a web browser. There is no fixed limit for Power Apps running in a mobile player but there are practical limits discussed below.
> - Don't use **SaveData** to store sensitive data in the web since it'll be stored in plain text.

Use these functions to improve app-startup performance by:

- Caching data in the **App.OnStart** formula on a first run.
- Reloading the local cache on next runs.

You can also use these functions to add simple offline capabilities to your app.

You can't use these functions inside a browser when:

- Authoring the app in Power Apps Studio.

To test your app, run it in Power Apps Mobile on an iPhone or Android device.

These functions are limited by the amount of available app memory as they operate on an in-memory collection. Available memory can vary depending on factors such as:

- The device and operating system.
- The memory that the Power Apps player uses.
- Complexity of the app with screens and controls.

Test your app with expected scenarios on the type of devices you expect the app to run when storing large data. Expect to have between 30 MB and 70 MB of available memory generally.

These functions depend on the collection being implicitly defined with **Collect** or **ClearCollect**. You don't need to call **Collect** or **ClearCollect** to load data into the collection for defining it. It's a common case when using **LoadData** after a previous **SaveData**. All that is needed is the presence of these functions in a formula to implicitly define the structure of the collection. For more information, see creating and removing variables.

The loaded data will be appended to the collection. Use the **Clear** function before calling **LoadData** if you want to start with an empty collection.

Data security

Consider carefully the isolation and encryption of data stored with **SaveData** and decide if it's appropriate for your needs, especially if devices are shared by multiple users.

Data stored with **SaveData** is isolated from other Power Apps by the Power Apps players. Data is stored based on the app's App ID, automatically isolating the **SaveData** name space between Power Apps.

The operating system and browser is responsible for isolating data between Power Apps and other apps on a device and with websites. For example, the operating system is responsible for isolating data stored in Microsoft Outlook from data stored in Power Apps, and also isolating that data from websites such as Bing.com or PowerApps.com. The operating system's built in app sandbox facilities are used for **SaveData** storage which is usually not accessible to or hidden from the user.

When using the same app, the operating system and browser is also responsible for isolating the data between different operating system level users. For example, if two different users share a computer and use two different Windows login credentials, the operating system is responsible for isolating data between the two Windows users.

Data may or may not be isolated between different Power Apps users if the operating system user is the same. Not every Power Apps player treats this the same way. For example, while

logged in as the same Windows user, in the Power Apps player, the user signs out of Power Apps and signs in as a different Power Apps user. Data stored in an app before the change of Power Apps user, may be accessible to the second Power Apps user within the same app. The data may also be removed and the first Power Apps user may no longer be able to access it. The behavior varies between Power Apps players.

The operating system may also encrypt the data or you can use a mobile device management tool such as Microsoft Intune. Data stored when playing an app in a web browser is not encrypted.

Syntax

SaveData(*Collection*, *Name*)
LoadData(*Collection*, *Name* [, *IgnoreNonexistentFile*])

- *Collection* - Required. Collection to be stored or loaded.
- *Name* - Required. Name of the storage. The name must be same to save and load same set of data. The name space isn't shared with other apps. Names must not contain any of these characters: `*".?:\<>|/`.
- *IgnoreNonexistentFile* - Optional. A Boolean value indicating what to do if the file doesn't already exist. Use *false* (default) to return an error and *true* to suppress the error.

ClearData([*Name*])

- *Name* - Optional. Name of the storage previously saved with **SaveData**. If *Name* is not provided, all storage associated with the app is cleared.

Examples

Expand table

Formula	Description	Result
SaveData(LocalCache, "MyCache")	Save the **LocalCache** collection to the user's device under the name "MyCache", suitable for **LoadData** to retrieve later.	Data is saved to the app host under the name "MyCache".
LoadData(LocalCache, "MyCache")	Loads the **LocalCache** collection from the user's device under the name "MyCache", previously stored with a call to **SaveData**.	Data is loaded from the app host under the name "MyCache".
ClearData("MyCache")	Clears the storage under the name "MyCache". Any data stored under this name will no longer be available through **LoadData**.	Data is removed from the app host under the name "MyCache".

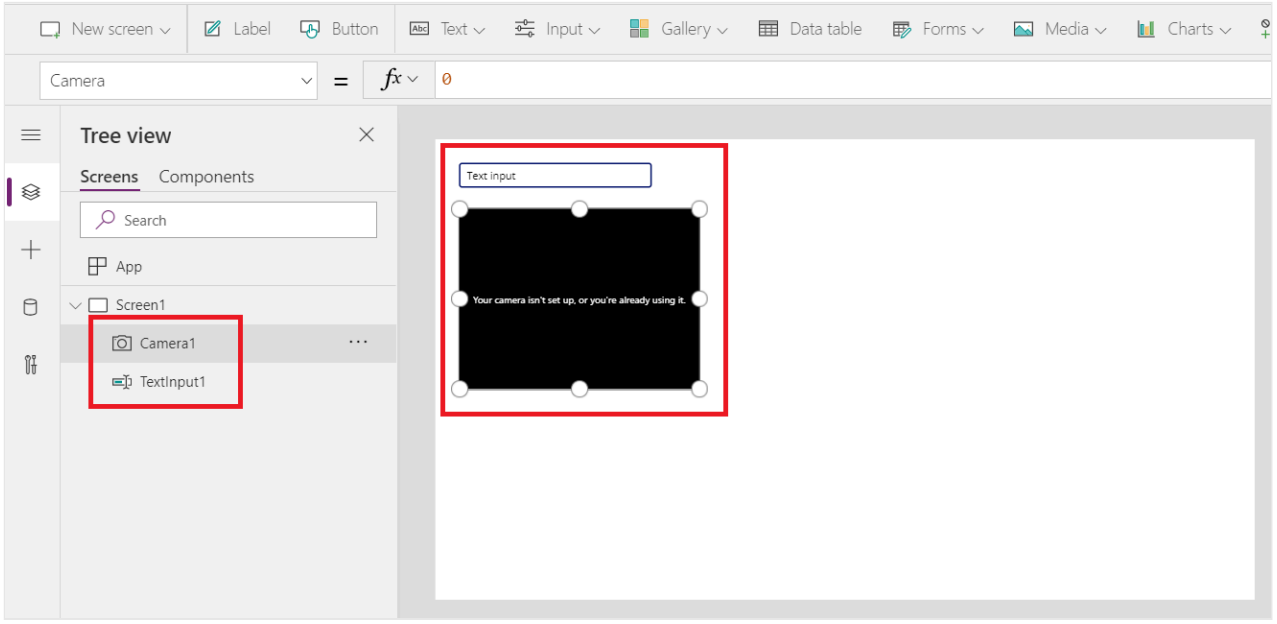
Formula	Description	Result
ClearData()	Clear all storage associated with this app. Data stored by other apps is not affected.	All data is removed from the app host.

Simple offline example

Following simple example captures and stores the names and pictures of everyday items while offline. It stores the information in the device's local storage for later use. This allows the app to be closed or the device to restart without losing data.

> **Note**
>
> This example uses a camera control to capture images. Since **SaveData** is limited to 1 MB of data when running in Teams or a web browser, this example will not work with more than a few images. Also, depending on the camera, it may not work with even one image. Use a device to work through this full example, or remove the camera control and picture part of this example to run in Teams or in a web browser.

1. Create a blank canvas app with a tablet layout. For more details, read creating an app from a template and select **Tablet layout** under **Blank app**.
2. Add a **Text input** control and a **Camera** control and arrange them roughly as shown:

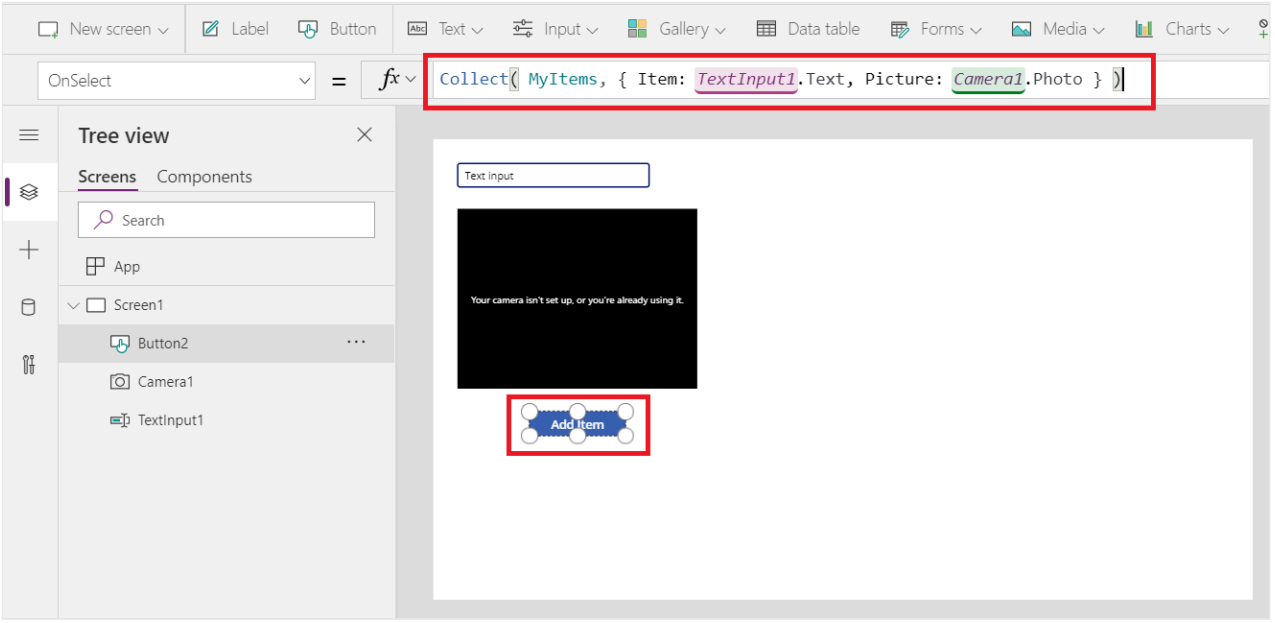


3. Add a **Button** control.
4. Double-click the button control to change the button text to **Add Item** (or modify the **Text** property).

5. Set the **OnSelect** property of the button control to this formula that will add an item to our collection:

```
Power Fx

Collect( MyItems, { Item: TextInput1.Text, Picture: Camera1.Photo } )
```



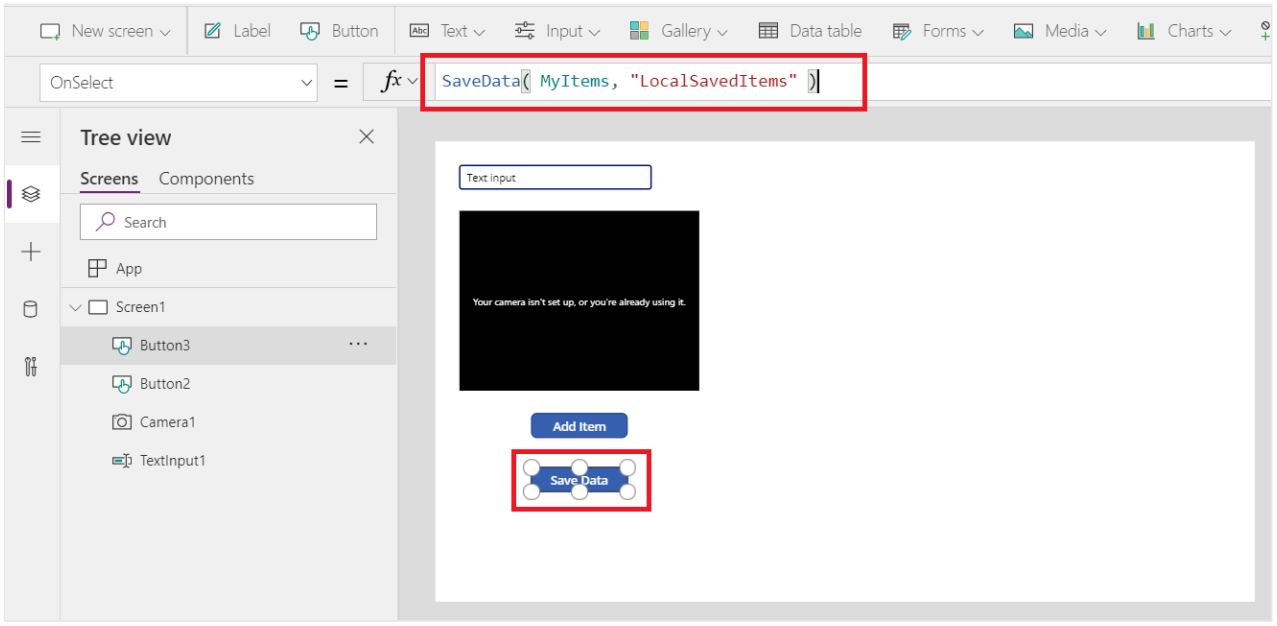
6. Add another **Button** control.

7. Double-click the button control to change the button text to **Save Data** (or modify the **Text** property).

8. Set the **OnSelect** property of the button control to this formula in order to save our collection to the local device:

```
Power Fx

SaveData( MyItems, "LocalSavedItems" )
```



It's tempting to test the button as it doesn't affect anything. But you'll only see an error as you're authoring in a web browser. Save the app first and open on a device before you follow the next steps to test this formula:

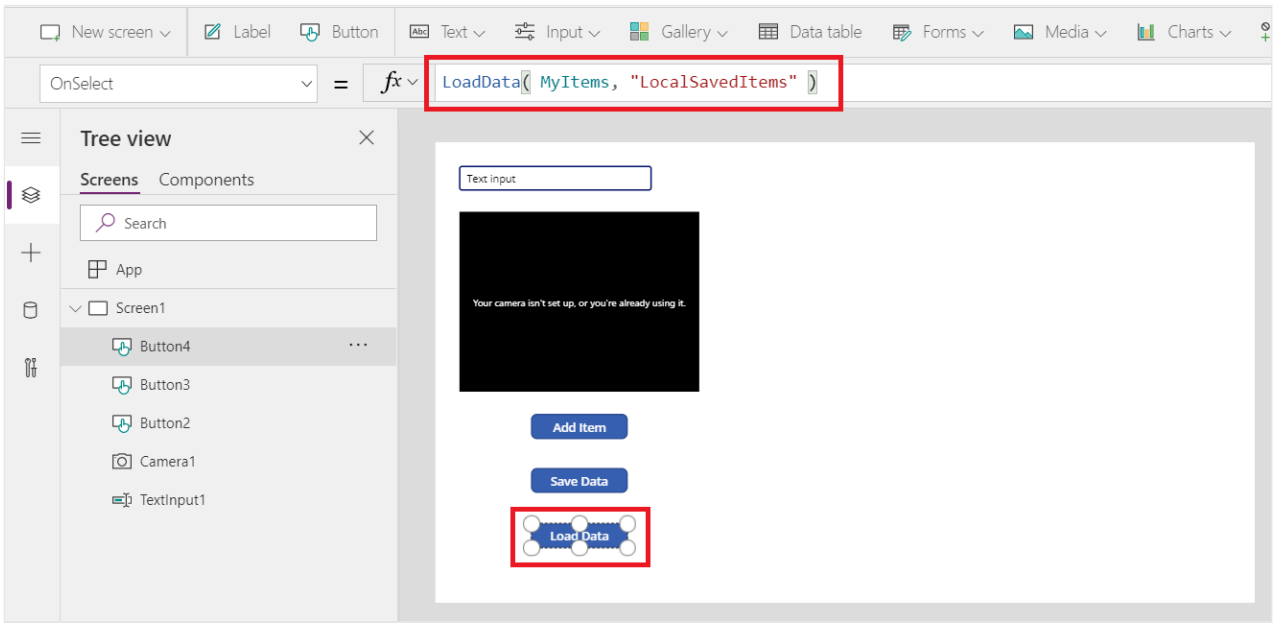
9. Add a third **Button** control.

10. Double-click the button control to change the button text to **Load Data** (or modify the **Text** property).

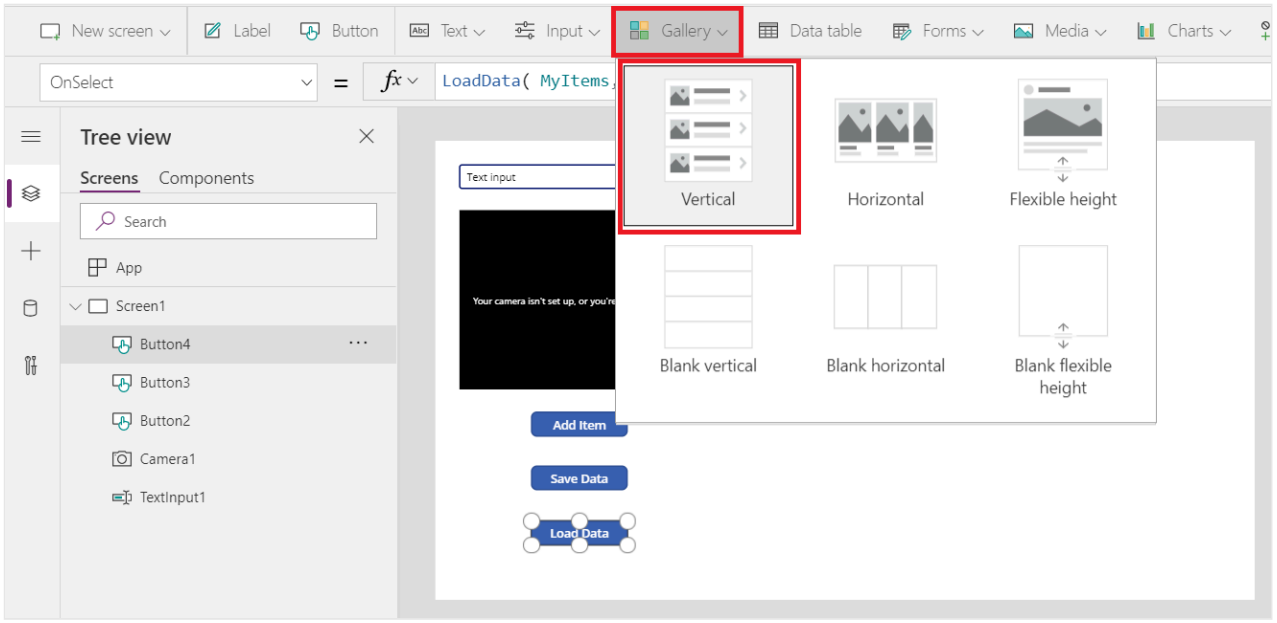
11. Set the **OnSelect** property of the button control to this formula in order to load our collection from the local device:

```
Power Fx

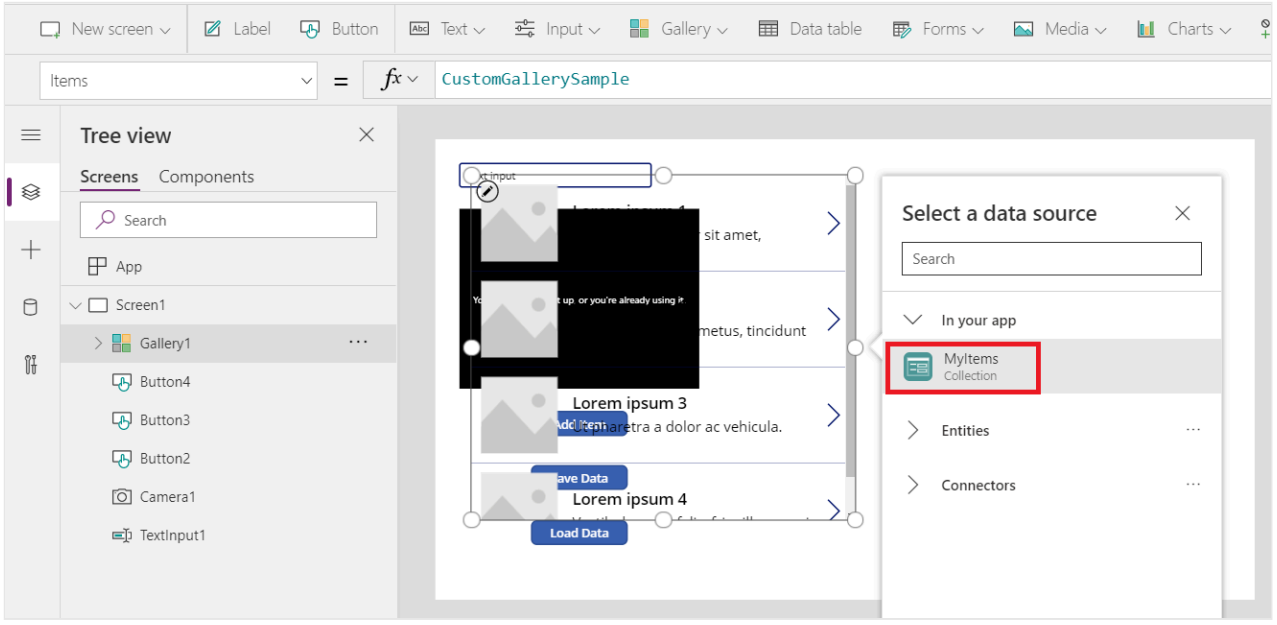
LoadData( MyItems, "LocalSavedItems" )
```



12. Add a Gallery control with a Vertical layout that includes a picture and text areas:

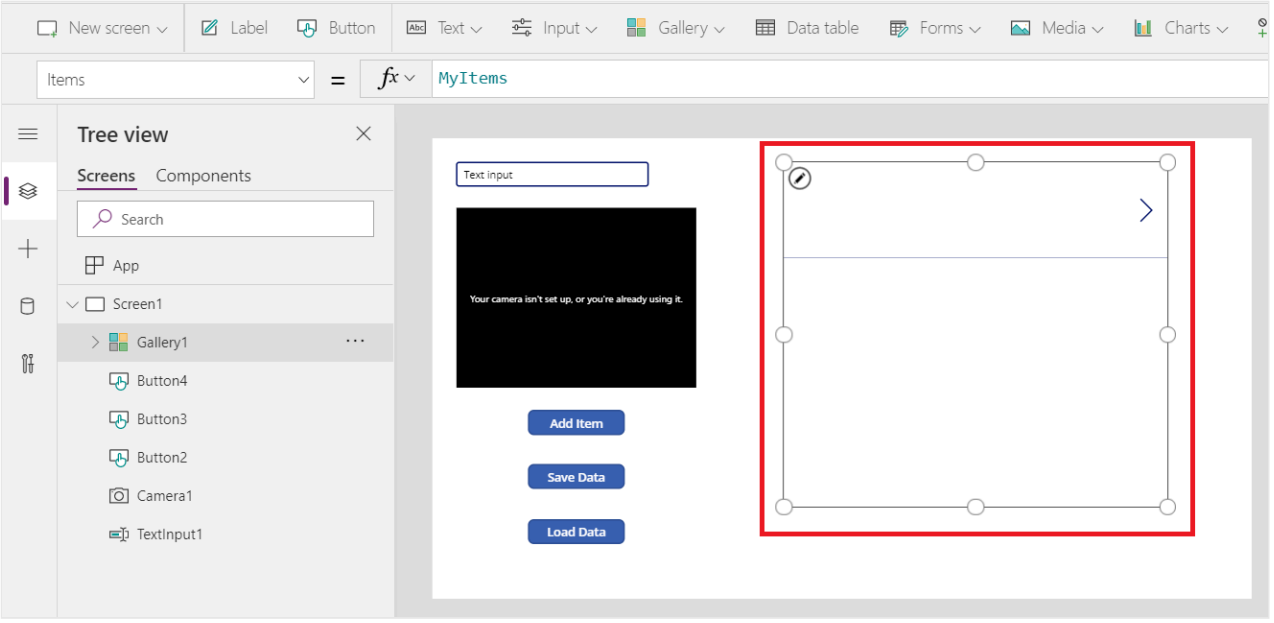


13. When prompted, select the **MyItems** collection as the data source for this gallery. This will set the **Items** property of the **Gallery** control:



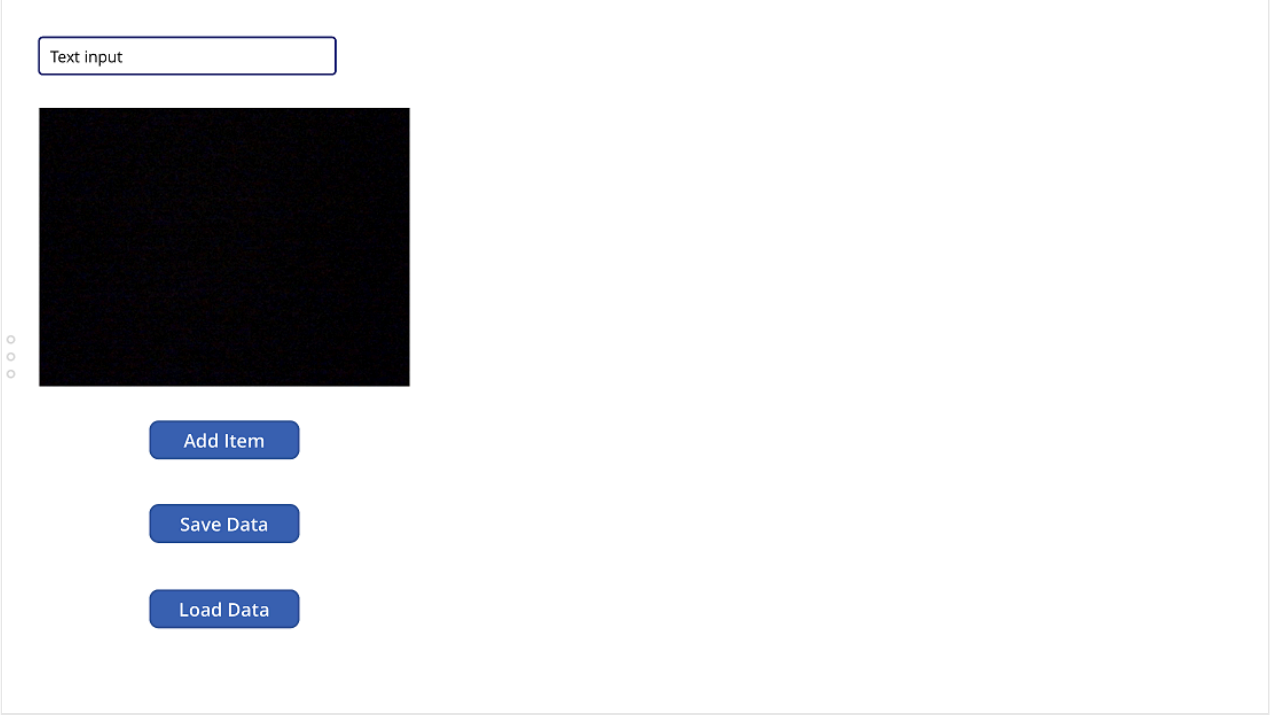
The image control in the gallery template should default its **Image** property to **ThisItem.Picture** and the label controls should both default their **Text** properties to **ThisItem.Item**. Check these formulas if after adding items in the following steps you don't see anything in the gallery.

14. Position the control to the right of the other controls:



15. Save your app. If it's the first time it has been saved, there's no need to publish it. If it's not the first time, publish the app after you save.

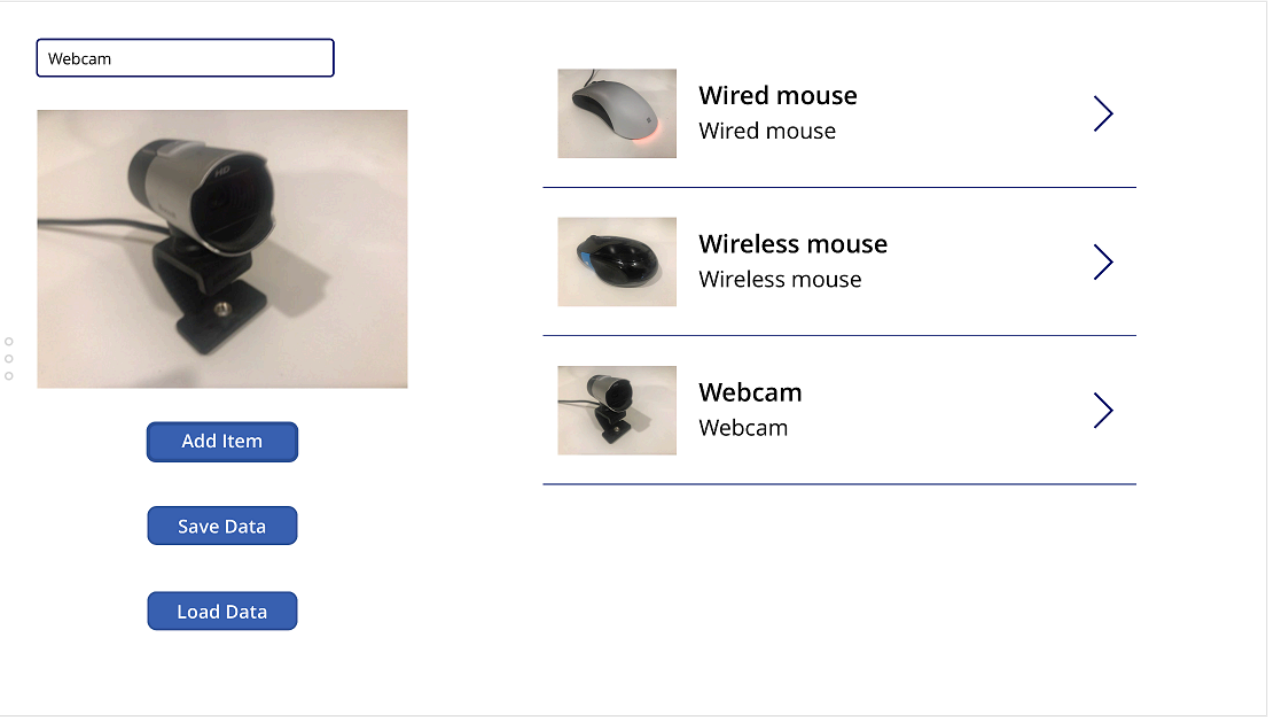
16. Open your app on a device such as a phone or tablet. **SaveData** and **LoadData** can't be used in Studio or in a web browser. Refresh your app list if you don't see your app immediately, it can take a few seconds for the app to appear on your device. Signing out and back in to your account can help too.



Once your app has been downloaded, you can disconnect from the network and run the app offline.

17. Enter the name and take a picture of an item.

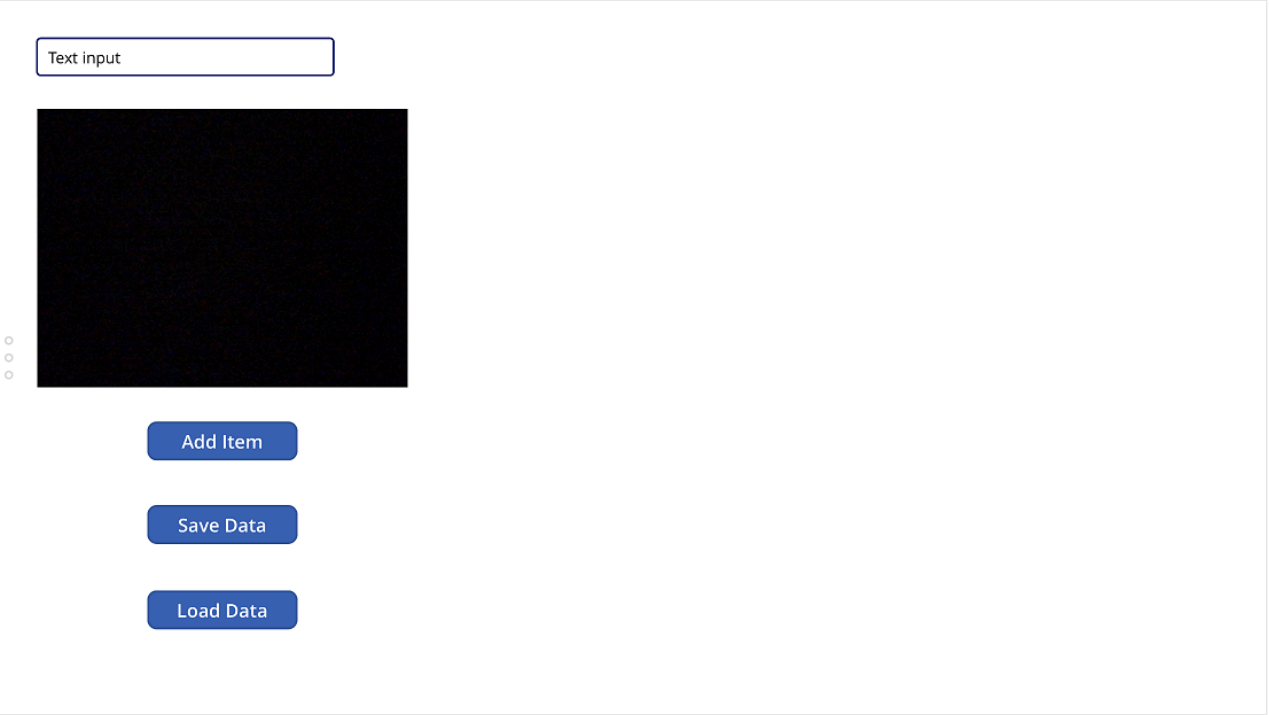
18. Select the **Add Item** button. Repeat adding items a couple of times to load up your collection.



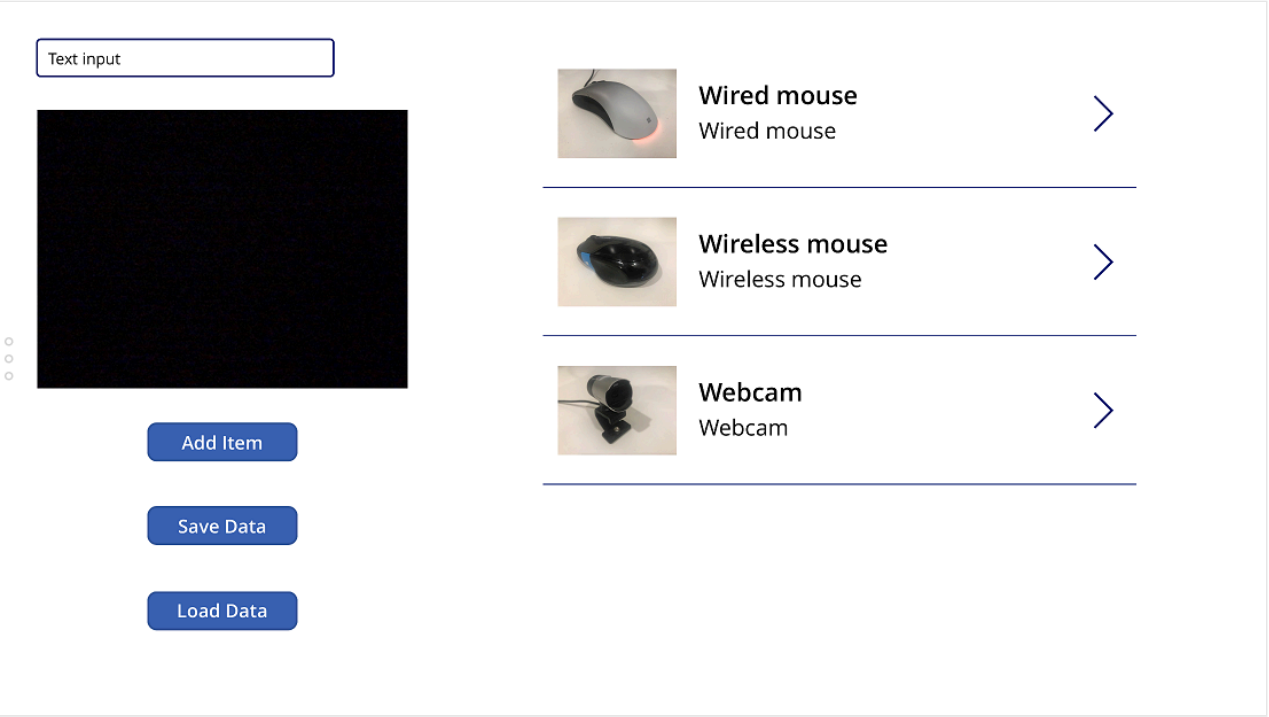
19. Select the **Save Data** button. This will save the data in your collection to your local device.

20. Close the app. Your collection in memory will be lost including all item names and pictures, but they'll still be there in the device's storage.

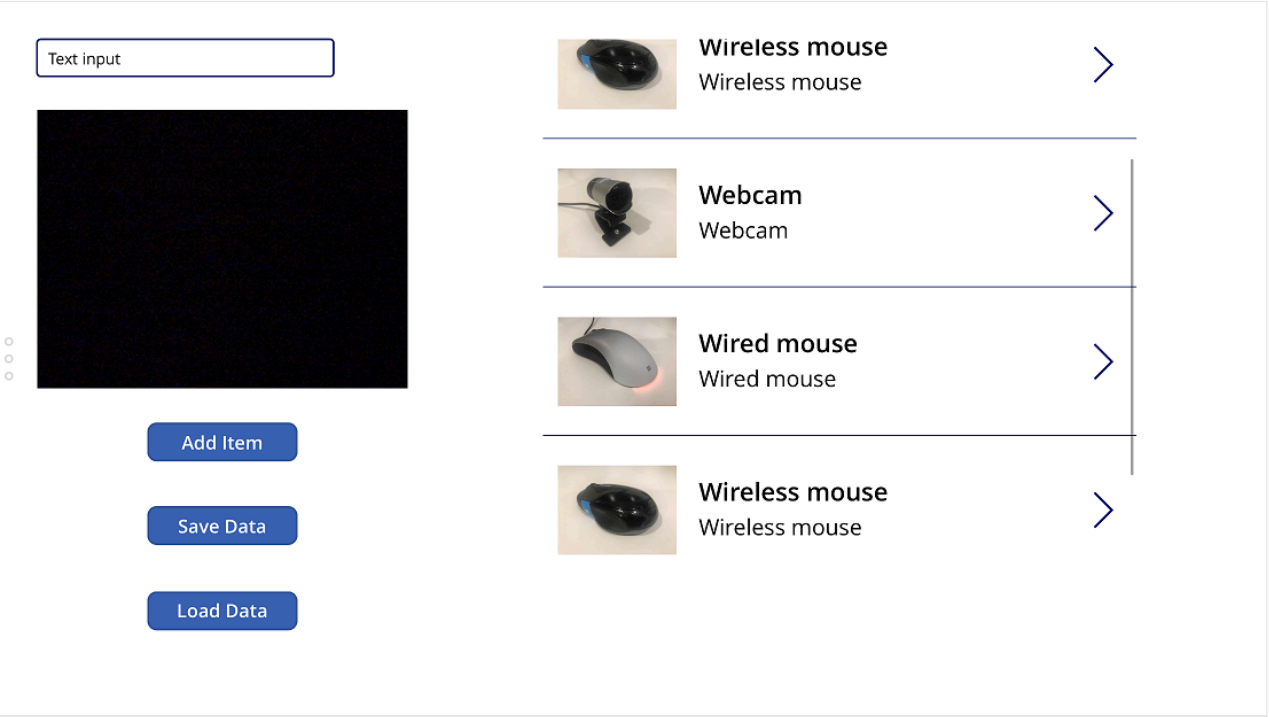
21. Launch the app again. The collection in memory will again show as empty in the gallery.



22. Select the **Load Data** button. The collection will be repopulated from the stored data on your device and your items will be back in the gallery. The collection was empty before this button calls the **LoadData** function; there was no need to call **Collect** or **ClearCollect** before loading the data from storage.



23. Select the **Load Data** button again. The stored data will be appended to the end of the collection and a scroll bar will appear on the gallery. If you would like to replace rather than append, use the **Clear** function first to clear out the collection before calling the **LoadData** function.



More advanced offline example

For a detailed example, see the article on simple offline capabilities.

Filter, Search, and LookUp functions

Applies to: ✅ Canvas apps ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Finds one or more records in a table.

Watch this video to learn how to use **Filter**, **Search**, and **LookUp** functions:

https://learn-video.azurefd.net/vod/player?id=55b2c144-b5ac-4d66-b398-fea03eb21f17&locale=en-us&embedUrl=%2Fpower-platform%2Fpower-fx%2Freference%2Ffunction-filter-lookup

> **Note**
>
> PAC CLI pac power-fx commands do not support the **Search** function.

Description

The **Filter** function finds records in a table that satisfy a formula. Use **Filter** to find a set of records that match one or more criteria and discard those records that don't.

The **LookUp** function finds the first record in a table that satisfies a formula. Use **LookUp** to find a single record that matches one or more criteria.

For both, the formula is evaluated for each record of the table. Records that result in *true* are included in the result. Besides the normal formula operators, you can use the **in** and **exactin** operators for substring matches.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

The **Search** function finds records in a table that contain a string in one of their columns. The string might occur anywhere within the column; for example, searching for "rob" or "bert" would find a match in a column that contains "Robert". Searching is case-insensitive. Unlike **Filter** and **LookUp**, the **Search** function uses a single string to match instead of a formula.

Filter and **Search** return a table that contains the same columns as the original table and the records that match the criteria. **LookUp** returns only the first record found, after applying a

formula to reduce the record to a single value. If no records are found, **Filter** and **Search** return an empty table, and **LookUp** returns *blank*.

Tables are a value in Power Apps, just like a string or number. They can be passed to and returned from functions. **Filter**, **Search**, and **LookUp** don't modify a table. Instead, they take a table as an argument and return a table, a record, or a single value from it. See working with tables for more details.

Delegation

When possible, Power Apps will delegate filter and sort operations to the data source and page through the results on demand. For example, when you start an app that shows a **Gallery** control filled with data, only the first set of records will be initially brought to the device. As the user scrolls, additional data is brought down from the data source. The result is a faster start time for the app and access to very large data sets.

However, delegation may not always be possible. Data sources vary on what functions and operators they support with delegation. If complete delegation of a formula isn't possible, the authoring environment will flag the portion that can't be delegated with a warning. When possible, consider changing the formula to avoid functions and operators that can't be delegated. The delegation list details which data sources and operations can be delegated.

If delegation is not possible, Power Apps will pull down only a small set of records to work on locally. Filter and sort functions will operate on a reduced set of records. What is available in the **Gallery** may not be the complete story, which could be confusing to users.

See the delegation overview for more information.

Syntax

Filter(Table*, *Formula1* [, *Formula2*, ...])

- *Table* - Required. Table to search.
- *Formula(s)* - Required. The formula by which each record of the table is evaluated. The function returns all records that result in **true**. You can reference columns within the table. If you supply more than one formula, the results of all formulas are combined with the **And** function.

Search(Table*, *SearchString*, *Column1* [, *Column2*, ...])

- *Table* - Required. Table to search.

- *SearchString* - Required. The string to search for. If *blank* or an empty string, all records are returned.
- *Column(s)* - Required. The names of columns within *Table* to search. If *SearchString* is found within the data of any of these columns as a partial match, the full record will be returned.

> **Note**
>
> In Power Apps prior to version 3.24042, column names for the **Search** function were specified with a text string using double quotes, and if connected to a data source they also needed to be logical names. For example, the logical name **"cr43e_name"** with double quotes was used instead of the display name **Name** without quotes. For SharePoint and Excel data sources that contain column names with spaces, each space was specified with **"_x0020_"**, for example **"Column Name"** as **"Column_x0020_Name"**. After this version, all apps were automatically updated to the new syntax described in this article.

LookUp(Table*, *Formula* [, *ReductionFormula*])

- *Table* - Required. Table to search. In the UI, the syntax is shown as *source* above the function box.
- *Formula* - Required. The formula by which each record of the table is evaluated. The function returns the first record that results in **true**. You can reference columns within the table. In the UI, the syntax is shown as *condition* above the function box.
- *ReductionFormula* - Optional. This formula is evaluated over the record that was found, and then reduces the record to a single value. You can reference columns within the table. If you don't use this parameter, the function returns the full record from the table. In the UI, the syntax is shown as *result* above the function box.

Examples

The following examples use the **IceCream** data source:

Flavor	Quantity	OnOrder
"Chocolate"	100	75
"Vanilla"	200	50
"Strawberry"	300	0
"Mint Chocolate"	60	100

Expand table

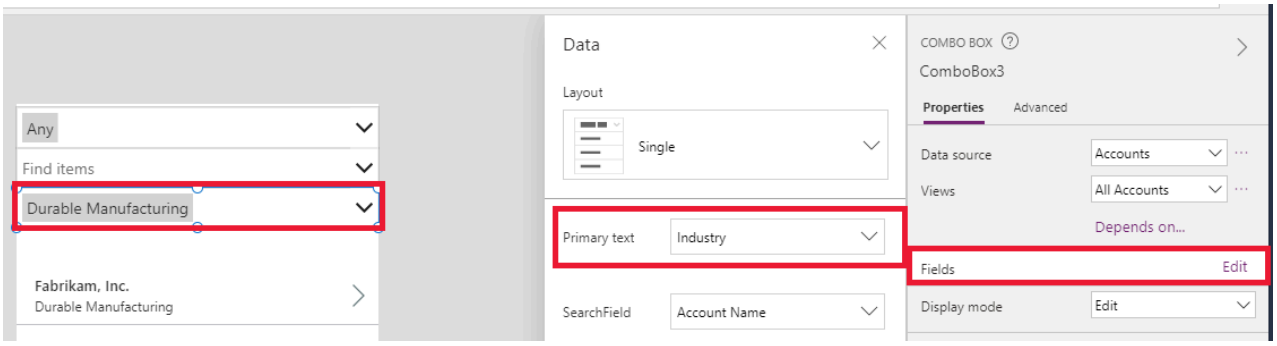
Formula	Description	Result
Filter(IceCream, OnOrder > 0)	Returns records where **OnOrder** is greater than zero.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Chocolate"</td><td>100</td><td>75</td></tr><tr><td>"Vanilla"</td><td>200</td><td>50</td></tr><tr><td>"Mint Chocolate"</td><td>60</td><td>100</td></tr></table>
Filter(IceCream, Quantity + OnOrder > 225)	Returns records where the sum of **Quantity** and **OnOrder** columns is greater than 225.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Vanilla"</td><td>200</td><td>50</td></tr><tr><td>"Strawberry"</td><td>300</td><td>0</td></tr></table>
Filter(IceCream, "chocolate" in Lower(Flavor))	Returns records where the word "chocolate" appears in the **Flavor** name, independent of uppercase or lowercase letters.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Chocolate"</td><td>100</td><td>75</td></tr><tr><td>"Mint Chocolate"</td><td>60</td><td>100</td></tr></table>
Filter(IceCream, Quantity < 10 && OnOrder < 20)	Returns records where the **Quantity** is less than 10 and **OnOrder** is less than 20. No records match these criteria, so an empty table is returned.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr></table>
Search(IceCream, "choc", Flavor)	Returns records where the string "choc" appears in the **Flavor** name, independent of uppercase or lowercase letters.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Chocolate"</td><td>100</td><td>75</td></tr><tr><td>"Mint Chocolate"</td><td>60</td><td>100</td></tr></table>
Search(IceCream, "", Flavor)	Because the search term is empty, all records are returned.	<table><tr><th>Flavor</th><th>Quantity</th><th>OnOrder</th></tr><tr><td>"Chocolate"</td><td>100</td><td>75</td></tr><tr><td>"Vanilla"</td><td>200</td><td>50</td></tr><tr><td>"Strawberry"</td><td>300</td><td>0</td></tr><tr><td>"Mint Chocolate"</td><td>60</td><td>100</td></tr></table>
LookUp(IceCream, Flavor = "Chocolate", Quantity)	Searches for a record with **Flavor** equal to "Chocolate", of which there's one. For the first record that's found, returns the **Quantity** of that record.	100
LookUp(IceCream, Quantity > 150, Quantity + OnOrder)	Searches for a record with **Quantity** greater than 150, of which there are multiple. For the first record that's found, which is "Vanilla" **Flavor**, returns the sum of **Quantity** and **OnOrder** columns.	250
LookUp(IceCream, Flavor = "Pistachio", OnOrder)	Searches for a record with **Flavor** equal to "Pistachio", of which there are none. Because none is found, **Lookup** returns *blank*.	*blank*
LookUp(IceCream, Flavor = "Vanilla")	Searches for a record with **Flavor** equal to "Vanilla", of which there's one. Since no reduction formula was supplied, the entire record is returned.	{ Flavor: "Vanilla", Quantity: 200, OnOrder: 75 }

Filtering with choice columns

The following example uses the **Account** table in Microsoft Dataverse as data source. This example shows how to **Filter** list of accounts based on selected Combo box control values:

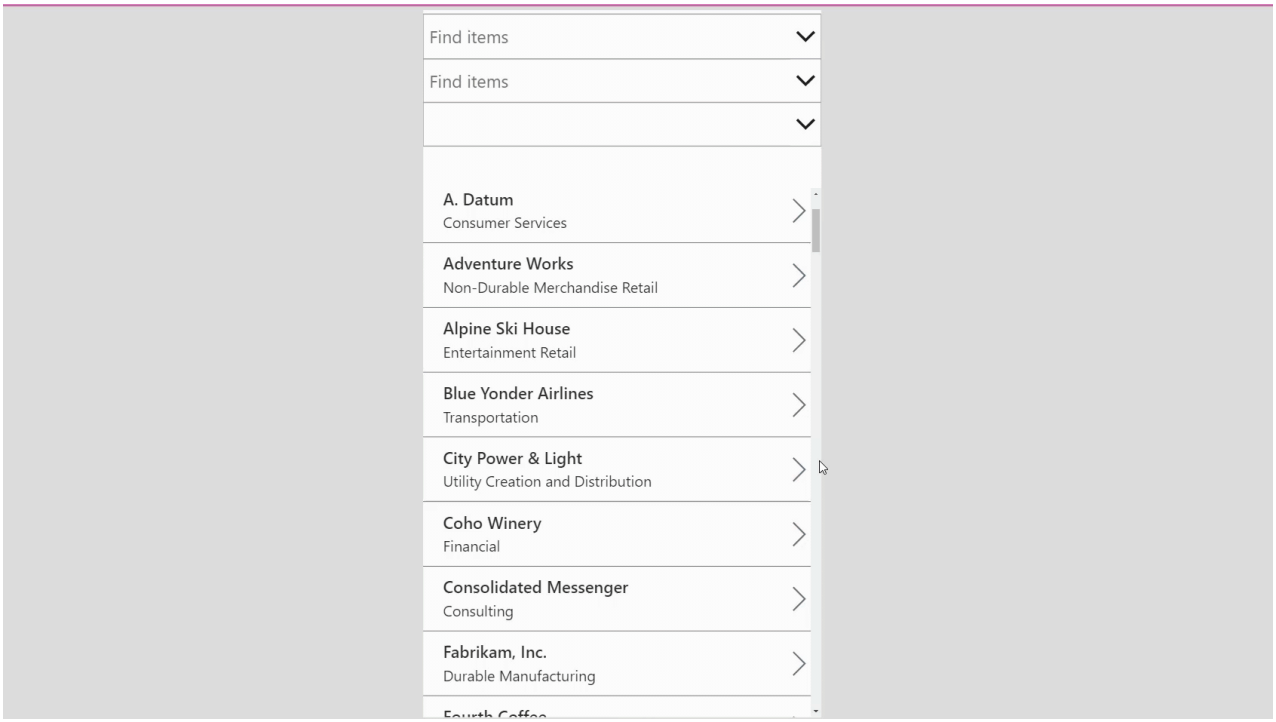
Step by step

1. Open a blank app.
2. Add a new screen by selecting the **New Screen** option.
3. On the **Insert** tab, select **Gallery** and then select **Vertical**.
4. On the **Properties** tab of the right-hand pane, open **Data Source** and then select **Accounts**.
5. (Optional) In the **Layout** list, select different options.
6. On the **Insert** tab, select **Input** and then select **Combo box**. Repeat the step to add two more combo box controls.
7. For each combo box control, on the **Properties** tab of the right-hand pane, open **Data Source** and then select **Accounts**. Select **Edit** next to **Fields** option and then select the **Primary text** and **SearchField** values. The **Primary text** should be the choices column you want to add to the combo box. Repeat the step for other two combo box controls.



8. Now select **Gallery** control and set the **Items** property to the following formula:

```
Filter(Accounts,
 'Industry' = ComboBox3.Selected.Industry Or
IsBlank(ComboBox3.Selected.Industry),
 'Relationship Type' = ComboBox2.Selected.'Relationship Type' Or
   IsBlank(ComboBox2.Selected.'Relationship Type'),
 'Preferred Method of Contact' = ComboBox1.Selected.'Preferred Method of
Contact' Or
   IsBlank(ComboBox1.Selected.'Preferred Method of Contact'))
```



Search user experience

The following examples use the **IceCream** data source:

In many apps, you can type one or more characters into a search box to filter a list of records in a large data set. As you type, the list shows only those records that match the search criteria.

The examples in the rest of this article show the results of searching a list, named **Customers**, that contain this data:

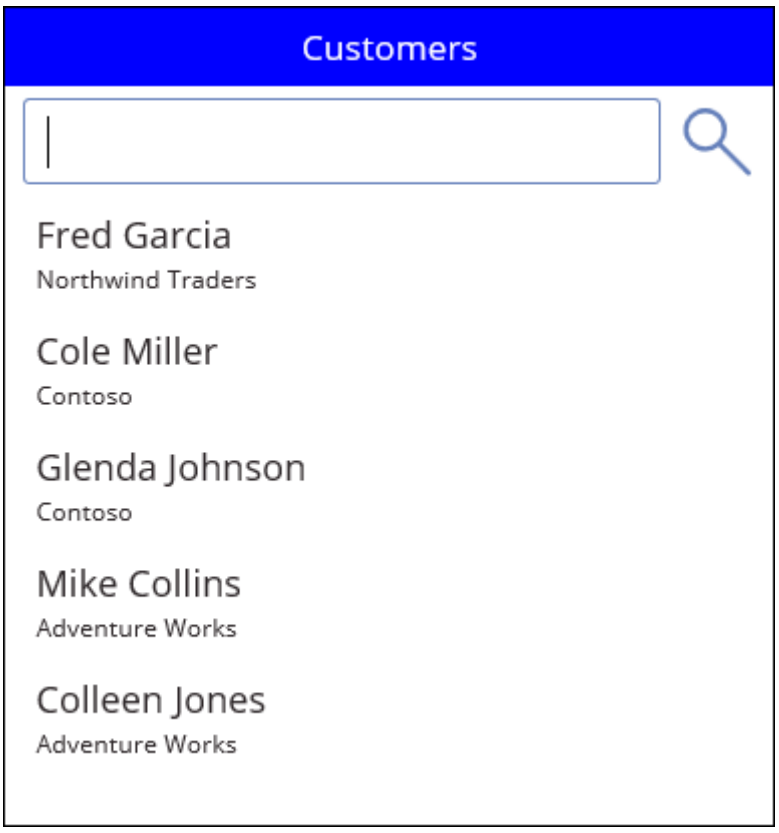
Name	Company
"Fred Garcia"	"Northwind Traders"
"Cole Miller"	"Contoso"
"Glenda Johnson"	"Contoso"
"Mike Collins"	"Adventure Works"
"Colleen Jones"	"Adventure Works"

To create this data source as a collection, create a **Button** control and set its **OnSelect** property to this formula:

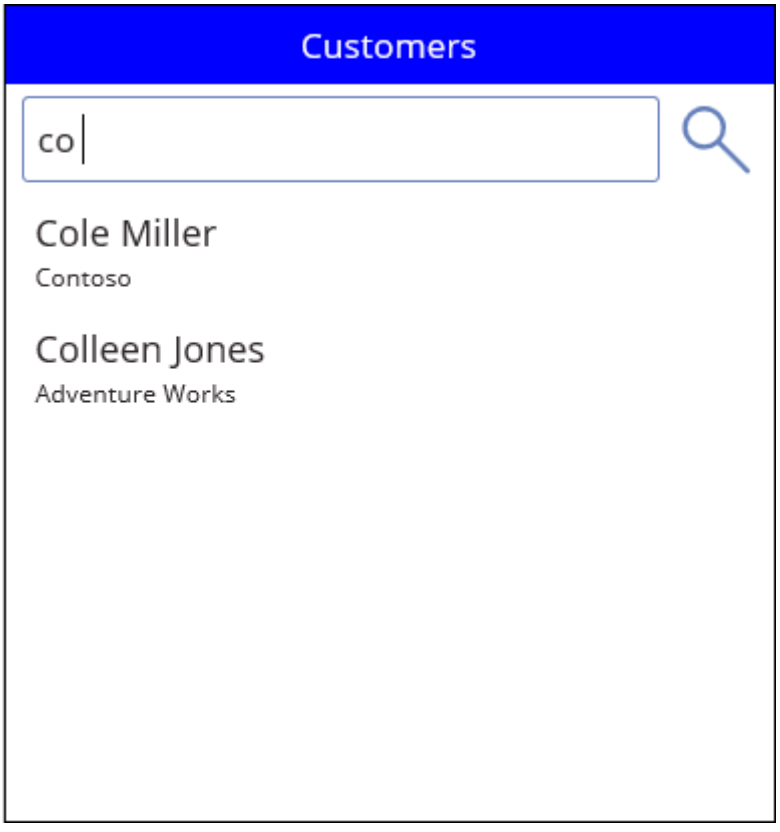
ClearCollect(Customers, Table({ Name: "Fred Garcia", Company: "Northwind Traders" }, { Name: "Cole Miller", Company: "Contoso" }, { Name: "Glenda Johnson", Company: "Contoso" }, { Name: "Mike Collins", Company: "Adventure Works" }, { Name: "Colleen Jones", Company: "Adventure Works" }))

As in this example, you can show a list of records in a **Gallery control** at the bottom of a screen. Near the top of the screen, you can add a **Text input** control, named **SearchInput**, so

that users can specify which records interest them.



As the user types characters in **SearchInput**, the results in the gallery are automatically filtered. In this case, the gallery is configured to show records for which the name of the customer (not the name of the company) starts with the sequence of characters in **SearchInput**. If the user types **co** in the search box, the gallery shows these results:



To filter based on the **Name** column, set the **Items** property of the gallery control to one of these formulas:

Expand table

Formula	Description	Result
Filter(Customers, StartsWith(Name, SearchInput.Text))	Filters the **Customers** data source for records in which the search string appears at the start of the **Name** column. The test is case insensitive. If the user types **co** in the search box, the gallery shows **Colleen Jones** and **Cole Miller**. The gallery doesn't show **Mike Collins** because the **Name** column for that record doesn't start with the search string.	
Filter(Customers, SearchInput.Text in Name)	Filters the **Customers** data source for records in which the search string appears anywhere in the **Name** column. The test is case insensitive. If the user types **co** in the search box, the gallery shows **Colleen Jones, Cole Miller,** and **Mike Collins** because the search string appears somewhere in the **Name** column of all of those records.	Search(Customers, SearchInput.Text, Name)	Similar to using the **in** operator, the **Search** function searches for a match anywhere within the **Name** column of each record. You must enclose the column name in double quotation marks.	

You can expand your search to include the **Company** column and the **Name** column:

Expand table

Formula	Description	Result
`Filter(Customers, StartsWith(Name, SearchInput.Text) || StartsWith(Company, SearchInput.Text) )`	Filters the **Customers** data source for records in which either the **Name** column or the **Company** column starts with the search string (for example, **co**). The || operator is *true* if either **StartsWith** function is *true*.	
`Filter(Customers, SearchInput.Text in Name || SearchInput. Text in Company)`	Filters the **Customers** data source for records in which either the **Name** column or the **Company** column contains the search string (for example, **co**) anywhere within it.	
`Search(Customers, SearchInput.Text, Name, Company)`	Similar to using the **in** operator, the **Search** function searches the **Customers** data source for records in which either the **Name** column or the **Company** column contains the search string (for example, **co**) anywhere within it. The **Search** function is easier to read and write	

Formula	Description	Result
	than **Filter** if you want to specify multiple columns and multiple **in** operators.	

Last updated on 02/06/2025

Day, Month, Year, Hour, Minute, Second, and Weekday functions

Article • 06/10/2024

Applies to: Canvas apps Dataverse formula columns Desktop flows Model-driven apps Power Pages Power Platform CLI

Returns individual components of a Date/Time value.

Description

The **Day** function returns the day component of a Date/Time value, ranging from 1 to 31.

The **Month** function returns the month component of a Date/Time value, ranging from 1 to 12.

The **Year** function returns the year component of a Date/Time value, starting with 1900.

The **Hour** function returns the hour component of a Date/Time value, ranging from 0 (12:00 AM) to 23 (11:00 PM).

The **Minute** function returns the minute component of a Date/Time value, ranging from 0 to 59.

The **Second** function returns the second component of a Date/Time value, ranging from 0 to 59.

The **Weekday** function returns the weekday of a Date/Time value. By default, the result ranges from 1 (Sunday) to 7 (Saturday). You can specify a different range with a Microsoft Excel Weekday function code or a StartOfWeek enumeration value:

Expand table

Excel code	StartOfWeek enumeration	Description
1, 17	StartOfWeek.Sunday	Numbers 1 (Sunday) through 7 (Saturday). Default.
2, 11	StartOfWeek.Monday	Numbers 1 (Monday) through 7 (Sunday).
3	StartOfWeek.MondayZero	Numbers 0 (Monday) through 6 (Sunday).
12	StartOfWeek.Tuesday	Numbers 1 (Tuesday) through 7 (Monday).

Excel code	StartOfWeek enumeration	Description
13	**StartOfWeek.Wednesday**	Numbers 1 (Wednesday) through 7 (Tuesday).
14	**StartOfWeek.Thursday**	Numbers 1 (Thursday) through 7 (Wednesday).
15	**StartOfWeek.Friday**	Numbers 1 (Friday) through 7 (Thursday).
16	**StartOfWeek.Saturday**	Numbers 1 (Saturday) through 7 (Friday).

All functions return a number.

See working with dates and times for more information.

Syntax

Day(*DateTime*)
Month(*DateTime*)
Year(*DateTime*)
Hour(*DateTime*)
Minute(*DateTime*)
Second(*DateTime*)

- *DateTime* - Required. Date/Time value to operate on.

Weekday(*DateTime* [, *WeekdayFirst*])

- *DateTime* - Required. Date/Time value to operate on.
- *WeekdayFirst* - Optional. Excel code specifying which day starts the week. If not supplied, 1 (Sunday first) is used.

Examples

For the following example, the current time is **3:59:37 PM** on **Thursday, April 9, 2015**.

Expand table

Formula	Description	Result
Year(Now())	Returns the year component of the current time and date.	2015
Month(Now())	Returns the month component of the current time and date.	4

Formula	Description	Result
Day(Now())	Returns the day component of the current time and date.	9
Hour(Now())	Returns the hour component of the current time and date.	15
Minute(Now())	Returns the minute component of the current time and date.	59
Second(Now())	Returns the second component of the current time and date.	37
Weekday(Now())	Returns the weekday component of the current time and date, using the default start of the week as Sunday.	5
Weekday(Now(), 14)	Returns the weekday component of the current time and date, using an Excel code to specify the start of the week as Thursday.	1
Weekday(Now(), StartOfWeek.Wednesday)	Returns the weekday component of the current time and date, using a **StartOfWeek** enumeration to specify the start of the week as Wednesday.	2

Select function

06/20/2025

Applies to: Canvas apps

Simulates a select action on a control, causing the **OnSelect** formula to be evaluated.

Description

The **Select** function simulates a select action on a control as if the user had clicked or tapped the control. As a result, the **OnSelect** formula on the target control is evaluated.

Use **Select** to propagate a select action to a parent control. This type of propagation is the default behavior in, for example, galleries. By default, the **OnSelect** property of any control in a Gallery control is set to **Select(Parent)**. That way, you can set the value of the **OnSelect** property of the gallery control itself, and that formula will be evaluated regardless of where in the gallery a user might click or tap.

If you want one or more controls in the gallery to perform different actions from the gallery itself, set the **OnSelect** property for those controls to something other than the default value. You can leave the default values for the **OnSelect** properties of most controls in the gallery if you want them to perform the same action as the gallery itself.

Select queues the target **OnSelect** for later processing, which may happen after the current formula has finished being evaluated. **Select** doesn't cause the target **OnSelect** to evaluate immediately, nor does **Select** wait for **OnSelect** to finish being evaluated.

You can't use **Select** across screens.

You can use **Select** only with controls that have an **OnSelect** property.

You can use **Select** only in behavior formulas.

A control can't **Select** itself directly or indirectly through other controls.

The select function can also be used with a gallery. For example, it can be used to specify the row or column to select in a gallery and the control to select within that row or column of the gallery. When you select a row or column, the gallery selection changes and the **OnSelect** formula on the gallery control is evaluated. If a control within the row or column is provided, the **OnSelect** formula for the child control will be evaluated.

Syntax

Select(*Control*)

- *Control* – Required. The control to select on behalf of the user.

Select(*Control, Row or column, Child Control*)

- *Control* – Required. The control to select on behalf of the user.
- *Row or column* – Not required. The number of row or column (starting with 1) in a gallery control to select on behalf of the user.
- *Child Control* - Not required. The child control of the control identified in the 'control' parameter to select.

Examples

- *Button*

  `Select(button1)`

- *Gallery*

  `Select(Gallery1, 1)`

  Simulates a user selecting row 1 or column 1 in Gallery1.

- *Gallery*

  `Select(Gallery1, 1, ChildControl1)`

  Simulates a user selecting ChildConttrol1 in row 1 or column 1 of Gallery1.

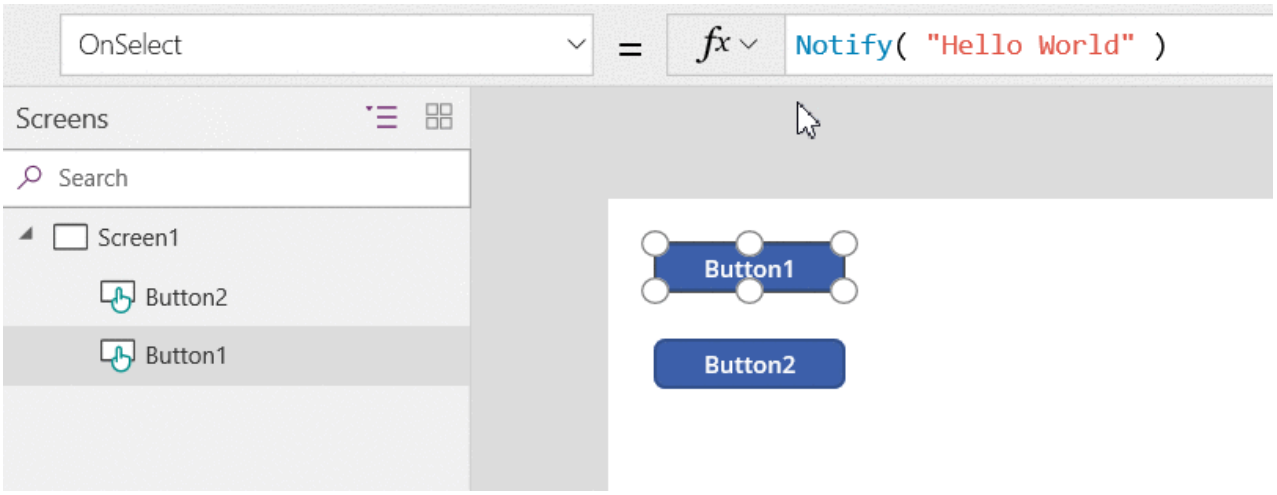
Basic usage

1. Add a Button control, and rename it **Button1** if it has a different name.
2. Set the **OnSelect** property of **Button1** to this formula:

   Notify("Hello World")
3. On the same screen, add a second **Button** control, and set its **OnSelect** property to this formula:

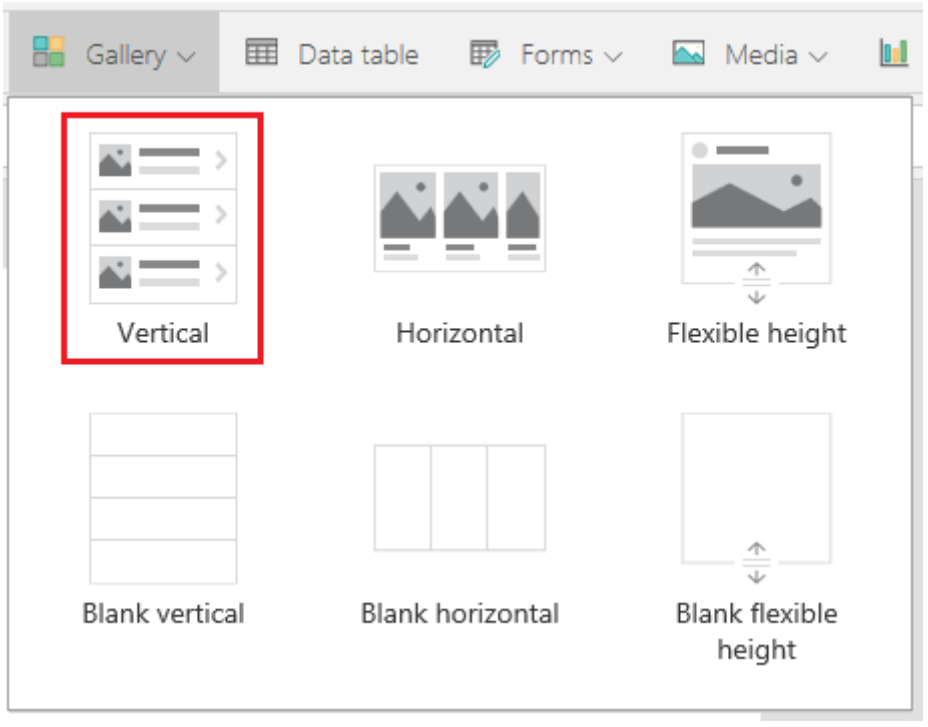
   Select(Button1)
4. While holding down the Alt key, select the second button.

A notification appears across the top of your app. The **OnSelect** property of **Button1** generated this notification.



Gallery control

1. Add a vertical Gallery control that contains other controls.



2. Set the **OnSelect** property of the gallery to this formula:

   Notify("Gallery Selected")

3. While holding down the Alt key, click or tap the background of the gallery or any control in the gallery.

   All actions will show the **Gallery Selected** notification at the top of the app.

Use the gallery's **OnSelect** property to specify the default action to take when the user clicks or taps an item in the gallery.

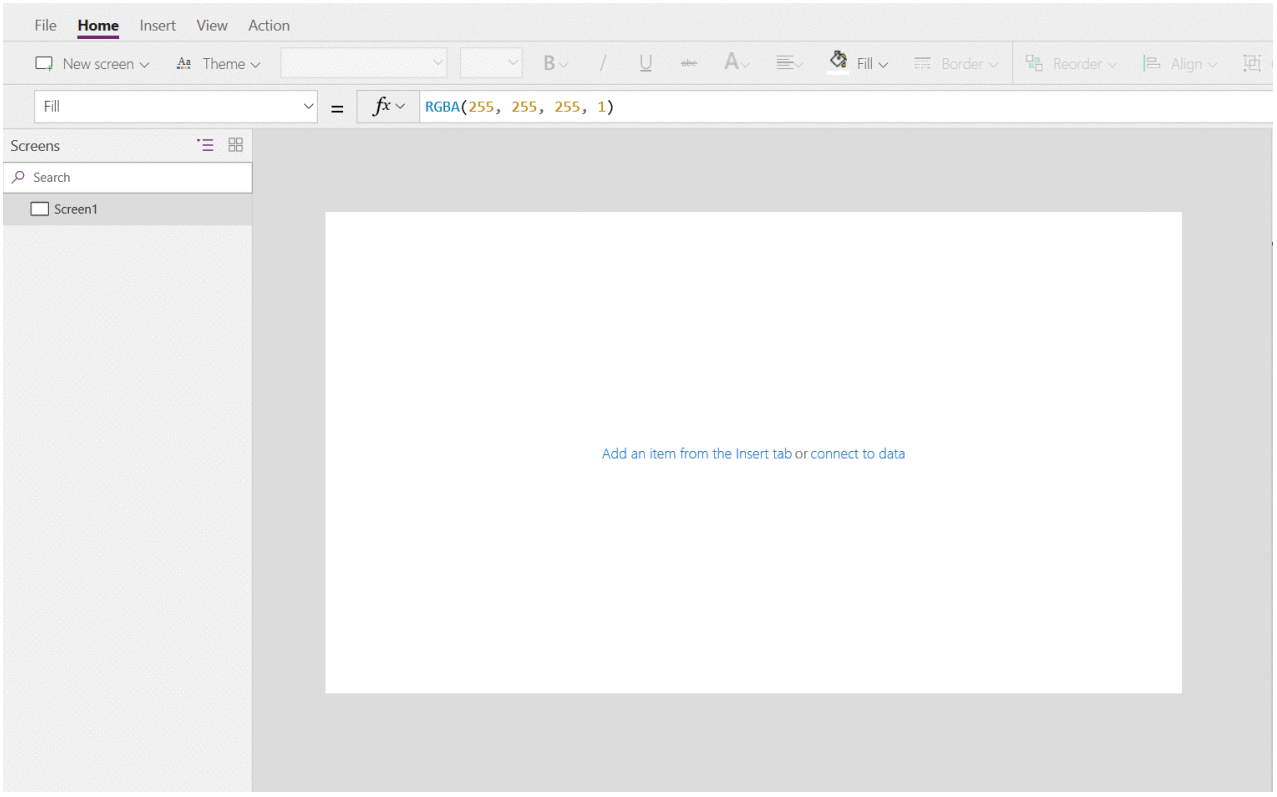
4. Set the **OnSelect** property of the image control to this formula:

   Notify("Image Selected", NotificationType.Success)

5. While holding down the Alt key, click or tap the various elements of the gallery.

   When you click or tap any control in the gallery except the image, **Gallery Selected** appears as before. When you click or tap the image, **Image Selected** appears.

   Use individual controls in the gallery to take actions that differ from the gallery's default action.



6. On the same screen, add a **Button** control, and set its **OnSelect** property to this formula:

   Select(Gallery1,2,Image1)

7. While holding down the Alt key, select the button.

   A **Image Selected** notification appears across the top of your app. The button click simulated selecting the image in row 2 of the gallery.

Operators and Identifiers in Power Apps

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Some of these operators are dependent on the language of the author. For more information about language support in canvas apps, see Global apps.

Expand table

Symbol	Type	Example	Description
'...'	Identifier	**'Account Name'**	Identifiers that contain special characters, including spaces, are enclosed in single quotes
"..."	Text string	**"Hello, World"**	Text strings are enclosed in double quotes
$"..."	String interpolation	**$"Dear {FirstName},"**	Formulas embedded within a text string
.	Property Selector	**Slider1.Value** **Color.Red** **Acceleration.X**	Extracts a property from a table, control, signal, or enumeration. For backward compatibility, **!** may also be used.
. [language dependent]	Decimal separator	**1.23**	Separator between whole and fractional parts of a number. The character depends on the language.
( )	Parentheses	**Filter(T, A < 10)** **(1 + 2) * 3**	Enforces precedence order, and groups subexpressions in a larger expression
+	Arithmetic operators	**1 + 2**	Addition
-		**2 - 1**	Subtraction and sign
*		**2 * 3**	Multiplication
/		**2 / 3**	Division (also see the **Mod** function)
^		**2 ^ 3**	Exponentiation, equivalent to the **Power** function

Symbol	Type	Example	Description
%		**20%**	Percentage (equivalent to "* 1/100")
=	Comparison operators	**Price = 100**	Equal to
>		**Price > 100**	Greater than
>=		**Price >= 100**	Greater than or equal to
<		**Price < 100**	Less than
<=		**Price <= 100**	Less than or equal to
<>		**Price <> 100**	Not equal to
&	String concatenation operator	**"hello" & " " & "world"**	Makes multiple strings appear continuous
&& or **And**	Logical operators	**Price < 100 && Slider1.Value = 20** or **Price < 100 And Slider1.Value = 20**	Logical conjunction, equivalent to the **And** function
|| or **Or**		**Price < 100 || Slider1.Value = 20** or **Price < 100 Or Slider1.Value = 20**	Logical disjunction, equivalent to the **Or** function
! or **Not**		**!(Price < 100)** or **Not (Price < 100)**	Logical negation, equivalent to the **Not** function
exactin	Membership operators	**Gallery1.Selected exactin SavedItems**	Belonging to a collection or a table
exactin		**"Windows" exactin "To display windows in the Windows operating system..."**	Substring test (case-sensitive)
in		**Gallery1.Selected in SavedItems**	Belonging to a collection or a table
in		**"The" in "The keyboard and the monitor..."**	Substring test (case-insensitive)
@	Disambiguation operator	**MyTable[@fieldname]**	Field disambiguation
@		**[@MyVariable]**	Global disambiguation

Symbol	Type	Example	Description
, [language dependent]	List separator	**If(X < 10, "Low", "Good")** **{ X: 12, Y: 32 }** **[1, 2, 3]**	Separates: • arguments in function calls • fields in a record • records in a table This character depends on the language.
; [language dependent]	Formula chaining	**Collect(T, A); Navigate(S1, "")**	Separate invocations of functions in behavior properties. The chaining operator depends on the language.
As	As operator	**AllCustomers As Customer**	Overrides **ThisItem** and **ThisRecord** in galleries and record scope functions. **As** is useful for providing a better, specific name and is especially important in nested scenarios.
Self	Self operator	**Self.Fill**	Access to properties of the current control
Parent	Parent operator	**Parent.Fill**	Access to properties of a control container
ThisItem	ThisItem operator	**ThisItem.FirstName**	Access to fields of a Gallery or form control
ThisRecord	ThisRecord operator	**ThisRecord.FirstName**	Access to the complete record and individual fields of the record within **ForAll**, **Sum**, **With**, and other record scope functions. Can be overridden with the **As** operator.

> ⓘ Note
>
> The @ operator can also be used to validate the type of the record object against a data source. For example, `Collect(coll,Account@{'Account Number: 1111')`

in and exactin operators

Use the **in** and **exactin** operators to find a string in a data source, such as a collection or an imported table. The **in** operator identifies matches regardless of case, and the **exactin** operator identifies matches only if they're capitalized the same way. Here's an example:

1. Create or import a collection named **Inventory**, and show it in a gallery, as the first procedure in Show images and text in a gallery describes.

2. Set the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" in ProductName)

   The gallery shows all products except Callisto because the name of that product is the only one that doesn't contain the letter you specified.

3. Change the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" exactin ProductName)

   The gallery shows only Europa because only its name contains the letter that you specified in the case that you specified.

ThisItem, ThisRecord, and As operators

A few controls and functions apply formulas to individual records of a table. To refer to the individual record in a formula, use one of the following:

Expand table

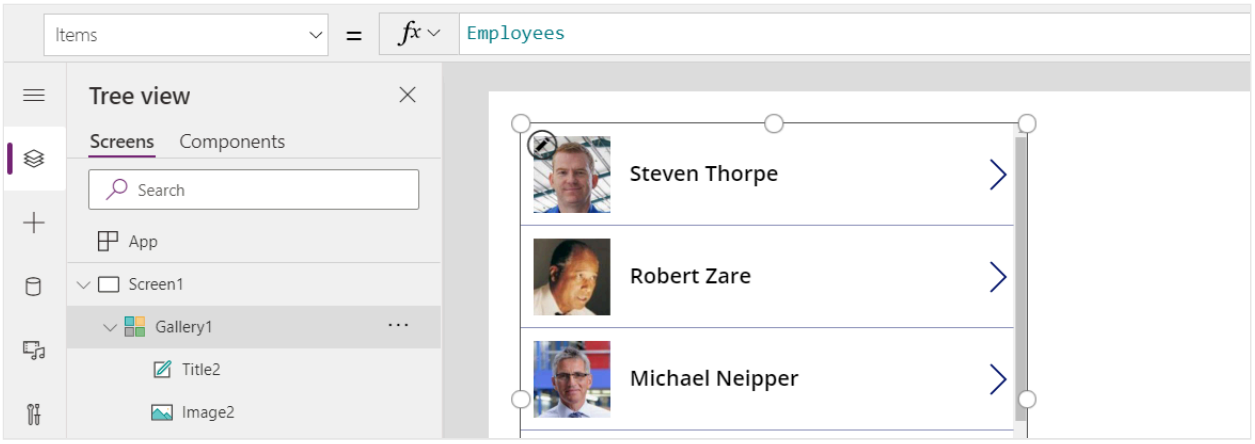
Operator	Applies to	Description
ThisItem	**Gallery** control **Edit form** control **Display form** control	The default name for the current record in a **Gallery** or form control.
ThisRecord	**ForAll**, **Filter**, **With**, **Sum** and other record scope functions	The default name for the current record in **ForAll** and other record scope functions.
As *name*	**Gallery** control **ForAll**, **Filter**, **With**, **Sum** and other record scope functions	Defines a *name* for the current record, replacing default **ThisItem** or **ThisRecord**. Use **As** to make formulas easier to understand and resolve ambiguity when nesting.

ThisItem operator

For example, in the following **Gallery** control, the **Items** property is set to the **Employees** data source (such as the **Employees** table included with the Northwind Traders sample):

Power Apps

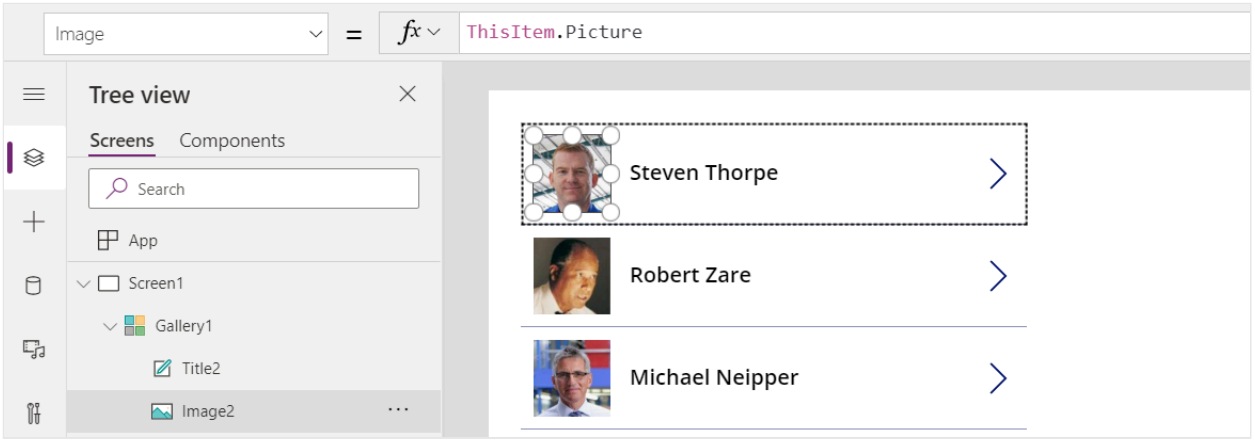
```
Employees
```



The first item in the gallery is a template that is replicated for each employee. In the template, the formula for the picture uses **ThisItem** to refer to the current item:

Power Apps

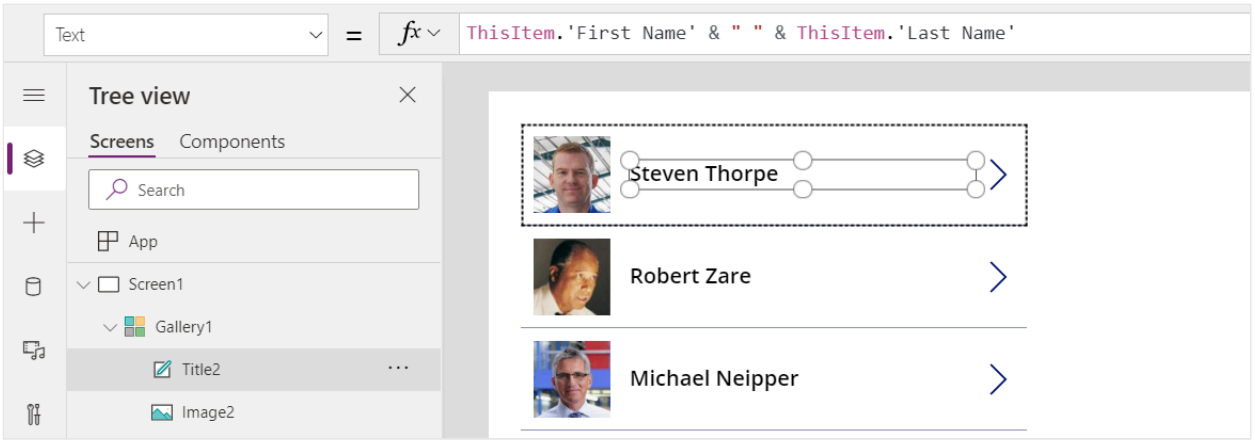
```
ThisItem.Picture
```



Likewise, the formula for the name also uses **ThisItem**:

Power Apps

```
ThisItem.'First Name' & " " & ThisItem.'Last Name'
```

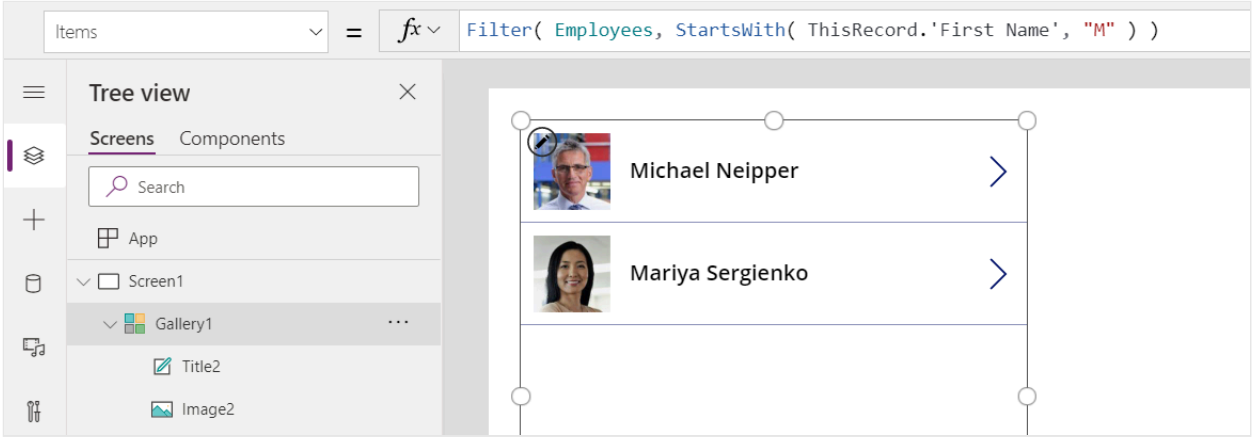


ThisRecord operator

ThisRecord is used in functions that have a record scope. For example, we can use the **Filter** function with our gallery's **Items** property to only show first names that being with *M*:

Power Apps

```
Filter( Employees, StartsWith( ThisRecord.Employee.'First Name', "M" ) )
```



ThisRecord is optional and implied by using the fields directly, for example, in this case, we could have written:

Power Apps

```
Filter( Employees, StartsWith( 'First Name', "M" ) )
```

Although optional, using **ThisRecord** can make formulas easier to understand and may be required in ambiguous situations where a field name may also be a relationship name. **ThisRecord** is optional while **ThisItem** is always required.

Use **ThisRecord** to reference the whole record with **Patch**, **Collect**, and other record scope functions. For example, the following formula sets the status for all inactive employees to active:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees,
              Patch( Employees, ThisRecord, { Status: 'Status
(Employees)'.Active } ) ) )
```

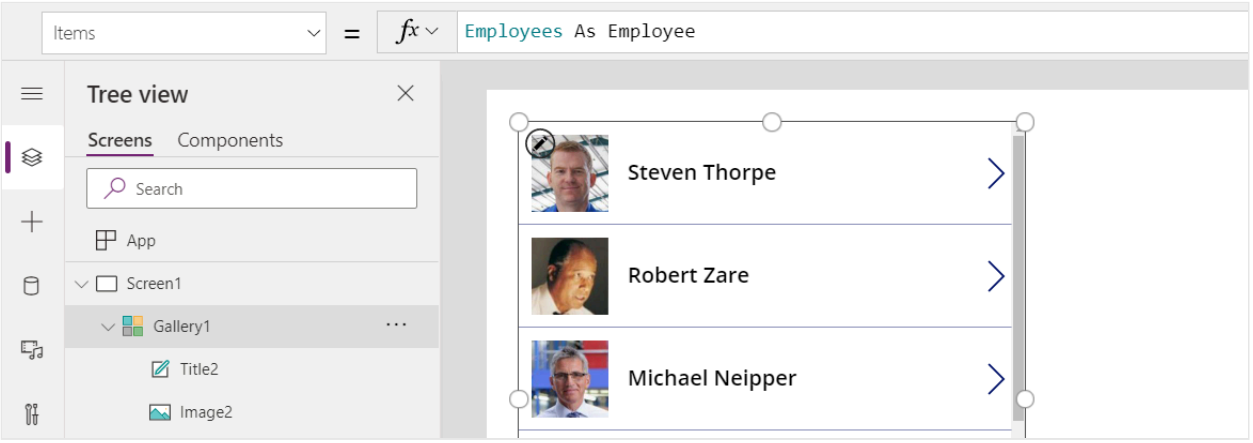
As operator

Use the **As** operator to name a record in a gallery or record scope function, overriding the default **ThisItem** or **ThisRecord**. Naming the record can make your formulas easier to understand and may be required in nested situations to access records in other scopes.

For example, you can modify the **Items** property of our gallery to use **As** to identify that we are working with an Employee:

Power Apps

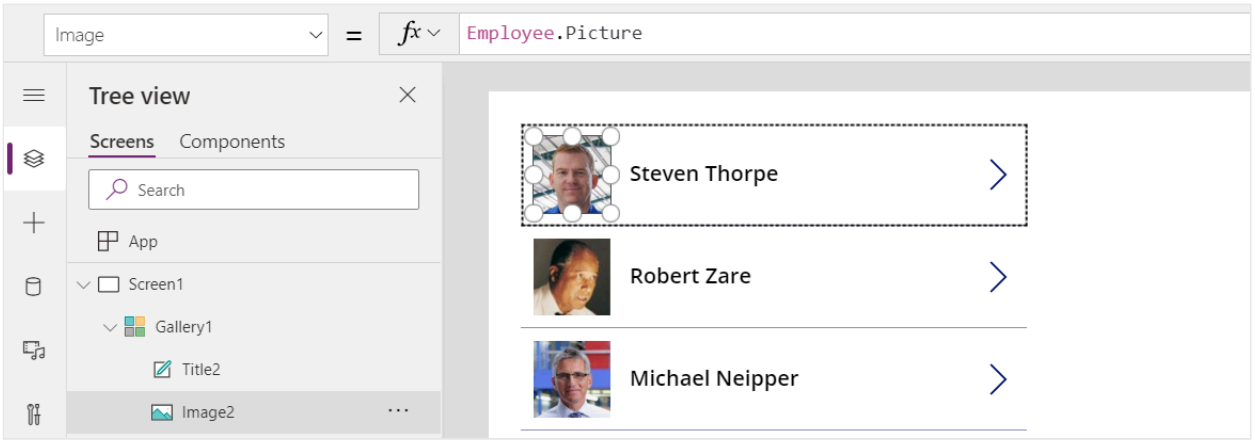
```
Employees As Employee
```



The formulas for the picture and name are adjusted to use this name for the current record:

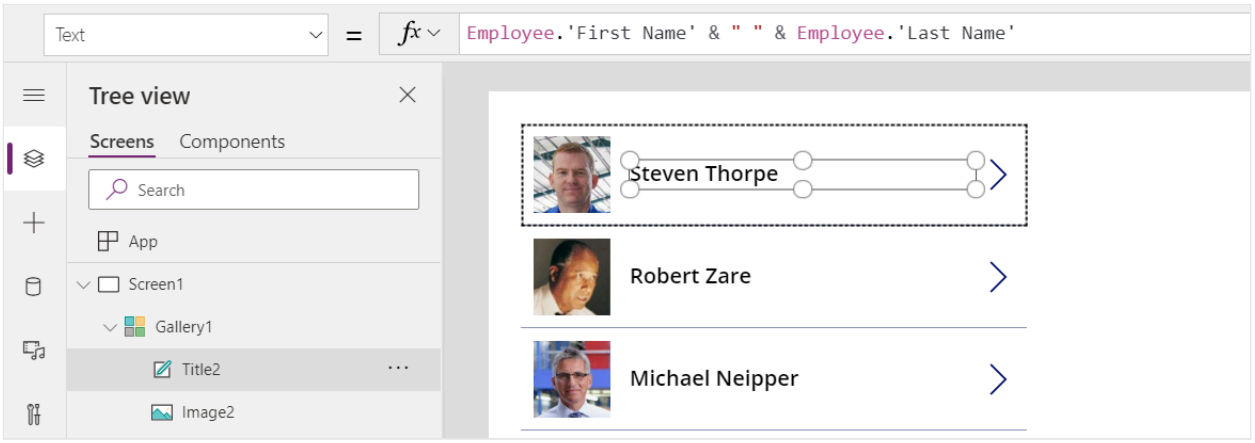
Power Apps

```
Employee.Picture
```



Power Apps

```
Employee.'First Name' & " " & Employee.'Last Name'
```



As can also be used with record scope functions to replace the default name **ThisRecord**. We can apply this to our previous example to clarify the record we're working with:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees As Employee,
              Patch( Employees, Employee, { Status: 'Status
(Employees)'.Active } ) ) )
```

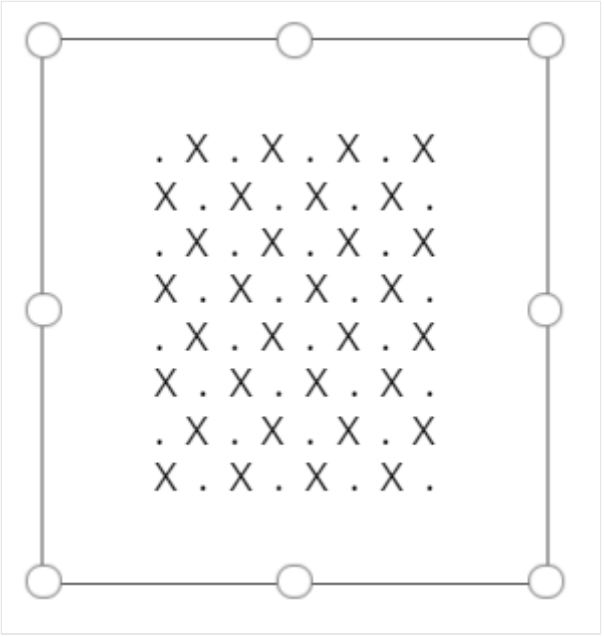
When nesting galleries and record scope functions, **ThisItem** and **ThisRecord** always refers to the inner most scope, leaving records in outer scopes unavailable. Use **As** to make all record scopes available by giving each a unique name.

For example, this formula produces a chessboard pattern as a text string by nesting two **ForAll** functions:

Power Apps

```
Concat(
    ForAll( Sequence(8) As Rank,
        Concat(
            ForAll( Sequence(8) As File,
                    If( Mod(Rank.Value + File.Value, 2) = 1, " X ", " . " )
            ),
            Value
        ) & Char(10)
    ),
    Value
)
```

Setting a **Label** control's **Text** property to this formula displays:



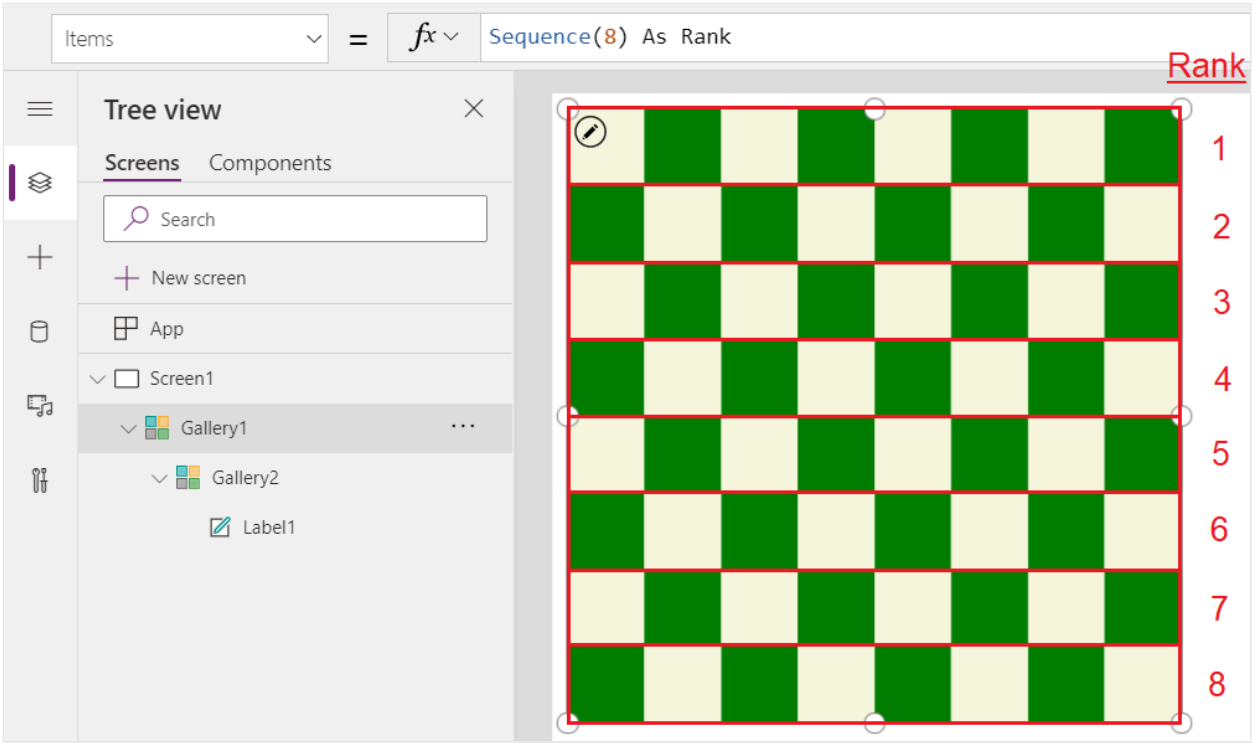
Let's unpack what is happening here:

- We start by iterating an unnamed table of 8 numbered records from the Sequence function. This loop is for each row of the board, which is commonly referred to as **Rank** and so we give it this name.
- For each row, we iterate another unnamed table of 8 columns, and we give the common name **File**.
- If **Rank.Value** + **File.Value** is an odd number, the square gets an **X**, otherwise a dot. This part of the formula is referencing both **ForAll** loops, made possible by using the **As** operator.
- Concat is used twice, first to assemble the columns and then the rows, with a Char(10) thrown in to create a new line.

A similar example is possible with nested **Gallery** controls instead of **ForAll** functions. Let's start with the vertical gallery for the **Rank**. This gallery control will have an **Items** formula of:

Power Apps

```
Sequence(8) as Rank
```



Within this gallery, we'll place a horizontal gallery for the **File**, that will be replicated for each **Rank**, with an **Items** property of:

Power Apps

```
Sequence(8) as File
```

And finally, within this gallery, we'll add a **Label** control that will be replicated for each **File** and each **Rank**. We'll size it to fill the entire space and use the **Fill** property to provide the color with this formula:

Power Apps

```
If( Mod( Rank.Value + File.Value, 2 ) = 1, Green, Beige )
```

Self and Parent operators

There are three ways to refer to a control and its properties within a formula:

Expand table

Method	Description
By control name	Any control can be referenced by name from anywhere within the app. For example, **Label1.Fill** refers to the fill property of the control who's name is **Label1**.
Self operator	It's often convenient to reference another property of the same control when writing a formula. Instead of using an absolute reference by name, it's easier and more portable to use a relative reference to one*self*. The **Self** operator provides that easy access to the current control. For example, **Self.Fill** refers to the fill color of the current control.

Method	Description
Parent operator	Some controls host other controls, such as the **Screen** and **Gallery** controls. The hosting control of the controls within it's called the *parent*. Like the **Self** operator, the **Parent** operator provides an easy relative reference to the container control. For example, **Parent.Fill** refers to the fill property of the control that is the container for the current control.

Self and **Parent** are operators and not properties on the controls themselves. Referring to **Parent.Parent**, **Self.Parent** or **Parent.Self** is not supported.

Identifier names

The names of variables, data sources, columns, and other objects can contain any Unicode.

Use single quotes around a name that contains a space or other special character. Use two single quotes together to represent one single quote in the name. Names that don't contain special characters don't require single quotes.

Here are some example column names you might encounter in a table, and how they're represented in a formula:

Expand table

Column name in a database	Column reference in a formula
SimpleName	`SimpleName`
NameWith123Numbers	`NameWith123Numbers`
Name with spaces	`'Name with spaces'`
Name with "double" quotes	`'Name with "double" quotes'`
Name with 'single' quotes	`'Name with ''single'' quotes'`
Name with an @ at sign	`'Name with an @ at sign'`

Double quotes are used to designate text strings.

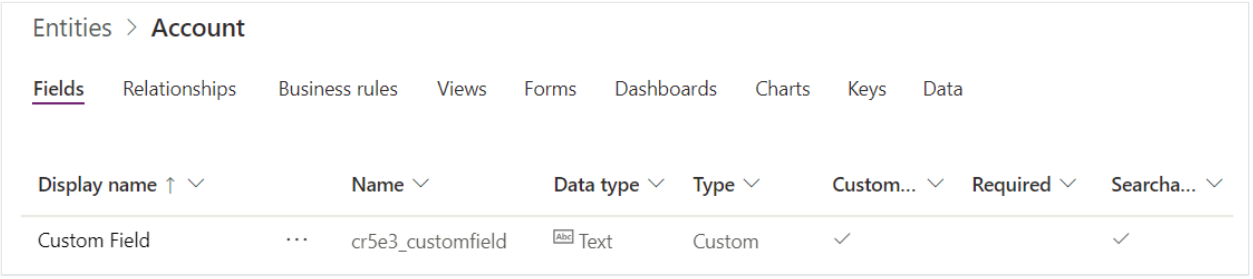
Display names and logical names

Some data sources such as SharePoint and Microsoft Dataverse have two different names to refer to the same table or column of data:

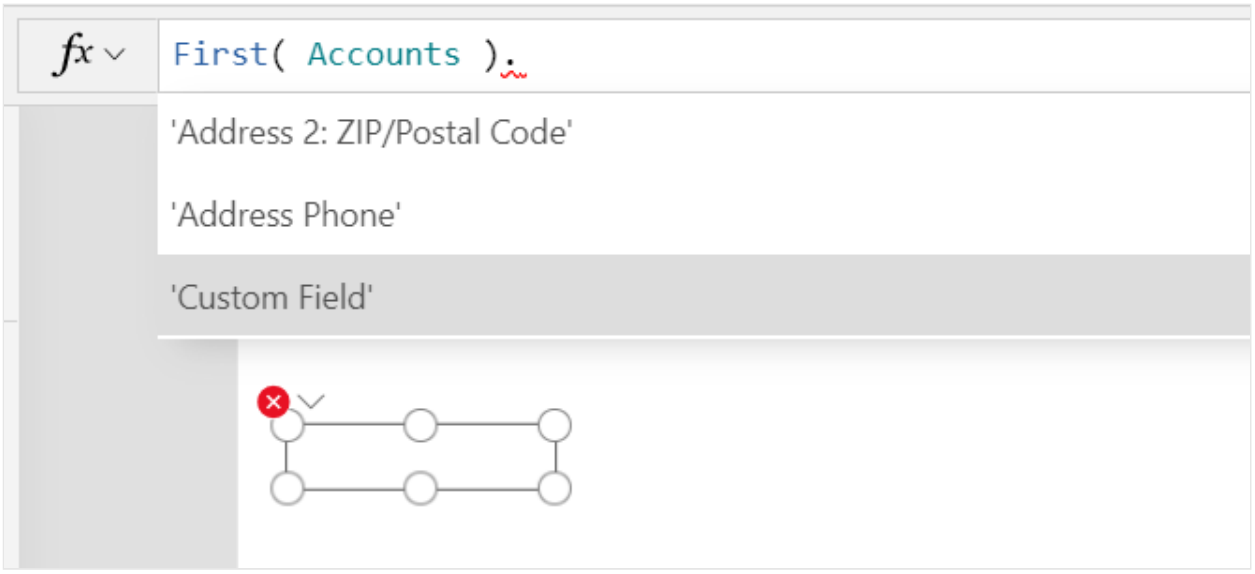
- **Logical name** - A name that is guaranteed to be unique, doesn't change after being created, usually doesn't allow spaces or other special characters, and isn't localized into different languages. As a result, the name can be cryptic. These names are used by professional developers. For example, **cra3a_customfield**. This name may also be referred to as **schema name** or just **name**.
- **Display name** - A name that is user-friendly and intended to be seen by end users. This name may not be unique, may change over time, may contain spaces and any Unicode character, and may be localized into different languages. Corresponding to the example above, the display name may be **Custom Field** with space in between the words.

Since display names are easier to understand, Canvas apps will suggest them as choices and not suggest logical names. Although logical names aren't suggested, they can still be used if typed indirectly.

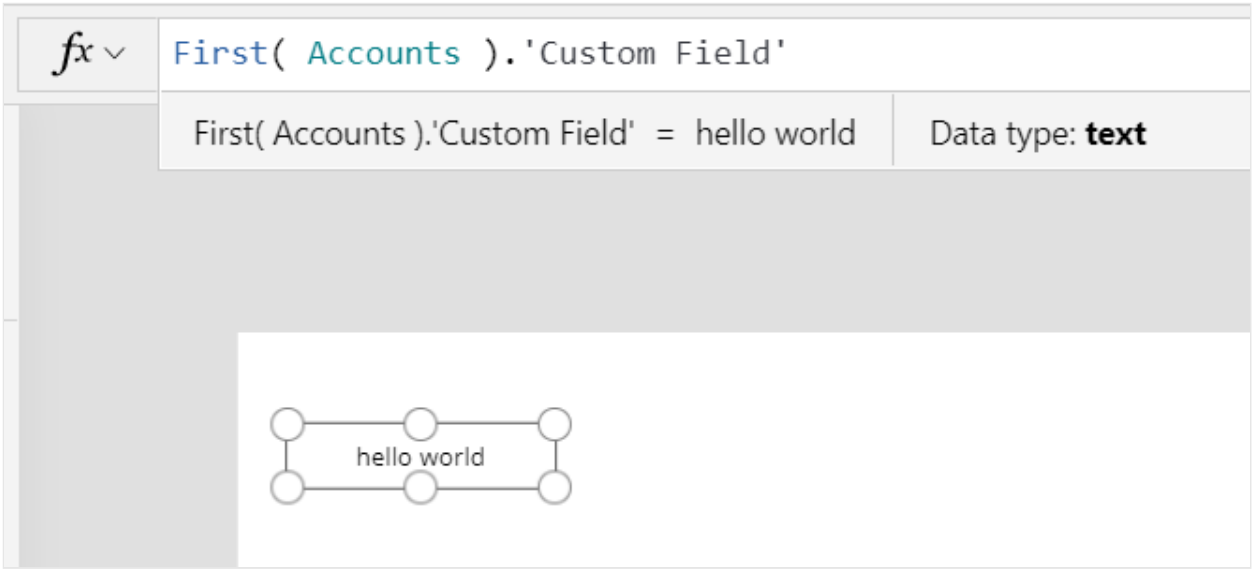
For example, imagine you've added a **Custom Field** to a table in Dataverse. A logical name will be assigned for you by the system, which you can modify only when creating the field. The result would look similar to:



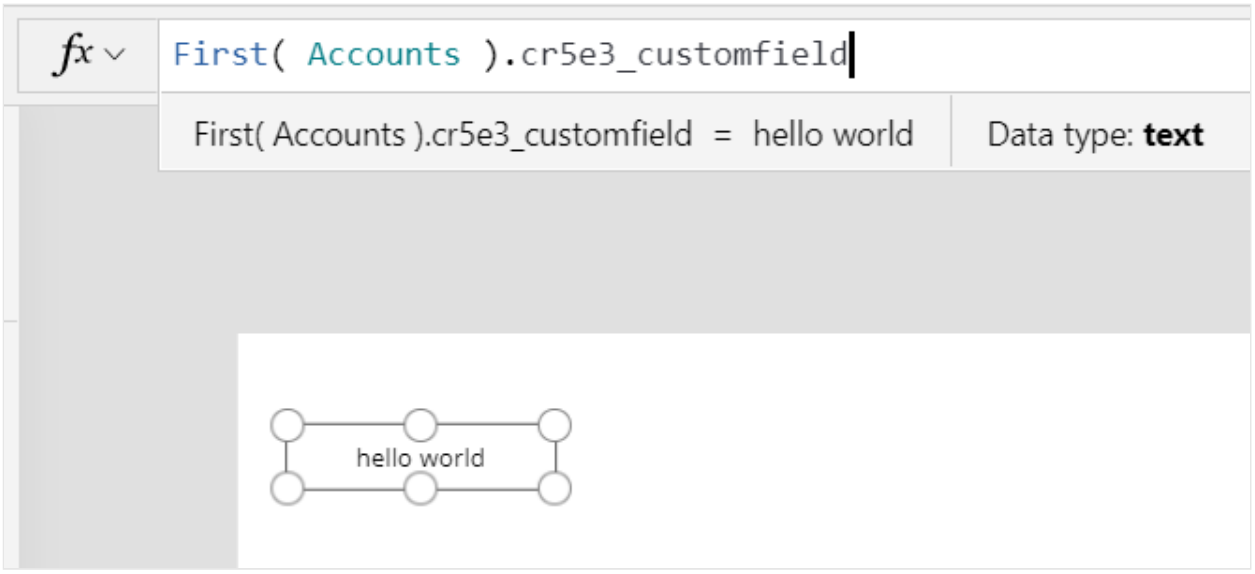
When authoring a reference to a field of Accounts, the suggestion will be made to use '**Custom Field**' since this is the display name. Single quotes must be used because this name has a space in it:



After selecting the suggestion, 'Custom Field' is shown in the formula bar and the data is retrieved:



Although it isn't suggested, we could also use the logical name for this field. This will result in the same data being retrieved. Single quotes are not required since this name doesn't contain spaces or special characters:

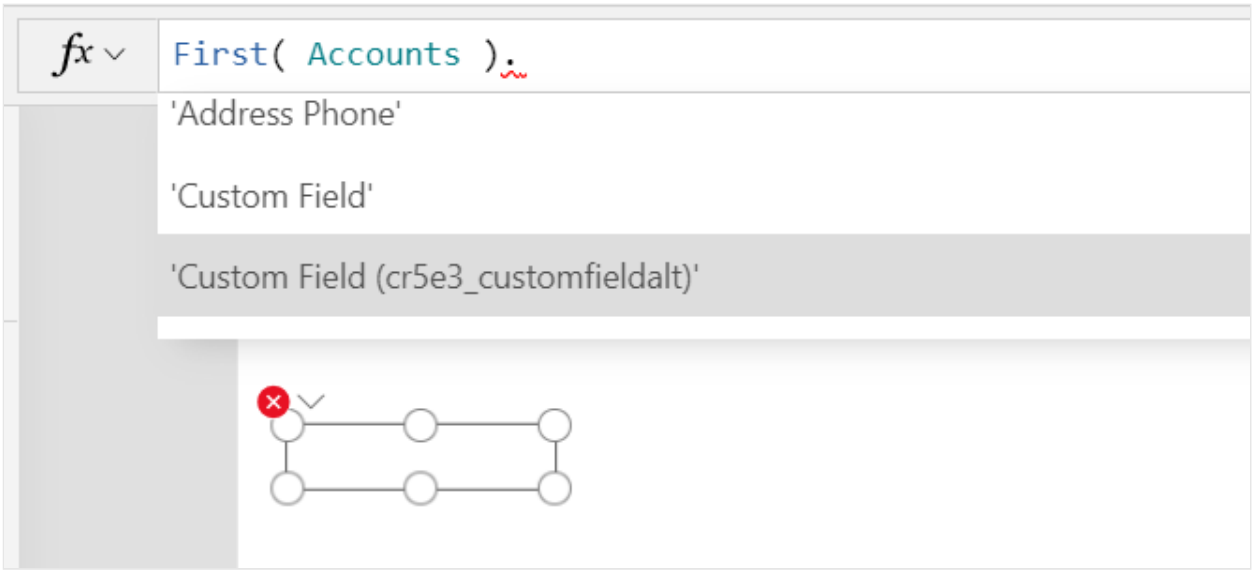


Behind the scenes, a mapping is maintained between the display names seen in formulas and the underlying logical names. Since logical names must be used to interact with the data source, this mapping is used to convert from the current display name to the logical name automatically and that is what is seen in the network traffic. This mapping is also used to convert back to logical names to switch into new display names, for example, if a display name changes or a maker in a different language edits the app.

> **Note**
>
> Logical names are not translated when moving an app between environments. For Dataverse system table and field names, this should not be a problem as logical names are consistent across environments. But any custom fields, such as **cra3a_customfield** in this example above, may have a different environment prefix (**cra3a** in this case). Display names are preferred as they can be matched against display names in the new environment.

Name disambiguation

Since display names aren't unique, the same display name may appear more than once in the same table. When this happens, the logical name will be added to the end of the display name in parentheses for one of more of the conflicting names. Building on the example above, if there was a second field with the same display name of **Custom Field** with a logical name of **cra3a_customfieldalt** then the suggestions would show:



Name disambiguation strings are added in other situations where name conflicts occur, such as the names of table, choices, and other Dataverse items.

Disambiguation operator

Some functions create record scopes for accessing the fields of table while processing each record, such as **Filter**, **AddColumns**, and **Sum**. Field names added with the record scope override the same names from elsewhere in the app. When this happens, you can still access values from outside the record scope with the @ disambiguation operator:

- To access values from nested record scopes, use the @ operator with the name of the table being operated upon using this pattern:
  Table[@*FieldName*]
- To access global values, such as data sources, collections, and context variables, use the pattern [@*ObjectName*] (without a table designation).

For more information and examples, see record scopes.

Set function

Article • 03/22/2024

Applies to: ✅ Canvas apps ✅ Cards ✅ Dataverse low-code plug-ins ✅ Power Platform CLI

Sets the value of a global variable.

Overview

Use the **Set** function to set the value of a global variable, which temporarily holds a piece of information, such as the number of times the user has selected a button or the result of a data operation.

Global variables are available throughout your app on all screens. These are the simplest kind of variables and fill the needs of most situations. There are also context variables which are scoped to a single screen and collections that allow row level modifications to tables. For more information about these other options, review Understand variables.

Power Apps are based on formulas that automatically recalculate as the user interacts with an app. Any formulas that depend on a variable will automatically update when it changes. However, the variable won't be automatically updated if the value of the formula used in the **Set** function changes. This requires the app maker to manually update the variable, which can be error prone and harder for others to understand. Before you use a variable, review Understand variables.

Description

Global variables are implicitly created by using the **Set** function. No explicit declaration is required. If you remove all the **Set** functions for a global variable, that global variable will cease to exist. To clear a variable, set its value to the result of the **Blank** function.

You can see your variables' values, definitions, and uses with the Variables view under the **File** menu in Power Apps Studio.

As the examples later in this topic show, global variables can hold several kinds of information, including these:

- a single value
- a record
- a table

- an object reference
- any result from a formula

A global variable holds its value until the app is closed. Once closed, the global variable's value will be lost and must be recreated when the app is loaded again.

Global variables cannot use the same name as an existing collection or control. It can use the same name as a context variable. To disambiguate between the two, use the disambiguation operator.

Set has no return value, and you can use it only within a behavior formula.

Syntax

Set(*VariableName*, *Value*)

- *VariableName* - Required. The name of a global variable to create or update.
- *Value* - Required. The value to assign to the context variable.

Examples

Expand table

Formula	Description	Result
Set(Counter, 1)	Creates or modifies the global variable **Counter**, setting its value to **1**.	**Counter** has the value **1**. You can reference that variable by using the name **Counter** in a formula on any screen.
Set(Counter, 2)	Sets the value of the **Counter** global variable from the previous example to **2**.	**Counter** has the value **2**.
Set(Counter, Counter + 1)	Increments the value of the **Counter** global variable from the previous example to **3**.	**Counter** has the value **3**.
Set(Name, "Lily")	Creates or modifies the global variable **Name** setting its value to **Lily**.	**Name** has the value **Lily**.

Formula	Description	Result
Set(Person, { Name: "Milton", Address: "1 Main St" })	Creates or modifies the global variable **Person**, setting its value to a record. The record contains two columns, named **Name** and **Address**. The value of the **Name** column is **Milton**, and the value of the **Address** column is **1 Main St**.	**Person** has the value of record **{ Name: "Milton", Address: "1 Main St" }**. Reference this record as a whole with the name **Person**, or reference an individual column of this record with **Person.Name** or **Person.Address**.
Set(Person, Patch(Person, {Address: "2 Main St" }))	Works with the **Patch** function to update the **Person** global variable by setting the value of the **Address** column to **2 Main St**.	**Person** now has the value of record **{ Name: "Milton", Address: "2 Main St" }**.

SetFocus function

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

Moves input focus to a specific control.

Description

The **SetFocus** function gives a control the input focus. The user's keystrokes are then received by that control, allowing them to type into a text input control or use the *Enter* key to select a button. The user can also use the *Tab* key, touch, mouse, or other gesture to move the input focus themselves. *Tab* key behavior is governed by the **TabIndex** property.

Use the **SetFocus** function to set the focus when (each with an example below):

- a newly exposed or enabled input control, to guide the user in what comes next and for faster data entry.
- a form is validated, to focus and display the offending input control for quick resolution.
- a screen is displayed, to focus the first input control with the **OnVisible** property of the **Screen**.

The control with focus may be visually different based on the **FocusedBorderColor** and **FocusedBorderThickness** properties.

Limitations

SetFocus can only be used with:

- **Button** control
- **Icon** control
- **Image** control
- **Label** control
- **TextInput** control

You cannot set the focus to controls that are within a **Gallery** control, **Edit form** control, or Component. **SetFocus** can be used with a control in a scrollbale screen.

You cannot set the focus to controls that are within a **Container** control.

You can only set the focus to controls on the same screen as the formula containing the **SetFocus** call.

Attempting to set the focus to a control that has its **DisplayMode** property set to **Disabled** has no effect. Focus will remain where it was previously.

On Apple iOS, the soft keyboard will only be displayed automatically if **SetFocus** was initiated by a direct user action. For example, invoking from a button's **OnSelect** property will display the soft keyboard while invoking from a screen's **OnVisible** will not.

You can use **SetFocus** only in behavior formulas.

Syntax

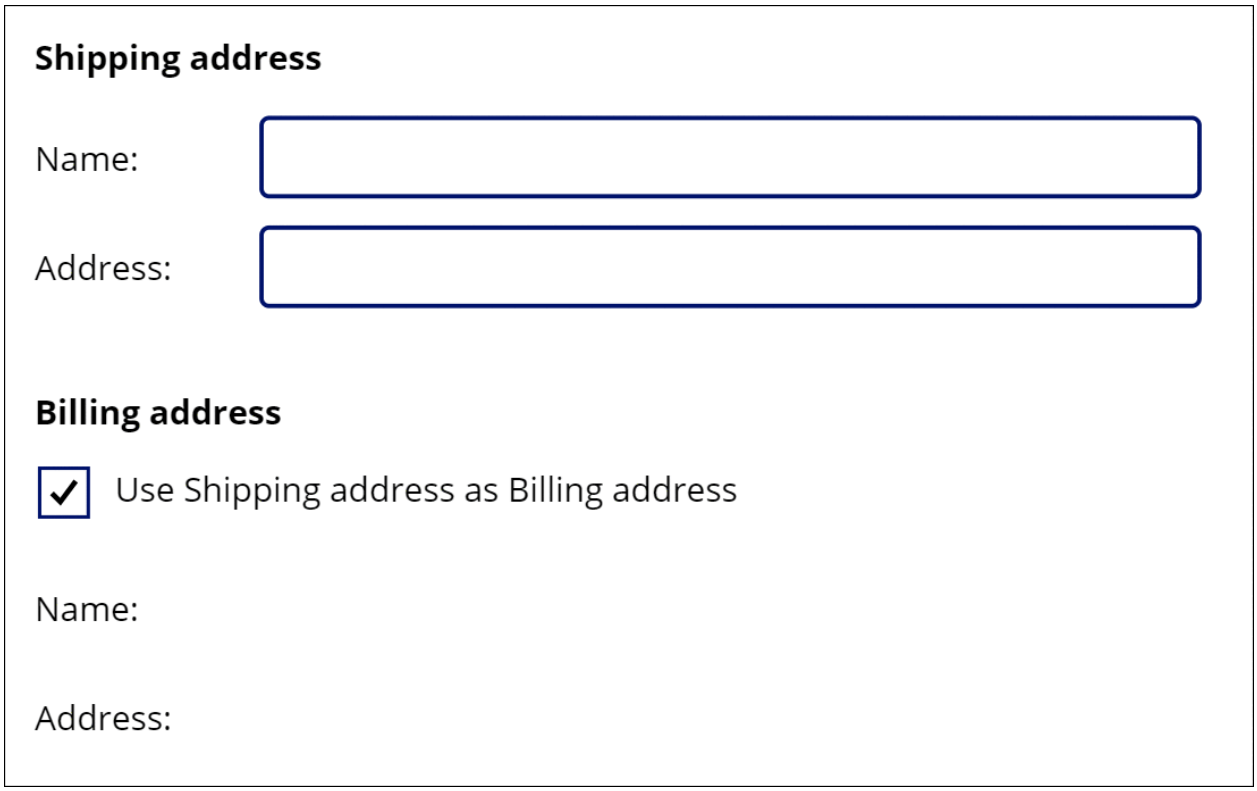
SetFocus(*Control*)

- *Control* – Required. The control to give the input focus.

Examples

Focus on a newly exposed or enabled input control

Many shopping carts allow the customer to use the shipping address as the billing address, alleviating the need to enter the same information twice. If a different billing address is desired, the billing address text input boxes are enabled, and it is helpful to guide the customer to the these newly enabled controls for faster data entry.



There are many formulas in play here, but the one that moves the focus is on the **OnUncheck** property of the **Check box** control:

```
powerappa-dot
SetFocus( BillingName )
```

The *Tab* key can also be used to move focus quickly from one field to another. To better illustrate, the *Tab* key was not used in the animation.

To create this example:

1. Create a new app.
2. Add **Label** controls with the text "Shipping address", "Name:", "Address:", "Billing Address", "Name:", and "Address:" and position them as shown in the animation.
3. Add a **Text Input** control and rename it **ShippingName**.
4. Add a **Text Input** control and rename it **ShippingAddress**.
5. Add a **Check box** control and rename it **SyncAddresses**.
6. Set the **Text** property of this control to the formula `"Use Shipping address as Billing address"`.
7. Add a **Text Input** control and rename it **BillingName**.
8. Set the **Default** property on this control to the formula `ShippingName`.
9. Set the **DisplayMode** property on this control to the formula `If( SyncAddresses.Value, DisplayMode.View, DisplayMode.Edit )`. This will

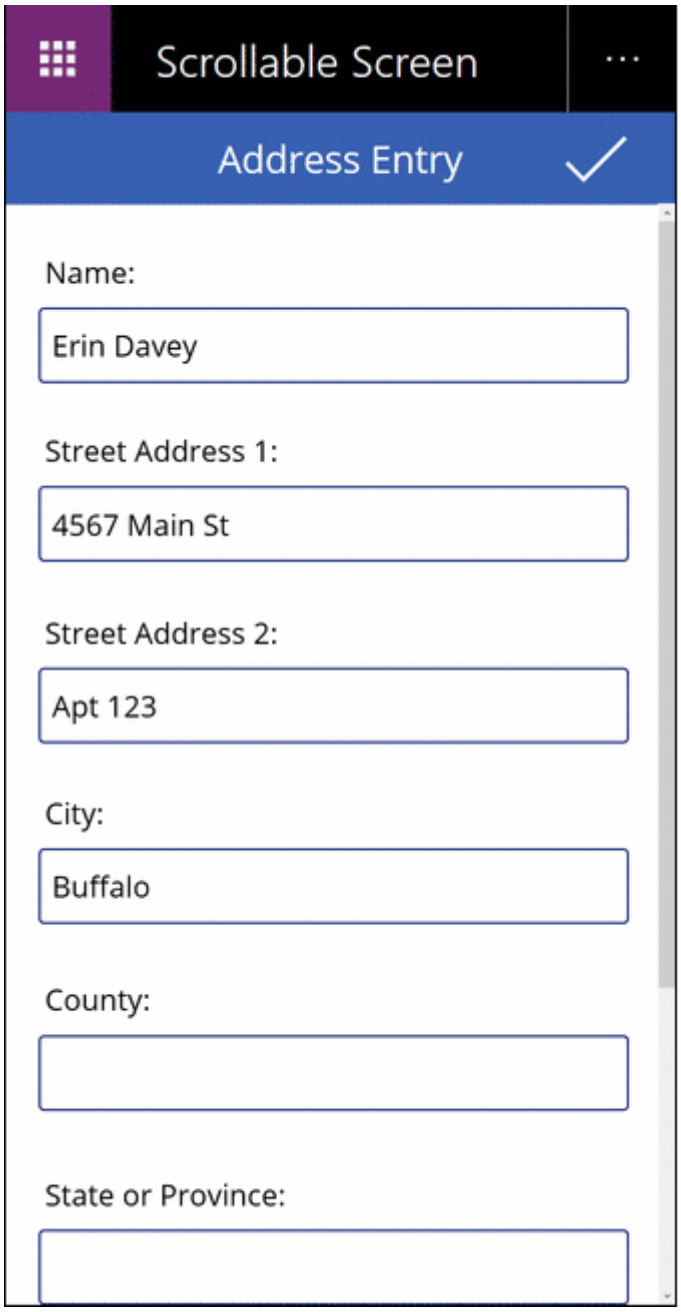
automatically enable or disable this control based on the state of the check box control.

10. Add a **Text Input** control and rename it **BillingAddress**.
11. Set the **Default** property on this control to the formula `ShippingAddress`.
12. Set the **DisplayMode** property on this control to the formula `If( SyncAddresses.Value, DisplayMode.View, DisplayMode.Edit )`. This will automatically enable or disable this control based on the state of the check box control.
13. Set the **Default** property of the check box to the formula `true`. This will default the Billing address to use the same value as the Shipping address.
14. Set the **OnCheck** property of the check box to the formula `Reset( BillingName ); Reset( BillingAddress )`. If the user chooses to sync Shipping and Billing addresses, this will clear any user input in the Billing address fields allowing the **Default** properties on each to pull the values from the corresponding Shipping address fields.
15. Set the **OnUncheck** property of the check box to the formula `SetFocus( BillingName )`. If the user chooses to have a different billing address, this will move the focus to the first control in the Billing address. The controls will have already been enabled due to their **DisplayMode** properties.

Focus on validation issues

> **Note**
>
> Although this example appears to be an **Edit form** control, unfortunately **SetFocus** is not yet supported by that control. Instead, this example uses a scrollable screen to host the input controls.

When validating a form, it can be helpful to not only display a message if there is a problem but to also take the user to the field that is offending. It can be particularly helpful if the field in question is scrolled off the screen and not visible.



In this animation, the validation button is repeatedly pressed until all the fields have been filled in properly. Note that the mouse pointer doesn't move down from the top of the screen. Instead the **SetFocus** function hsa moved the input focus to the control that requires attention with this formula:

Power Apps

```
If( IsBlank( Name ),
        Notify( "Name requires a value", Error ); SetFocus( Name ),
    IsBlank( Street1 ),
        Notify( "Street Address 1 requires a value", Error ); SetFocus(
Street1 ),
    IsBlank( Street2 ),
        Notify( "Street Address 2 requires a value", Error ); SetFocus(
Street2 ),
    IsBlank( City ),
        Notify( "City requires a value", Error ); SetFocus( City ),
    IsBlank( County ),
```

```
        Notify( "County requires a value", Error ); SetFocus( County ),
    IsBlank( StateProvince ),
        Notify( "State or Province requires a value", Error ); SetFocus(
StateProvince ),
    IsBlank( PostalCode ),
        Notify( "Postal Code requires a value", Error ); SetFocus(
PostalCode ),
    IsBlank( Phone ),
        Notify( "Contact Phone requires a value", Error ); SetFocus( Phone
),
    Notify( "Form is Complete", Success )
)
```

To create this example:

1. Create a new, blank phone app.
2. From the **Insert** menu, select **New screen**, and then select **Scrollable**.
3. In the center section of the screen, add **Text input** controls and name them **Name**, **Street1**, **Street2**, **City**, **County**, **StateProvince**, **PostalCode**, and **Phone**. Add **Label** controls above each one to identify the fields. You may need to resize the section if it is not long enough to fit all the controls.
4. Add a checkmark **Icon** control at the top of the screen, above the scrollable section.
5. Set the **OnSelect** property of the icon control to the formula `If( IsBlank( ...` given above.

Focus when displaying a screen

> ⓘ Note
>
> Although this example appears to be an **Edit form** control, unforutnatley **SetFocus** is not yet supported by that control. Instead, this example uses a scrollable screen to host the input controls.

Similar to exposing an input control, when displaying a data entry screen it is helpful to focus the first input control for faster data entry.

In this animation, the data entry screen on the left is not using **SetFocus**. Upon display no input control has focus, requiring the user to tab, touch, mouse, or use another means to focus the **Name** field before a value can be typed into it.

On the right we have exactly the same app with the **OnVisible** property of the data entry screen set to this formula:

Power Apps

```
SetFocus( Name )
```

This sets the focus to the **Name** field automatically. The user can begin typing and tabbing between fields immediately with no prior action required.

To create this example:

1. Create the "Focus on validation issues" app above.
2. On this screen, set the **OnVisible** property to the formula `SetFocus( Name )`.

3. Add a second screen.
4. Add a **Button** control.
5. Set the **OnSelect** property of this control to the formula `Navigate( Screen1 )`.
6. Preview the app from this screen. Press the button. The **OnVisible** formula will be evaluated and the **Name** field will automatically be in focus.

SetProperty function

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

The SetProperty function simulates interactions with input controls as if the user had entered or set a value on the control. This function is only available if you are writing tests in the Power Apps Test Studio. The following properties can be set using the SetProperty function.

> **Important**
>
> **Assert** function is only available for Test Studio in Power Apps.

Syntax

SetProperty(Control Property, value)

- *Control Property* – Required. The control property to set on behalf of the user.
- *Value* – Required. The value of the property to set on behalf of the user.

Examples

Expand table

Control	Property	Example expression
TextInput	Text	`SetProperty(TextInput1.Text, "Sample text")`
RichTextEditor	HtmlText	`SetProperty(RichTextEditor1.HtmlText, "<p>Sample text</p>")`
Toggle	Value	`SetProperty(Toggle1.Value, false)`
Checkbox	Value	`SetProperty(Checkbox1.Value, false)`
Slider	Value	`SetProperty(Slider1.Value, 10)`
Rating	Value	`SetProperty(Rating1.Value, 5)`
DatePicker	SelectedDate	`SetProperty(DatePicker1.SelectedDate, Date(2020,3,10))`
Radio	Selected	`SetProperty(Radio1.Selected, "Yes")`

Control	Property	Example expression
Radio	SelectedText	`SetProperty(Radio1.SelectedText, "Yes")`
Dropdown	Selected	`SetProperty(Dropdown1.Selected, {Value:"Sample value"})`
Dropdown	SelectedText	`SetProperty(Dropdown1.SelectedText, {Value:"Sample value"})`
Combobox	Selected	`SetProperty(Dropdown1.Selected, {Value:"Sample value"})`
Combobox	SelectedItems	`SetProperty(ComboBox1.SelectedItems, Table({Value:"Sample value"},({Value:"Sample value"}))`
ListBox	Selected	`SetProperty(Listbox1.Selected, {'Value':"Sample value"})`
ListBox	SelectedItems	`SetProperty(Listbox1.SelectedItems, Table({Value:"Sample value"},({Value:"Sample value"}))`

Sequence function

04/20/2025

Applies to: ✅ Canvas apps ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions

Generate a table of sequential numbers.

Description

The **Sequence** function generates a single column table of sequential numbers, such as 1, 2, 3. The name of the column is **Value**. `Sequence( 4 )` is equivalent to `[1,2,3,4]`.

Use **Sequence** with the **ForAll** function to iterate a specific number of times. For example, the following formula adds 10 random numbers to the collection **MyRandomNumbers**:

```
Power Fx
ForAll( Sequence( 10 ), Collect( MyRandomNumbers, Rand() ) )
```

ForAll can also be used to transform the value into other data types and return a new table. For example, the following formula returns a table of the next 10 days:

```
Power Fx
ForAll( Sequence( 10 ), DateAdd( Today(), Value, Days ) )
```

The number of records to generate is rounded down to the nearest whole number and must be in the range 0 to 50,000. Generating a table with zero records results in an *empty* table.

> ⓘ **Note**
>
> **Sequence** is limited to 50,000 records.

Syntax

Sequence(*Records* [, *Start* [, *Step*]])

- *Records* – Required. The number of records to create. Must be in the range 0 to 50,000.
- *Start* – Optional. The starting number for the sequence. Default is 1.

- *Step* – Optional. The increment for each successive number in the sequence. *Step* can be negative to count down from the *Start*. Default is 1.

Examples

Basic usage

Expand table

Formula	Description	Result
Sequence(4)	Generates a 4 record table starting at the default 1 and incrementing by the default 1.	**Value** 1 2 3 4
Sequence(4, 24)	Generates a 4 record table starting at 24 and incrementing by the default 1.	**Value** 24 25 26 27
Sequence(4, 4, -1)	Generates a 4 record table starting at 4 and incrementing by -1, effectively counting backward.	**Value** 4 3 2 1
Sequence(4, -100, 0.5)	Generates a 4 record table starting at -100 and incrementing by 0.5.	**Value** -100 -99.5 -99 -98.5
Sequence(0.9)	Generates an *empty* table as the count rounds down to 0.	**Value**

Formula	Description	Result
ForAll(Sequence(4), Rand())	Generates a 4 record table of random numbers.	**Value** 0.51171399 0.21144117 0.95787123 0.22094083 *Actual numbers will vary.*
Concat(Sequence(5), Text(Value) & " ")	Generates a string of numbers from 1 to 5.	**"1 2 3 4 5 "**

Character map

See the Char function reference for two **Sequence** functions working together to display a character map in a two-dimensional layout.

Chessboard

See the As operator reference for two **Sequence** functions working together to create a chessboard in a text string and in two nested galleries.

AddColumns, DropColumns, RenameColumns, and ShowColumns functions

06/21/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions

Shapes a table or record by adding, dropping, renaming, and selecting its columns.

The ForAll function can also be used to shape a table, by returning a table of new records created from existing columns.

Overview

These functions shape a table or record by adjusting its columns:

- Reduce a table or record that contains multiple columns down to a single column for use with single-column functions, such as **Lower** or **Sqrt**.
- Add a calculated column to a table or record (for example, a **Total Price** column that shows the results of multiplying **Quantity** by **Unit Price**).
- Rename a column to something more meaningful, for display to users or for use in formulas.

A table is a value in Power Apps, just like a string or a number. You can specify a table as an argument in a formula, and functions can return a table as a result.

> **Note**
>
> The functions that this topic describes don't modify the original table. Instead, they take that table as an argument and return a new table with a transform applied. For more information, see working with tables.

You can't modify the columns of a data source by using these functions. You must modify the data at its source. You can add columns to a collection with the **Collect** function. For more information, see working with data sources.

Description

The **AddColumns** function adds a column to a table or record, and a formula defines the values in that column. Existing columns remain unmodified.

The formula is evaluated for the provided record, or for each record of the provided table.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

The **DropColumns** function excludes columns from a table or record. All other columns remain unmodified. **DropColumns** excludes columns, and **ShowColumns** includes columns.

Use the **RenameColumns** function to rename one or more columns of a table or record by providing at least one argument pair that specifies the name of a column that the table or record contains (the old name, which you want to replace) and the name of a column that the table or record doesn't contain (the new name, which you want to use). The old name must already exist in the table or record, and the new name must not exist. Each column name may appear only once in the argument list as either an old column name or a new column name. To rename a column to an existing column name, first drop the existing column with **DropColumns**, or rename the existing column out of the way by nesting one **RenameColumns** function within another.

The **ShowColumns** function includes columns of a table or record and drops all other columns. You can use **ShowColumns** to create a single-column table or record from a multi-column table or record. **ShowColumns** includes columns, and **DropColumns** excludes columns.

For all these functions, the result is a new table or record with the transform applied. The original table or record isn't modified. You can't modify an existing table or record with a formula. SharePoint, Microsoft Dataverse, SQL Server, and other data sources provide tools for modifying the columns of lists and tables, which are often referred to as the schema. The functions in this topic only transform an input table or record, without modifying the original, into an output table or record for further use.

The arguments to these functions support delegation. For example, a **Filter** function used as an argument to pull in related records searches through all listings, even if the '**[dbo].[AllListings]**' data source contains a million rows:

Power Fx

```
AddColumns( RealEstateAgents,
   Listings,
```

```
    Filter(  '[dbo].[AllListings]', ListingAgentName = AgentName )
)
```

However, the output of these functions is subject to the non-delegation record limit. In this example, only 500 records are returned even if the **RealEstateAgents** data source has 501 or more records.

If you use **AddColumns** in this manner, **Filter** must make separate calls to the data source for each of those first records in **RealEstateAgents**, which causes lots of network chatter. If **[dbo](.[AllListings]** is small enough and doesn't change often. You can call the **Collect** function in OnStart to cache the data source in your app when it starts. As an alternative, you could restructure your app so that you pull in the related records only when the user asks for them.

> **Note**
>
> In Power Apps prior to version 3.24042, column names were specified with a text string using double quotes, and if connected to a data source they also needed to be logical names. For example, the logical name **"cr43e_name"** with double quotes was used instead of the display name **Name** without quotes. For SharePoint and Excel data sources that contain column names with spaces, each space was specified with **"_x0020_"**, for example **"Column Name"** as **"Column_x0020_Name"**. After this version, all apps were automatically updated to the new syntax described in this article.

Syntax

AddColumns(*TableOrRecord*, *ColumnName1*, *Formula1* [, *ColumnName2*, *Formula2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.
- *ColumnName(s)* - Required. Names of the columns to add.
- *Formula(s)* - Required. Formulas to evaluate for each record. The result is added as the value of the corresponding new column. You can reference other columns of the table or record in this formula.

DropColumns(*TableOrRecord*, *ColumnName1* [, *ColumnName2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.
- *ColumnName(s)* - Required. Names of the columns to drop.

RenameColumns(*TableOrRecord*, *OldColumnName1*, *NewColumnName1* [, *OldColumnName2*, *NewColumnName2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.

- *OldColumnName(s)* - Required. Names of the columns to rename from the original table or record. This element appears first in the argument pair (or first in each argument pair if the formula includes more than one pair).
- *NewColumnName(s)* - Required. Replacement names. This element appears last in the argument pair (or last in each argument pair if the formula includes more than one pair).

ShowColumns(*TableOrRecord*, *ColumnName1* [, *ColumnName2*, ...])

- *TableOrRecord* - Required. Table or record to operate on.
- *ColumnName(s)* - Required. Names of the columns to include.

Examples

The examples in this section use the **IceCreamSales** data source, which contains the data in this table:

Flavor	UnitPrice	QuantitySold
"Strawberry"	1.99	20
"Chocolate"	2.99	45
"Vanilla"	1.50	35

None of these examples modify the **IceCreamSales** data source. Each function transforms the value of the data source as a table and returns that value as the result.

Expand table

Formula	Description	Result
AddColumns(IceCreamSales, Revenue, UnitPrice * QuantitySold)	Adds a **Revenue** column to the result. For each record, **UnitPrice * QuantitySold** is evaluated, and the result is placed in the new column.	
DropColumns(IceCreamSales, UnitPrice)	Excludes the **UnitPrice** column from the result. Use this function to exclude columns, and use **ShowColumns** to include them.	ShowColumns(IceCreamSales, Flavor)	Includes only the **Flavor** column in the result. Use this function include columns, and use **DropColumns** to exclude them.	
RenameColumns(IceCreamSales, UnitPrice, Price)	Renames the **UnitPrice** column in the result.	

Formula	Description	Result
RenameColumns(IceCreamSales, UnitPrice, Price, QuantitySold, Number)	Renames the **UnitPrice** and **QuantitySold** columns in the result.	<table><tr><th>Flavor</th><th>Price</th><th>Number</th></tr><tr><td>"Strawberry"</td><td>1.99</td><td>20</td></tr><tr><td>"Chocolate"</td><td>2.99</td><td>45</td></tr><tr><td>"Vanilla"</td><td>1.50</td><td>35</td></tr></table>
DropColumns(RenameColumns(AddColumns(IceCreamSales, Revenue, UnitPrice * QuantitySold), UnitPrice, Price), Quantity)	Performs the following table transforms in order, starting from the inside of the formula: 1. Adds a **Revenue** column based on the per record calculation of **UnitPrice * Quantity**. 2. Renames **UnitPrice** to **Price**. 3. Excludes the **Quantity** column. Order is important, for example we can't calculate with **UnitPrice** after it's renamed.	<table><tr><th>Flavor</th><th>Price</th><th>Revenue</th></tr><tr><td>"Strawberry"</td><td>1.99</td><td>39.80</td></tr><tr><td>"Chocolate"</td><td>2.99</td><td>134.55</td></tr><tr><td>"Vanilla"</td><td>1.49</td><td>52.15</td></tr></table>

Step by step

Let's try some of the examples from earlier in this article.

1. Create a collection by adding a **Button** control and setting its **OnSelect** property to this formula:

   Power Fx

   ```
   ClearCollect( IceCreamSales,
      Table(
          { Flavor: "Strawberry", UnitPrice: 1.99, QuantitySold: 20 },
          { Flavor: "Chocolate", UnitPrice: 2.99, QuantitySold: 45 },
          { Flavor: "Vanilla", UnitPrice: 1.50, QuantitySold: 35 }
      )
   )
   ```

2. Run the formula by selecting the button while holding down the Alt key.

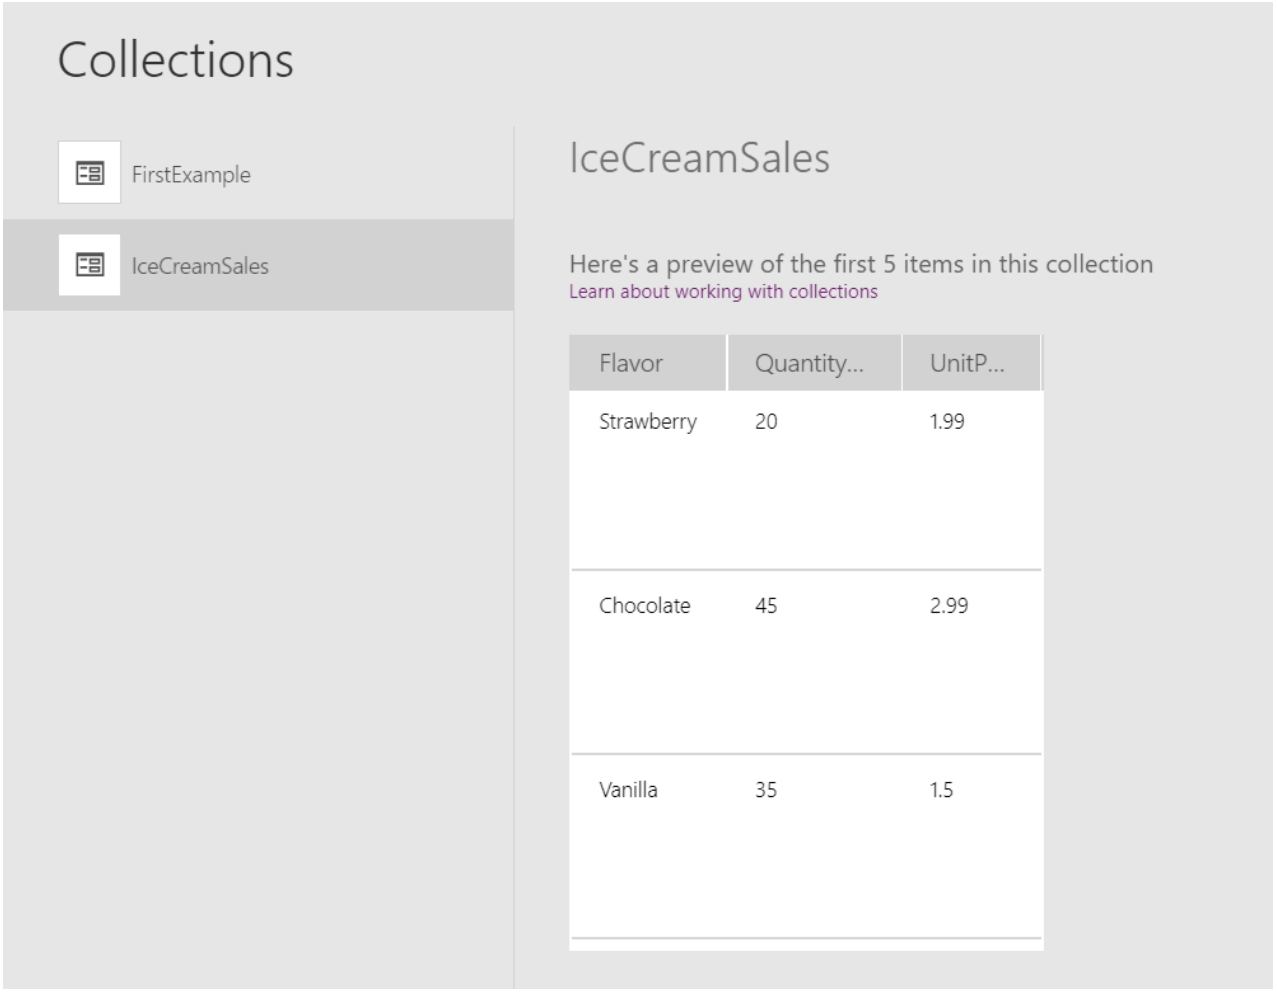
3. Add a second **Button** control, set its **OnSelect** property to this formula, and then run it:

   Power Fx

   ```
   ClearCollect( FirstExample,
      AddColumns( IceCreamSales, Revenue, UnitPrice * QuantitySold )
   )
   ```

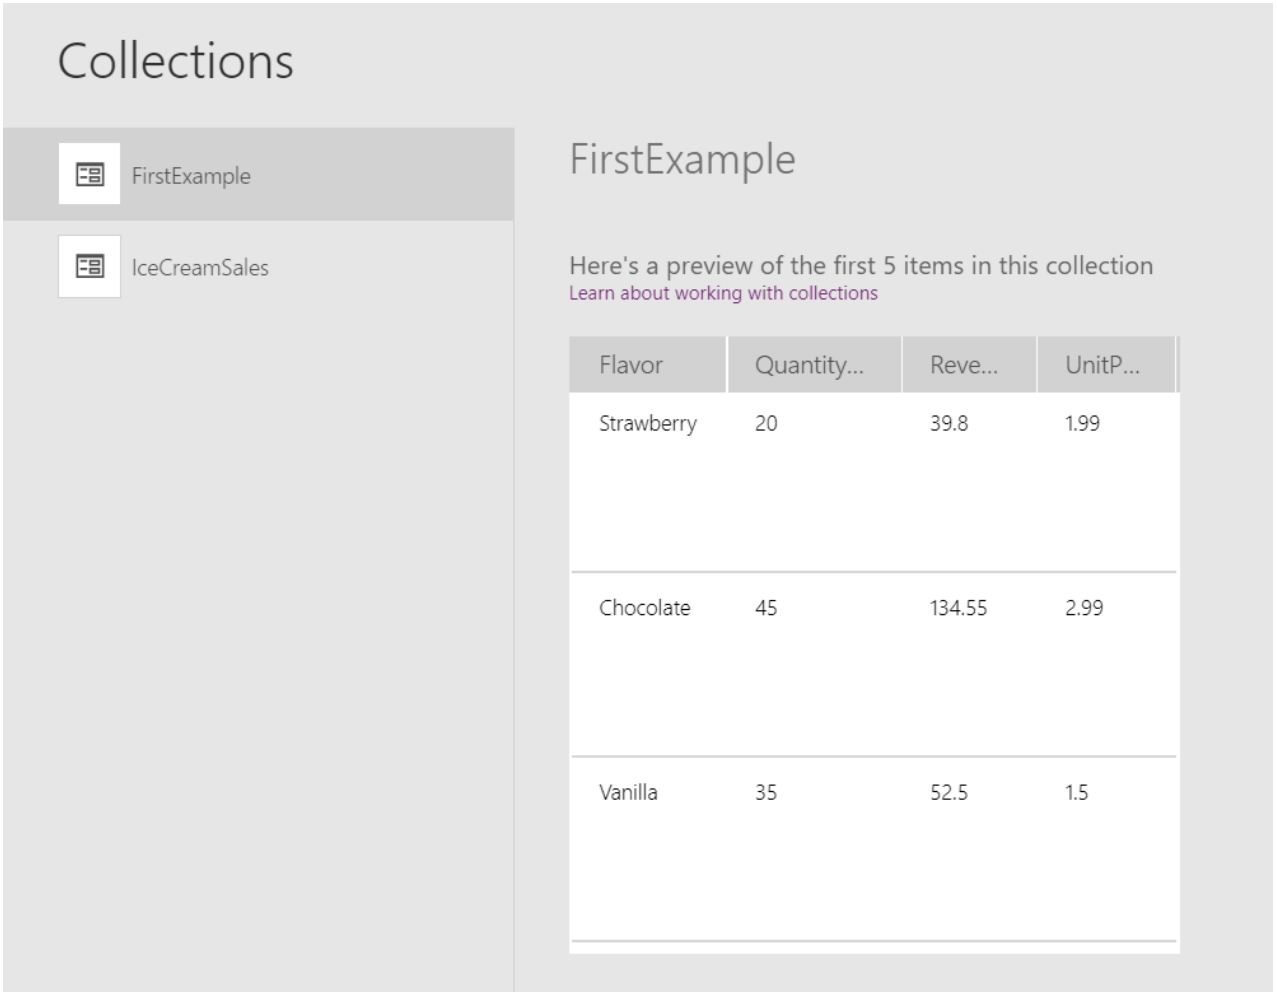
4. On the **File** menu, select **Collections**, and then select **IceCreamSales** to show that collection.

As this graphic shows, the second formula didn't modify this collection. The **AddColumns** function used **IceCreamSales** as a read-only argument; the function didn't modify the table to which that argument refers.



5. Select **FirstExample**.

   As this graphic shows, the second formula returned a new table with the added column. The **ClearCollect** function captured the new table in the **FirstExample** collection, adding something to the original table as it flowed through the function without modifying the source:



Map columns in a component

See Map columns.

Shuffle function

Article • 04/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions

Randomly reorders the records of a table.

Description

The **Shuffle** function reorders the records of a table.

Shuffle returns a table that has the same columns and number of rows as the argument.

Syntax

Shuffle(*Table*)

- *Table* - Required. Table to shuffle.

Example

If you stored details about playing cards in a collection named **Deck**, this formula would return a copy of that collection that has been randomly shuffled.

Shuffle(Deck)

Acos, Acot, Asin, Atan, Atan2, Cos, Cot, Degrees, Pi, Radians, Sin, and Tan functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Calculates trigonometric values.

Description

Primary functions

The **Cos** function returns the cosine of its argument, an angle specified in radians.

The **Cot** function returns the cotangent of its argument, an angle specified in radians.

The **Sin** function returns the sine of its argument, an angle specified in radians.

The **Tan** function returns the tangent of its argument, an angle specified in radians.

Inverse functions

The **Acos** function returns the arccosine, or inverse cosine, of its argument. The arccosine is the angle whose cosine is the argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Acot** function returns the principal value of the arccotangent, or inverse cotangent, of its argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Asin** function returns the arcsine, or inverse sine, of its argument. The arcsine is the angle whose sine is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan** function returns the arctangent, or inverse tangent, of its argument. The arctangent is the angle whose tangent is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan2** function returns the arctangent, or inverse tangent, of the specified *x* and *y* coordinates as arguments. The arctangent is the angle from the *x*-axis to a line that contains the origin (0, 0) and a point with coordinates (*x*, *y*). The angle is given in radians between -π and π, excluding -π. A positive result represents a counterclockwise angle from the *x*-axis; a negative result represents a clockwise angle. **Atan2(*a*, *b*)** equals **Atan(*b*/*a*)**, except that ***a*** can equal 0 (zero) with the **Atan2** function.

Helper functions

The **Degrees** function converts radians to degrees. π radians equals 180 degrees.

The **Pi** function returns the transcendental number π, which begins 3.141592...

The **Radians** function converts degrees to radians.

Notes

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results with a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined value, the result is *blank*. This can happen, for example, when using inverse functions with arguments that are out of range.

Syntax

Primary Functions

Cos(*Radians*)
Cot(*Radians*)
Sin(*Radians*)
Tan(*Radians*)

- *Radians* - Required. Angle to operate on.

Cos(*SingleColumnTable*)
Cot(*SingleColumnTable*)
Sin(*SingleColumnTable*)
Tan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of angles to operate on.

Inverse Functions

Acos(*Number*)
Acot(*Number*)
Asin(*Number*)
Atan(*Number*)

- *Number* - Required. Number to operate on.

Acos(*SingleColumnTable*)
Acot(*SingleColumnTable*)
Asin(*SingleColumnTable*)
Atan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Atan2(*X*, *Y*)

- *X* - Required. *X*-axis coordinate.
- *Y* - Required. *Y*-axis coordinate.

Helper Functions

Degrees(*Radians*)

- *Radians* - Required. Angle in radians to convert to degrees.

Pi()

Radians(*Degrees*)

- *Degrees* - Required. Angle in degrees to convert to radians.

Examples

Single number

Expand table

Formula	Description	Result
Cos(1.047197)	Returns the cosine of 1.047197 radians or 60 degrees.	0.5
Cot(Pi()/4)	Returns the cotangent of 0.785398... radians or 45 degrees.	1
Sin(Pi()/2)	Returns the sine of 1.570796... radians or 90 degrees.	1
Tan(Radians(60))	Returns the tangent of 1.047197... radians or 60 degrees.	1.732050...
Acos(0.5)	Returns the arccosine of 0.5, in radians.	1.047197...
Acot(1)	Returns the arccotangent of 1, in radians.	0.785398...
Asin(1)	Returns the arcsine of 1, in radians.	1.570796...
Atan(1.732050)	Returns the arctangent of 1.732050, in radians.	1.047197...
Atan2(5, 3)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (5,3), which is approximately 31 degrees.	0.540419...
Atan2(4, 4)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (4,4), which is exactly π/4 radians or 45 degrees.	0.785398...
Degrees(1.047197)	Returns the equivalent number of degrees for 1.047197 radians.	60
Pi()	Returns the transcendental number π.	3.141592...
Radians(15)	Returns the equivalent number of radians for 15 degrees.	0.261799...

Single-column table

The examples in this section use a data source that's named **ValueTable** and that contains the following data. The last record in the table is π/2 radians or 90 degrees.

Expand table

Value
0.5
-2
1.570796...

Expand table

Formula	Description	Result
Cos(ValueTable)	Returns the cosine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.877582..., -0.416146..., 0
Cot(ValueTable)	Returns the cotangent of each number in the table.	A single-column table with a `Value` column containing the following values: 1.830487..., 0.457657..., 0
Sin(ValueTable)	Returns the sine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.479425, -0.909297..., 1
Tan(ValueTable)	Returns the tangent of each number in the table.	A single-column table with a `Value` column containing the following values: 0.546302..., 2.185039..., 3060023.306952...
Acos(ValueTable)	Returns the arccosine of each number in the table.	A single-column table with a `Value` column containing the following values: 1.047197..., Blank(), Blank()
Acot(ValueTable)	Returns the arccotangent of each number in the table.	A single-column table with a `Value` column containing the following values: 1.107138..., 2.677945..., 0.566911...
Asin(ValueTable)	Returns the arcsine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.523598..., Blank(), Blank()
Atan(ValueTable)	Returns the arctangent of each number in the table.	A single-column table with a `Value` column containing the following values: 0.463647..., -1.107148..., 1.00388...
Degrees(ValueTable)	Returns the equivalent number of degrees for each number in the table, assumed to be angles in radians.	A single-column table with a `Value` column containing the following values: 28.647889..., -114.591559..., 90
Radians(ValueTable)	Returns the equivalent number of radians for each number in the table, assumed to be angles in degrees.	A single-column table with a `Value` column containing the following values: 0.008726..., -0.034906..., 0.027415...

Sort and SortByColumns functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Sorts a table.

> ⓘ **Note**
>
> PAC CLI pac power-fx commands do not support the **SortByColumns** function.

Description

The **Sort** function sorts a table based on a formula.

The formula is evaluated for each record of the table, and the results are used to sort the table. The formula must result in a number, a string, or a Boolean value; it can't result in a table or a record.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

To sort first by one column and then by another, you embed a **Sort** formula within another. For example, you can use this formula to sort a **Contacts** table first by a **LastName** column and then by a **FirstName** column: **Sort(Sort(Contacts, LastName), FirstName)**

The **SortByColumns** function can also be used to sort a table based on one or more columns.

The parameter list for **SortByColumns** provides the names of the columns to sort by and the sort direction per column. Sorting is performed in the order of the parameters (sorted first by the first column, then the second, and so on). Column names are specified as strings, requiring double quotes if directly included in the parameter list. For example, **SortByColumns(CustomerTable, "LastName")**.

You can combine **SortByColumns** with a **Drop down** or **List box** control to enable users to select which column to sort by.

In addition to sorting ascending or descending, **SortByColumns** can sort based on a single column table of values. For example, you can sort record based on the name of a day of the week by supplying **["Monday", "Tuesday", "Wednesday", "Thursday", "Friday", "Saturday", "Sunday"]** as the sort order. All records which have **Monday"** will come first, followed by **Tuesday**, and so on. Records found that do not appear in the sort table are put at the end of the list.

Tables are a value in Power Apps, just like a string or number. They can be passed to and returned from functions. **Sort** and **SortByColumn** don't modify a table; instead they take a table as an argument and return a new table that has been sorted. See working with tables for more details.

Delegation

When possible, Power Apps will delegate filter and sort operations to the data source and page through the results on demand. For example, when you start an app that shows a **Gallery** control filled with data, only the first set of records will be initially brought to the device. As the user scrolls, additional data is brought down from the data source. The result is a faster start time for the app and access to very large data sets.

However, delegation may not always be possible. Data sources vary on what functions and operators they support with delegation. If complete delegation of a formula isn't possible, the authoring environment will flag the portion that can't be delegated with a warning. When possible, consider changing the formula to avoid functions and operators that can't be delegated. The delegation list details which data sources and operations can be delegated.

If delegation is not possible, Power Apps will pull down only a small set of records to work on locally. Filter and sort functions will operate on a reduced set of records. What is available in the **Gallery** may not be the complete story, which could be confusing to users.

See the delegation overview for more information.

Syntax

Sort(*Table*, *Formula* [, *SortOrder*])

- *Table* - Required. Table to sort.

- *Formula* - Required. This formula is evaluated for each record of the table, and the results are used to sort the table. You can reference columns within the table.
- *SortOrder* - Optional. Specify **SortOrder.Descending** to sort the table in descending order. **SortOrder.Ascending** is the default value.

SortByColumns(*Table*, *ColumnName1* [, *SortOrder1*, *ColumnName2*, *SortOrder2*, ...])

- *Table* - Required. Table to sort.
- *ColumnName(s)* - Required. The column names to sort on, as strings.
- *SortOrder(s)* - Optional. **SortOrder.Ascending** or **SortOrder.Descending**. **SortOrder.Ascending** is the default. If multiple *ColumnNames* are supplied, all but the last column must include a *SortOrder*.

  > ⓘ **Note**
  >
  > For SharePoint and Excel data sources that contain column names with spaces, specify each space as "**_x0020_**". For example, specify "**Column Name**" as "**Column_x0020_Name**".

SortByColumns(*Table*, *ColumnName*, *SortOrderTable*)

- *Table* - Required. Table to sort.
- *ColumnName* - Required. The column name to sort on, as strings.
- *SortOrderTable* - Required. Single column table of values to sort by.

  > ⓘ **Note**
  >
  > For SharePoint and Excel data sources that contain column names with spaces, specify each space as "**_x0020_**". For example, specify "**Column Name**" as "**Column_x0020_Name**".

Examples

For the following examples, we'll use the **IceCream** data source, which contains the data in this table:

Flavor	Quantity	OnOrder
"Chocolate"	100	150
"Vanilla"	200	20
"Strawberry"	300	0
"Mint Chocolate"	60	100
"Pistachio"	200	10

Expand table

Formula	Description	Result
Sort(IceCream, Flavor) **SortByColumns(IceCream, "Flavor")**	Sorts **IceCream** by its **Flavor** column. The **Flavor** column contains strings, so the table is sorted alphabetically. By default, the sort order is ascending.	Sort(IceCream, Quantity) **SortByColumns(IceCream, "Quantity")**	Sorts **IceCream** by its **Quantity** column. The **Quantity** column contains numbers, so the table is sorted numerically. By default, the sort order is ascending.	Sort(IceCream, Quantity, SortOrder.Descending) **SortByColumns(IceCream, "Quantity", SortOrder.Descending)**	Sorts **IceCream** by its **Quantity** column. The **Quantity** column contains numbers, so the sort is done numerically. The sort order has been specified as descending.	Sort(IceCream, Quantity + OnOrder)	Sorts **IceCream** by the sum of its **Quantity** and **OnOrder** columns for each record individually. The sum is a number, so the table is sorted numerically. By default, the sort order is ascending. Since we are sorting by a formula and not by raw column values, there is no equivalent using **SortByColumns**.	Sort(Sort(IceCream, OnOrder), Quantity) **SortByColumns(IceCream, "OnOrder", SortOrder.Ascending, "Quantity", SortOrder.Ascending)**	Sorts **IceCream** first by its **OnOrder** column, and then by its **Quantity** column. Note that "Pistachio" rose above "Vanilla" in the first sort based on **OnOrder**, and then together they moved to their appropriate place based on **Quantity**.	SortByColumns(IceCream, "Flavor", ["Pistachio", "Strawberry"])	Sorts **IceCream** by it's **Flavor** column based on the single column table containing "Pistachio" and "Strawberry". Records which have a **Flavor** of "Pistachio" will appear first in the result,	

Formula	Description	Result
	followed by records that contain "Strawberry". For values in the **Flavor** column that are not matched, such as "Vanilla", they will appear after the items that were matched.	

Step by step

To run these examples yourself, create the **IceCream** data source as a collection:

1. Add a button, and set its OnSelect property to this formula:
   ClearCollect(IceCream, { Flavor: "Chocolate", Quantity: 100, OnOrder: 150 }, { Flavor: "Vanilla", Quantity: 200, OnOrder: 20 }, { Flavor: "Strawberry", Quantity: 300, OnOrder: 0 }, { Flavor: "Mint Chocolate", Quantity: 60, OnOrder: 100 }, { Flavor: "Pistachio", Quantity: 200, OnOrder: 10 })
2. Preview the app, select the button, and then press Esc to return to the default workspace.
3. Select **Collections** on the **File** menu to display the collection that you just created, and then press Esc to return to the default workspace.

Sort

1. Add another button, and set its OnSelect property to this formula:
   ClearCollect(SortByFlavor, Sort(IceCream, Flavor))

   The previous formula creates a second collection, named **SortByFlavor**, that contains the same data as **Ice Cream**. However, the new collection contains the data sorted alphabetically by the **Flavor** column in ascending order.

2. Press F5, select the new button, and then press Esc.

3. Select **Collections** on the **File** menu to display both collections, and then press Esc to return to the default workspace.

4. Repeat the last three steps, but change the name of the collection that you want to create, and replace the **Sort** formula with a different formula from the table of examples earlier in this section that uses **Sort**.

SortByColumns

1. Add another button, and set its OnSelect property to this formula:
   ClearCollect(SortByQuantity, SortByColumns(IceCream, "Quantity",

SortOrder.Ascending, "Flavor", SortOrder.Descending))

The previous formula creates a third collection, named **SortByQuantity**, that contains the same data as **Ice Cream**. However, the new collection contains the data sorted numerically by the **Quantity** column in ascending order, and then by the **Flavor** column in descending order.

2. Press F5, select the new button, and then press Esc.

3. Select **Collections** on the **File** menu to display all three collections, and then press Esc to return to the default workspace.

4. Repeat the last three steps, but change the name of the collection that you want to create, and replace the **SortByColumns** formula with a different formula from the table of examples earlier in this section that uses **SortByColumns**.

Sort and SortByColumns functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Sorts a table.

> ⓘ **Note**
>
> PAC CLI pac power-fx commands do not support the **SortByColumns** function.

Description

The **Sort** function sorts a table based on a formula.

The formula is evaluated for each record of the table, and the results are used to sort the table. The formula must result in a number, a string, or a Boolean value; it can't result in a table or a record.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

To sort first by one column and then by another, you embed a **Sort** formula within another. For example, you can use this formula to sort a **Contacts** table first by a **LastName** column and then by a **FirstName** column: **Sort(Sort(Contacts, LastName), FirstName)**

The **SortByColumns** function can also be used to sort a table based on one or more columns.

The parameter list for **SortByColumns** provides the names of the columns to sort by and the sort direction per column. Sorting is performed in the order of the parameters (sorted first by the first column, then the second, and so on). Column names are specified as strings, requiring double quotes if directly included in the parameter list. For example, **SortByColumns(CustomerTable, "LastName")**.

You can combine **SortByColumns** with a **Drop down** or **List box** control to enable users to select which column to sort by.

In addition to sorting ascending or descending, **SortByColumns** can sort based on a single column table of values. For example, you can sort record based on the name of a day of the week by supplying **["Monday", "Tuesday", "Wednesday", "Thursday", "Friday", "Saturday", "Sunday"]** as the sort order. All records which have **Monday"** will come first, followed by **Tuesday**, and so on. Records found that do not appear in the sort table are put at the end of the list.

Tables are a value in Power Apps, just like a string or number. They can be passed to and returned from functions. **Sort** and **SortByColumn** don't modify a table; instead they take a table as an argument and return a new table that has been sorted. See working with tables for more details.

Delegation

When possible, Power Apps will delegate filter and sort operations to the data source and page through the results on demand. For example, when you start an app that shows a **Gallery** control filled with data, only the first set of records will be initially brought to the device. As the user scrolls, additional data is brought down from the data source. The result is a faster start time for the app and access to very large data sets.

However, delegation may not always be possible. Data sources vary on what functions and operators they support with delegation. If complete delegation of a formula isn't possible, the authoring environment will flag the portion that can't be delegated with a warning. When possible, consider changing the formula to avoid functions and operators that can't be delegated. The delegation list details which data sources and operations can be delegated.

If delegation is not possible, Power Apps will pull down only a small set of records to work on locally. Filter and sort functions will operate on a reduced set of records. What is available in the **Gallery** may not be the complete story, which could be confusing to users.

See the delegation overview for more information.

Syntax

Sort(*Table*, *Formula* [, *SortOrder*])

- *Table* - Required. Table to sort.

- *Formula* - Required. This formula is evaluated for each record of the table, and the results are used to sort the table. You can reference columns within the table.
- *SortOrder* - Optional. Specify **SortOrder.Descending** to sort the table in descending order. **SortOrder.Ascending** is the default value.

SortByColumns(*Table*, *ColumnName1* [, *SortOrder1*, *ColumnName2*, *SortOrder2*, ...])

- *Table* - Required. Table to sort.
- *ColumnName(s)* - Required. The column names to sort on, as strings.
- *SortOrder(s)* - Optional. **SortOrder.Ascending** or **SortOrder.Descending**. **SortOrder.Ascending** is the default. If multiple *ColumnNames* are supplied, all but the last column must include a *SortOrder*.

  > ⓘ **Note**
  >
  > For SharePoint and Excel data sources that contain column names with spaces, specify each space as "**_x0020_**". For example, specify "**Column Name**" as "**Column_x0020_Name**".

SortByColumns(*Table*, *ColumnName*, *SortOrderTable*)

- *Table* - Required. Table to sort.
- *ColumnName* - Required. The column name to sort on, as strings.
- *SortOrderTable* - Required. Single column table of values to sort by.

  > ⓘ **Note**
  >
  > For SharePoint and Excel data sources that contain column names with spaces, specify each space as "**_x0020_**". For example, specify "**Column Name**" as "**Column_x0020_Name**".

Examples

For the following examples, we'll use the **IceCream** data source, which contains the data in this table:

Flavor	Quantity	OnOrder
"Chocolate"	100	150
"Vanilla"	200	20
"Strawberry"	300	0
"Mint Chocolate"	60	100
"Pistachio"	200	10

Expand table

Formula	Description	Result
Sort(IceCream, Flavor) **SortByColumns(IceCream, "Flavor")**	Sorts **IceCream** by its **Flavor** column. The **Flavor** column contains strings, so the table is sorted alphabetically. By default, the sort order is ascending.	Sort(IceCream, Quantity) **SortByColumns(IceCream, "Quantity")**	Sorts **IceCream** by its **Quantity** column. The **Quantity** column contains numbers, so the table is sorted numerically. By default, the sort order is ascending.	Sort(IceCream, Quantity, SortOrder.Descending) **SortByColumns(IceCream, "Quantity", SortOrder.Descending)**	Sorts **IceCream** by its **Quantity** column. The **Quantity** column contains numbers, so the sort is done numerically. The sort order has been specified as descending.	Sort(IceCream, Quantity + OnOrder)	Sorts **IceCream** by the sum of its **Quantity** and **OnOrder** columns for each record individually. The sum is a number, so the table is sorted numerically. By default, the sort order is ascending. Since we are sorting by a formula and not by raw column values, there is no equivalent using **SortByColumns**.	Sort(Sort(IceCream, OnOrder), Quantity) **SortByColumns(IceCream, "OnOrder", SortOrder.Ascending, "Quantity", SortOrder.Ascending)**	Sorts **IceCream** first by its **OnOrder** column, and then by its **Quantity** column. Note that "Pistachio" rose above "Vanilla" in the first sort based on **OnOrder**, and then together they moved to their appropriate place based on **Quantity**.	SortByColumns(IceCream, "Flavor", ["Pistachio", "Strawberry"])	Sorts **IceCream** by it's **Flavor** column based on the single column table containing "Pistachio" and "Strawberry". Records which have a **Flavor** of "Pistachio" will appear first in the result,	

Formula	Description	Result
	followed by records that contain "Strawberry". For values in the **Flavor** column that are not matched, such as "Vanilla", they will appear after the items that were matched.	

Step by step

To run these examples yourself, create the **IceCream** data source as a collection:

1. Add a button, and set its OnSelect property to this formula:
   ClearCollect(IceCream, { Flavor: "Chocolate", Quantity: 100, OnOrder: 150 }, { Flavor: "Vanilla", Quantity: 200, OnOrder: 20 }, { Flavor: "Strawberry", Quantity: 300, OnOrder: 0 }, { Flavor: "Mint Chocolate", Quantity: 60, OnOrder: 100 }, { Flavor: "Pistachio", Quantity: 200, OnOrder: 10 })
2. Preview the app, select the button, and then press Esc to return to the default workspace.
3. Select **Collections** on the **File** menu to display the collection that you just created, and then press Esc to return to the default workspace.

Sort

1. Add another button, and set its OnSelect property to this formula:
   ClearCollect(SortByFlavor, Sort(IceCream, Flavor))

   The previous formula creates a second collection, named **SortByFlavor**, that contains the same data as **Ice Cream**. However, the new collection contains the data sorted alphabetically by the **Flavor** column in ascending order.

2. Press F5, select the new button, and then press Esc.

3. Select **Collections** on the **File** menu to display both collections, and then press Esc to return to the default workspace.

4. Repeat the last three steps, but change the name of the collection that you want to create, and replace the **Sort** formula with a different formula from the table of examples earlier in this section that uses **Sort**.

SortByColumns

1. Add another button, and set its OnSelect property to this formula:
   ClearCollect(SortByQuantity, SortByColumns(IceCream, "Quantity",

SortOrder.Ascending, "Flavor", SortOrder.Descending))

The previous formula creates a third collection, named **SortByQuantity**, that contains the same data as **Ice Cream**. However, the new collection contains the data sorted numerically by the **Quantity** column in ascending order, and then by the **Flavor** column in descending order.

2. Press F5, select the new button, and then press Esc.

3. Select **Collections** on the **File** menu to display all three collections, and then press Esc to return to the default workspace.

4. Repeat the last three steps, but change the name of the collection that you want to create, and replace the **SortByColumns** formula with a different formula from the table of examples earlier in this section that uses **SortByColumns**.

Split function

Article • 04/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Splits a text string into a table of substrings.

Description

The **Split** function breaks a text string into a table of substrings. Use **Split** to break up comma delimited lists, dates that use a slash between date parts, and in other situations where a well defined delimiter is used.

A separator string is used to break the text string apart. The separator can be zero, one, or more characters that are matched as a whole in the text string. Using a zero length or *blank* string results in each character being broken out individually. The matched separator characters are not returned in the result. If no separator match is found, then the entire text string is returned as a single result.

Use the **Concat** function to recombine the string without the separators.

Use the **MatchAll** function to split a string using a regular expression.

The examples show how **Split** can be used with the **First** and **Last** functions to extract a single delimited substring. The **Match** function is often a more concise and powerful choice for regular expressions.

Syntax

Split(*Text*, *Separator*)

- *Text* - Required. Text to split.
- *Separator* - Required. Separator to use in splitting the string. Can be zero, one, or more characters.

Examples

Basic usage

Expand table

Formula	Description	Result
`Split( "Apples, Oranges, Bananas", "," )`	Splits the different fruits apart, based on the comma separator. The split is performed based on only the comma and not the space after it, resulting in a space at the front of " Oranges" and " Bananas".	A single-column table with a `Value` column containing the following values: "Apples", " Oranges", " Bananas"
`TrimEnds( Split( "Apples, Oranges, Bananas", "," ) )`	Same as the previous example, but in this case the space is removed by the **TrimEnds** function, operating on the single column table that is produced by **Split**. We could have also used the separator **", "** which includes the space after the comma, but that wouldn't have worked properly if there's no space or there are two spaces.	A single-column table with a `Value` column containing the following values: "Apples", "Oranges", "Bananas"
`Split( "08/28/17", "/" )`	Splits the date apart, using a forward slash as the separator.	A single-column table with a `Value` column containing the following values: "08", "28", "17"

Different delimiters

Expand table

Formula	Description	Result
`Split( "Hello, World", "," )`	Splits the words apart, using a comma as the separator. The second result starts with a space since it is the character immediately following the comma.	A single-column table with a `Value` column containing the following values: "Hello", " World"
`Split( "Hello, World", "o" )`	Splits the string apart, using the character "o" as the separator.	A single-column table with a `Value` column containing the following values: "Hell", ", W", "rld"
`Split( "Hello, World", "l" )`	Splits the string apart, using the single character "l" as the separator. Since there were no characters between both the l's in **Hello**, a *blank* value was returned.	A single-column table with a `Value` column containing the following values: "He", Blank(), "o, Wor", "d"
`Split( "Hello, World", "ll" )`	Splits the string apart, using the double character "ll" as the separator.	A single-column table with a `Value` column containing the following values: "He", "o, World"

Formula	Description	Result
`Split( "Hello, World", "%" )`	Splits the string apart, using the percent sign as the separator. Since this separator doesn't appear in the string, the entire string is returned as one result.	A single-column table with a `Value` column containing the following value: "Hello, World"
`Split( "Hello, World", "" )`	Splits the string apart, using an empty string as the separator (zero characters). This will break the string on each character.	A single-column table with a `Value` column containing the following values: "H", "e", "l", "l", "o", ",", " ", "W", "o", "r", "l", "d"

Substring extraction

Expand table

Formula	Description	Result
`First( Split( Last( Split( "Bob Jones <bob.jones@contoso.com>", " <" ) ).Result, ">" ) ).Result`	Splits the string apart based on an opening delimiter (<) and extracts the string to the right of the delimiter with **Last**. The formula then splits that result based on the closing delimiter (>) and extracts the string the left of the delimiter with **Right**.	"bob.jones@contoso.com"
`Match( "Bob Jones <bob.jones@contoso.com>", "<(?<email>.+)>" ).email`	Performs the same delimiter based extraction as the last example but uses the **Match** function and a regular expression instead.	"bob.jones@contoso.com"

Abs, Exp, Ln, Power, Log, and Sqrt functions

Article • 04/20/2025

Expand table

Functions	Applies to
Abs **Exp** **Ln** **Power** **Sqrt**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Log	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Calculates absolute values, logarithms, square roots, and the results of raising *e* or any number to specified powers.

Description

The **Abs** function returns the non-negative value of its argument. If a number is negative, **Abs** returns the positive equivalent.

The **Exp** function returns *e* raised to the power of its argument. The transcendental number *e* begins 2.7182818...

The **Ln** function returns the natural logarithm (base *e*) of its argument.

The **Power** function returns a number raised to a power. It's equivalent to using the ^ operator.

The **Log** function returns the logarithm of its first argument in the base specified by its second argument (or 10 if not specified).

The **Sqrt** function returns the number that, when multiplied by itself, equals its argument.

If you pass a single number, the return value is a single result based on the function called. If you pass a single-column table that contains numbers, the return value is a single-column table of results in a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined valued, the result is *blank*. Which can happen with square roots and logarithms of negative numbers.

Syntax

Abs(*Number*)
Exp(*Number*)
Ln(*Number*)
Sqrt(*Number*)

- *Number* - Required. Number to operate on.

Power(*Base*, *Exponent*)

- *Base* - Required. Base number to raise.
- *Exponent* - Required. The exponent to which the base number is raised.

Log(*Number*, *Base*)

- *Number* - Required. Number to calculate the logarithm.
- *Base* - Optional. The base of the logarithm to calculate. By default, 10 (when not specified).

Abs(*SingleColumnTable*)
Exp(*SingleColumnTable*)
Ln(*SingleColumnTable*)
Sqrt(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Examples

Single number

Expand table

Formula	Description	Result
Abs(-55)	Returns the number without the negative sign.	55
Exp(2)	Returns *e* raised to the power of 2, or *e* * *e*.	7.389056...
Ln(100)	Returns the natural logarithm (base *e*) of the number 100.	4.605170...
Log(100)	Returns the logarithm in base 10 of the number 100.	2
Log(64, 2)	Returns the logarithm in base 2 of the number 64.	6

Formula	Description	Result
Power(5, 3)	Returns 5 raised to the power of 3, or 5 * 5 * 5.	125
Sqrt(9)	Returns the number that, when multiplied by itself, results in 9.	3

Single-column table

The examples in this section use a data source that's named **ValueTable** and that contains this data:

Expand table

Value
9
-4
2

Expand table

Formula	Description	Result
Abs(ValueTable)	Returns the absolute value of each number in the table.	A single-column table with a `Value` column containing the following values: 9, 4, 2
Exp(ValueTable)	Returns *e* raised to the power of each number in the table.	A single-column table with a `Value` column containing the following values: 8103.083927..., 0.018315..., 7.389056...
Ln(ValueTable)	Returns the natural logarithm of each number in the table.	A single-column table with a `Value` column containing the following values: 2.197224..., Blank(), 0.693147...
Sqrt(ValueTable)	Returns the square root of each number in the table	A single-column table with a `Value` column containing the following values: 3, Blank(), 1.414213...

Step-by-step example

1. Add a **Text input** control, and name it **Source**.
2. Add a **Label** control, and set its **Text** property to this formula:
   Sqrt(Value(Source.Text))

3. Type a number into **Source**, and confirm that the **Label** control shows the square root of the number that you typed.

EndsWith and StartsWith functions

Article • 04/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Tests whether a text string begins or ends another text string.

Description

The **EndsWith** function tests whether one text string ends with another.

The **StartsWith** function tests whether one text string begins with another.

For both functions, the tests are case insensitive if the back-end datasource supports it by default. For example, collections, Dataverse, SharePoint, and SQL Server support case insensitivity by default. Oracle does not. The return value of both is a Boolean **true** or **false**.

Use **EndsWith** and **StartsWith** with the **Filter** function to search the data within your app. You can also use the **in** operator or the **Search** function to look anywhere within text strings, not just at the beginning or end. Your choice of functions will depend on the needs of your app and which function can be delegated for your particular data source. If one of these functions can't be delegated, a delegation warning will appear at authoring time to warn you of this limitation.

Syntax

EndsWith(*Text*, *EndText*)

- *Text* – Required. The text to test.
- *EndText* – Required. The text to search for at the end of *Text*. If *EndText* is an empty string, **EndsWith** returns *true*.

StartsWith(*Text*, *StartText*)

- *Text* – Required. The text to test.
- *StartText* – Required. The text to search for at the beginning of *Text*. If *StartText* is an empty string, **StartsWith** returns *true*.

Examples

Expand table

Formula	Description	Result
EndsWith("Hello World", "world")	Tests whether **"Hello World"** ends with **"world"**. The test is case insensitive.	**true**
EndsWith("Good bye", "good")	Tests whether **"Good bye"** ends with **"good"**. The *EndText* argument (**"good"**) appears in the text but not at the end.	**false**
EndsWith("Always say hello", "hello")	Tests whether **"Always say hello"** ends with **"hello"**.	**true**
EndsWith("Bye bye", "")	Tests whether **"Bye bye"** ends with an empty text string (**Len** returns 0). Easing its use in **Filter** expressions, **EndsWith** is defined to return **true** in this case.	**true**

Expand table

Formula	Description	Result
StartsWith("Hello World", "hello")	Tests whether **"Hello World"** begins with **"hello"**. The test is case insensitive.	**true**
StartsWith("Good bye", "hello")	Tests whether **"Good bye"** begins with **"hello"**.	**false**
StartsWith("Always say hello", "hello")	Tests whether **"Always say hello"** begins with **"hello"**. Although **"hello"** appears in the text, it doesn't appear at the beginning.	**false**
StartsWith("Bye bye", "")	Tests whether **"Bye bye"** starts with an empty text string (**Len** returns 0). Easing its use in **Filter** expressions, **StartsWith** is defined to return **true** in this case.	**true**

Search user experience

In many apps, you can type one or more characters into a search box to filter a list of records in a large data set. As you type, the list shows only those records that match the search criteria.

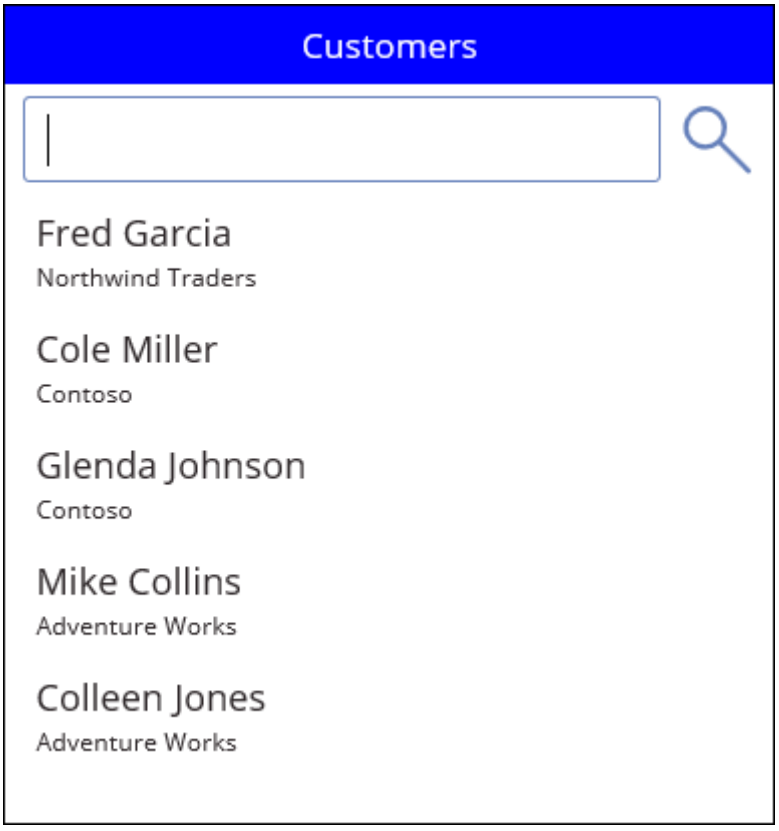
The examples in the rest of this topic show the results of searching a **Customers** list that contains this data:

Name	Company
"Fred Garcia"	"Northwind Traders"
"Cole Miller"	"Contoso"
"Glenda Johnson"	"Contoso"
"Mike Collins"	"Adventure Works"
"Colleen Jones"	"Adventure Works"

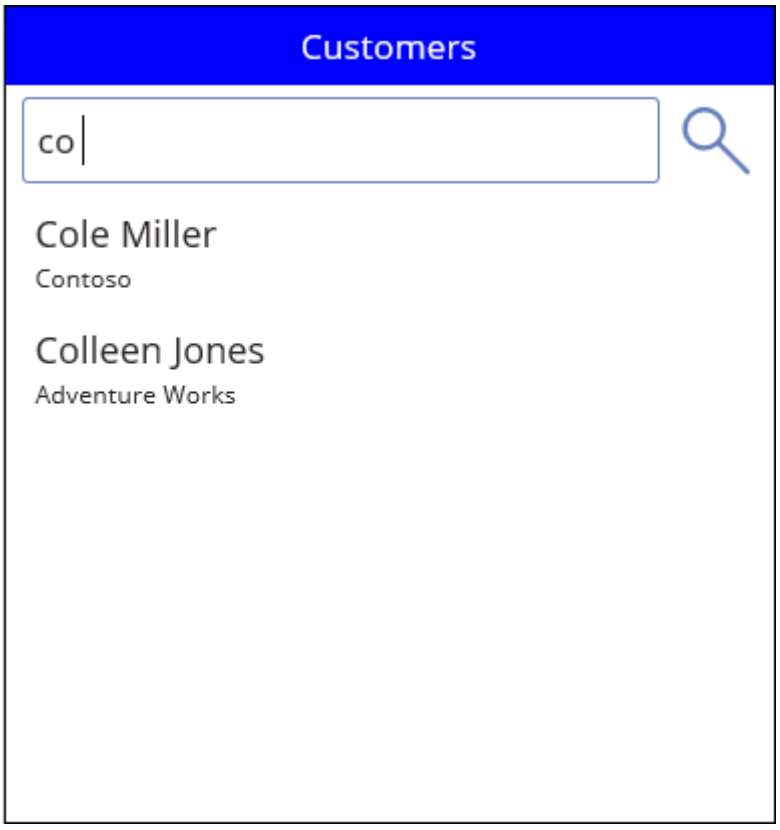
To create this data source as a collection, create a **Button** control and set its **OnSelect** property to this formula:

ClearCollect(Customers, Table({ Name: "Fred Garcia", Company: "Northwind Traders" }, { Name: "Cole Miller", Company: "Contoso" }, { Name: "Glenda Johnson", Company: "Contoso" }, { Name: "Mike Collins", Company: "Adventure Works" }, { Name: "Colleen Jones", Company: "Adventure Works" }))

As in this example, you can show a list of records in a **Gallery control** at the bottom of a screen. Near the top of the screen, you can add a **Text input** control, named **SearchInput**, so that users can specify which records interest them.



As the user types characters in **SearchInput**, the results in the gallery are automatically filtered. In this case, the gallery is configured to show records for which the name of the customer (not the name of the company) starts with the sequence of characters in **SearchInput**.If the user types **co** in the search box, the gallery shows these results:



To filter based on the **Name** column, set the **Items** property of the gallery control to one of these formulas:

Expand table

Formula	Description	Result
Filter(Customers, StartsWith(Name, SearchInput.Text))	Filters the **Customers** data source for records in which the search string appears at the start of the **Name** column. The test is case insensitive. If the user types **co** in the search box, the gallery shows **Colleen Jones** and **Cole Miller**. The gallery doesn't show **Mike Collins** because the **Name** column for that record doesn't start with the search string.	
Filter(Customers, SearchInput.Text in Name)	Filters the **Customers** data source for records in which the search string appears anywhere in the **Name** column. The test is case insensitive. If the user types **co** in the search box, the gallery shows **Colleen Jones**, **Cole Miller,** and **Mike Collins** because the search string appears somewhere in the **Name** column of all of those records.	
Search(Customers, SearchInput.Text, "Name")	Similar to using the **in** operator, the **Search** function searches for a match anywhere within the **Name** column of each record. Note that you must enclose the column name in double quotation marks.	

You can expand your search to include the **Company** column as well as the **Name** column:

Expand table

Formula	Description	Result
Filter(Customers, StartsWith(Name, SearchInput.Text) || StartsWith(Company, SearchInput.Text))	Filters the **Customers** data source for records in which either the **Name** column or the **Company** column starts with the search string (for example, **co**). The || operator is *true* if either **StartsWith** function is *true*.	
Filter(Customers, SearchInput.Text in Name || SearchInput.Text in Company)	Filters the **Customers** data source for records in which either the **Name** column or the **Company** column contains the search string (for example, **co**) anywhere within it.	
Search(Customers, SearchInput.Text, "Name", "Company")	Similar to using the **in** operator, the **Search** function searches the **Customers** data source for records in which either the **Name** column or the **Company** column contains the search string (for example, **co**) anywhere within it. The **Search** function is easier to read and write than **Filter** if you want to specify multiple columns and multiple **in** operators. Note that you must enclose the names of the columns in double quotation marks.	

Average, Max, Min, StdevP, Sum, and VarP functions

Article • 04/20/2025

Expand table

Functions	Applies to
Average **Max** **Min** **Sum**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
StdevP **VarP**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Aggregate functions that summarize a set of numbers.

Description

The **Average** function calculates the average, or arithmetic mean, of its arguments.

The **Max** function finds the maximum value.

The **Min** function finds the minimum value.

The **Sum** function calculates the sum of its arguments.

The **StdevP** function calculates the standard deviation of its arguments.

The **VarP** function calculates the variance of its arguments.

You can supply the values for these functions as:

- Separate arguments. For example, **Sum(1, 2, 3)** returns 6.
- A table and a formula to operate over that table. The aggregate will be calculated on the values of the formula for each record.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

These functions operate on numeric values only. Other types of values, such as strings or records, are ignored. Use the **Value** function to convert a string into a number.

The **Average**, **Max**, **Min**, and **Sum** functions can be delegated when used with a data source that supports delegation for these functions. However, **StdevP** and **VarP** can't be delegated for any data sources. If delegation is not supported, only the first portion of the data will be retrieved and then the function applied locally. The result may not represent the complete story. A delegation warning will appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

Syntax

Average(*NumericalFormula1*, [*NumericalFormula2*, ...])
Max(*NumericalFormula1*, [*NumericalFormula2*, ...])
Min(*NumericalFormula1*, [*NumericalFormula2*, ...])
Sum(*NumericalFormula1*, [*NumericalFormula2*, ...])
StdevP(*NumericalFormula1*, [*NumericalFormula2*, ...])
VarP(*NumericalFormula1*, [*NumericalFormula2*, ...])

- *NumericalFormula(s)* - Required. Numeric values to operate on.

Average(*Table*, *NumericalFormula*)
Max(*Table*, *NumericalFormula*)
Min(*Table*, *NumericalFormula*)
Sum(*Table*, *NumericalFormula*)
StdevP(*Table*, *NumericalFormula*)
VarP(*Table*, *NumericalFormula*)

- *Table* - Required. Table to operate on.
- *NumericalFormula* - Required. Formula to evaluate for each record. The result of this formula is used for the aggregation. You can use columns of the table in the formula.

Examples

Step by step

Let's say that you had a data source named **Sales** that contained a **CostPerUnit** column and a **UnitsSold** column, and you set the **Text** property of a label to this function:
Sum(Sales, CostPerUnit * UnitsSold)

The label would show total sales by multiplying the values in those columns for each record and then adding the results from all records together:

Units sold	Cost per unit
30	$150
45	$125
20	$175

Total sales:

$13625

As a different example, let's say that you had sliders that were named **Slider1**, **Slider2**, and **Slider3** and a label with its **Text** property set to this formula:

Sum(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the sum of all values to which the sliders were set.

Average(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the average of all values to which the sliders were set.

Max(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the maximum of all values to which the sliders were set.

Min(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the minimum of all values to which the sliders were set.

StdevP(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the standard deviation of all values to which the sliders were set.

VarP(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the variance of all values to which the sliders were set.

Replace and Substitute functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Dataverse formula columns ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Replace a portion of a string of text with another string.

Description

The **Replace** function identifies the text to replace by starting position and length.

The **Substitute** function identifies the text to replace by matching a string. If more than one match is found, you can replace all of them or specify one to replace.

If you pass a single string, the return value is the modified string. If you pass a single-column table that contains strings, the return value is a single-column table with a **Value** column of modified strings. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

Syntax

Replace(*String*, *StartingPosition*, *NumberOfCharacters*, *NewString*)

- *String* - Required. The string to operate on.
- *StartingPosition* - Required. Character position to start the replacement. The first character of *String* is at position 1.
- *NumberOfCharacters* - Required. The number of characters to replace in *String*.
- *NewString* - Required. The replacement string. The number of characters in this argument can differ from the *NumberOfCharacters* argument.

Substitute(*String*, *OldString*, *NewString* [, *InstanceNumber*])

- *String* - Required. The string to operate on.
- *OldString* - Required. The string to replace.
- *NewString* - Required. The replacement string. *OldString* and *NewString* can have different lengths.
- *InstanceNumber* - Optional. Use this argument to specify which instance of *OldString* to replace if *String* contains more than one instance. If you don't specify this argument, all instances will be replaced.

Replace(*SingleColumnTable*, *StartingPosition*, *NumberOfCharacters*, *NewString*)

- *SingleColumnTable* - Required. A single-column table of strings to operate on.
- *StartingPosition* - Required. Character position to start the replacement. The first character of each string in the table is at position 1.
- *NumberOfCharacters* - Required. The number of characters to replace in each string.
- *NewString* - Required. The replacement string. The number of characters in this argument can differ from the *NumberOfCharacters* argument.

Substitute(*SingleColumnTable*, *OldString*, *NewString* [, *InstanceNumber*])

- *SingleColumnTable* - Required. A single-column table of strings to operate on.
- *OldString* - Required. The string to replace.
- *NewString* - Required. The replacement string. *OldString* and *NewString* can have different lengths.
- *InstanceNumber* - Optional. Use this argument to specify which instance of *OldString* to replace if *String* contains more than one instance. If you don't specify this argument, all instances will be replaced.

Examples

Expand table

Formula	Description	Result
Replace("abcdefghijk", 6, 5, "*")	Replaces five characters in "abcdefghijk" with a single "*" character, starting with the sixth character ("f").	"abcde*k"
Replace("2019", 3, 2, "20")	Replaces the last two characters of "2019" with "20".	"2020"
Replace("123456", 1, 3, "_")	Replaces the first three characters of "123456" with a single "_" character.	"_456"
Substitute("Sales Data", "Sales", "Cost")	Substitutes the string "Cost" for "Sales".	"Cost Data"
Substitute("Quarter 1, 2018", "1", "2", 1)	Substitutes only the first instance of "1" with "2" because the fourth argument	"Quarter 2, 2018"

Formula	Description	Result
	(*InstanceNumber*) is provided with a 1.	
Substitute("Quarter 1, 2011", "1", "2", 3)	Substitutes only the third instance of "1" with "2" because the fourth argument (*InstanceNumber*) is provided with a 3.	"Quarter 1, 2012"
Substitute("Quarter 1, 2011", "1", "2")	Substitutes all instances of "1" with "2" because the fourth argument (*InstanceNumber*) isn't provided.	"Quarter 2, 2022"
Replace(["Quarter 1, 2018", "Quarter 2, 2011", "Quarter 4, 2019"], 9, 1, "3")	Replaces the ninth character in each record of the single-column table with "3".	A single-column table with a `Value` column containing the following values: ["Quarter 3, 2018", "Quarter 3, 2011", "Quarter 3, 2019"]
Substitute(["Qtr 1, 2018", "Quarter 1, 2011", "Q1, 2019"], "1", "3", 1)	Because the fourth argument (*InstanceNumber*) is provided with a value of 1, substitutes only the first instance of "1" in each record of the single-column table with "3".	A single-column table with a `Value` column containing the following values: ["Qtr 3, 2018", "Quarter 3, 2011", "Q3, 2019"]
Substitute(["Qtr 1, 2018", "Quarter 1, 2011", "Q1, 2019"], "1", "3")	Because the fourth argument (*InstanceNumber*) isn't provided, substitutes all instances of "1" in each record of the single-column table with "3".	A single-column table with a `Value` column containing the following values: ["Qtr 3, 2038", "Quarter 3, 2033", "Q3, 2039"]

EditForm, NewForm, SubmitForm, ResetForm, and ViewForm functions

Article • 03/22/2024

Applies to: Canvas apps

View, edit, or create an item, save the contents, and reset the controls in an **Edit form** control.

Overview

These functions change the state of the **Edit form** control. The form control can be in one of these modes:

Expand table

Mode	Description
FormMode.Edit	The form is populated with an existing record and the user can modify the values of the fields. Once complete, the user can save the changes to the record.
FormMode.New	The form is populated with default values and the user can modify the values of the fields. Once complete, the user can add the record to the data source.
FormMode.View	The form is populated with an existing record but the user cannot modify the values of the fields.

Description

These functions are often invoked from the **OnSelect** formula of a **Button** or **Image** control so that the user can save edits, abandon edits, or create a record. You can use controls and these functions together to create a complete solution.

These functions return no values.

You can use these functions only in behavior formulas.

SubmitForm

Use the **SubmitForm** function in the **OnSelect** property of a Button control to save any changes in a Form control to the data source.

Before submitting any changes, this function checks for validation issues with any field that's marked as required or that has one or more constraints on its value. This behavior matches that of the **Validate** function.

SubmitForm also checks the **Valid** property of the Form, which is an aggregation of all the **Valid** properties of the **Card** controls that the Form control contains. If a problem occurs, the data isn't submitted, and the **Error** and **ErrorKind** properties of the Form control are set accordingly.

If validation passes, **SubmitForm** submits the change to the data source.

- If successful, the Form's **OnSuccess** behavior runs, and the **Error** and **ErrorKind** properties are cleared. If the form was in **FormMode.New** mode, it is returned to **FormMode.Edit** mode.
- If unsuccessful, the Form's **OnFailure** behavior runs, and the **Error** and **ErrorKind** properties are set accordingly. The mode of the form is unchanged.

EditForm

The **EditForm** function changes the Form control's mode to **FormMode.Edit**. In this mode, the contents of the Form control's **Item** property are used to populate the form. If the **SubmitForm** function runs when the form is in this mode, a record is changed, not created. **FormMode.Edit** is the default for the Form control.

> ⓘ **Note**
>
> When the form is in edit mode and Item is null, data card properties are not evaluated and will return default values.

NewForm

The **NewForm** function changes the Form control's mode to **FormMode.New**. In this mode, the contents of the Form control's **Item** property are ignored, and the default values of the Form's **DataSource** property populate the form. If the **SubmitForm** function runs when the form is in this mode, a record is created, not changed.

ResetForm

The **ResetForm** function resets the contents of a form to their initial values, before the user made any changes. If the form is in **FormMode.New** mode, the form is reset to **FormMode.Edit** mode. The **OnReset** behavior of the form control also runs. You can also reset individual controls with the **Reset** function but only from within the form.

ViewForm

The **ViewForm** function changes the Form control's mode to **FormMode.View**. In this mode, the contents of the Form control's **Item** property are used to populate the form. The **SubmitForm** and **ResetForm** functions have no effect when in this mode.

DisplayMode Property

The current mode can be read through the **Mode** property. The mode also determines the value of the **DisplayMode** property, which can be used by data cards and controls within the form control. Often, the data card's **DisplayMode** property will be set to **Parent.DisplayMode** (referencing the form) as will the control's **DisplayMode** property (referencing the data card):

Expand table

Mode	DisplayMode	Description
FormMode.Edit	**DisplayMode.Edit**	Data cards and controls are editable, ready to accept changes to a record.
FormMode.New	**DisplayMode.Edit**	Data cards and controls are editable, ready to accept a new record.
FormMode.View	**DisplayMode.View**	Data cards and controls are not editable and optimized for viewing.

Syntax

SubmitForm(*FormName*)

- *FormName* - Required. Form control to submit to the data source.

EditForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.Edit** mode.

NewForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.New** mode.

ResetForm(*FormName*)

- *FormName* - Required. Form control to reset to initial values. Also switches the form from **FormMode.New** mode to **FormMode.Edit** mode.

ViewForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.View** mode.

Examples

See Understand data forms for complete examples.

1. Add a Button control, set its **Text** property to show **Save**, and set its **OnSelect** property to this formula:

   SubmitForm(EditForm)

2. Set the **OnFailure** property of a Form control to blank and its **OnSuccess** property to this formula:

   Back()

3. Name a **Label** control **ErrorText**, and set its **Text** property to this formula:

   EditForm.Error

   When the user selects the **Save** button, any changes in the Form control are submitted to the underlying data source.

   - If the submission succeeds, any changes are saved or, if the Form control is in **New** mode, a record is created. **ErrorText** is *blank* and the previous screen reappears.
   - If the submission fails, **ErrorText** shows a user-friendly error message, and the current screen remains visible so that the user can correct the problem and try again.

4. Add a Button control, set its **Text** property to show **Cancel**, and set its **OnSelect** property to this formula:

   ResetForm(EditForm); Back()

   When the user selects the **Cancel** button, the values in the Form control are reset to what they were before the user started to edit it, the previous screen reappears,

and the Form control is returned to **Edit** mode if it was in **New** mode.

5. Add a Button control, set its Text property to show **New**, and set its OnSelect property to this formula:

   NewForm(EditForm); Navigate(EditScreen, None)

   When the user selects the **New** button, the Form control switches to **New** mode, the default values for the Form control's data source populate that control, and the screen that contains the Form control appears. When the **SubmitForm** function runs, a record is created instead of updated.

Average, Max, Min, StdevP, Sum, and VarP functions

Article • 04/20/2025

Expand table

Functions	Applies to
Average **Max** **Min** **Sum**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
StdevP **VarP**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Aggregate functions that summarize a set of numbers.

Description

The **Average** function calculates the average, or arithmetic mean, of its arguments.

The **Max** function finds the maximum value.

The **Min** function finds the minimum value.

The **Sum** function calculates the sum of its arguments.

The **StdevP** function calculates the standard deviation of its arguments.

The **VarP** function calculates the variance of its arguments.

You can supply the values for these functions as:

- Separate arguments. For example, **Sum(1, 2, 3)** returns 6.
- A table and a formula to operate over that table. The aggregate will be calculated on the values of the formula for each record.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

These functions operate on numeric values only. Other types of values, such as strings or records, are ignored. Use the **Value** function to convert a string into a number.

The **Average**, **Max**, **Min**, and **Sum** functions can be delegated when used with a data source that supports delegation for these functions. However, **StdevP** and **VarP** can't be delegated for any data sources. If delegation is not supported, only the first portion of the data will be retrieved and then the function applied locally. The result may not represent the complete story. A delegation warning will appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

Syntax

Average(*NumericalFormula1*, [*NumericalFormula2*, ...])
Max(*NumericalFormula1*, [*NumericalFormula2*, ...])
Min(*NumericalFormula1*, [*NumericalFormula2*, ...])
Sum(*NumericalFormula1*, [*NumericalFormula2*, ...])
StdevP(*NumericalFormula1*, [*NumericalFormula2*, ...])
VarP(*NumericalFormula1*, [*NumericalFormula2*, ...])

- *NumericalFormula(s)* - Required. Numeric values to operate on.

Average(*Table*, *NumericalFormula*)
Max(*Table*, *NumericalFormula*)
Min(*Table*, *NumericalFormula*)
Sum(*Table*, *NumericalFormula*)
StdevP(*Table*, *NumericalFormula*)
VarP(*Table*, *NumericalFormula*)

- *Table* - Required. Table to operate on.
- *NumericalFormula* - Required. Formula to evaluate for each record. The result of this formula is used for the aggregation. You can use columns of the table in the formula.

Examples

Step by step

Let's say that you had a data source named **Sales** that contained a **CostPerUnit** column and a **UnitsSold** column, and you set the **Text** property of a label to this function:
Sum(Sales, CostPerUnit * UnitsSold)

The label would show total sales by multiplying the values in those columns for each record and then adding the results from all records together:

Units sold	Cost per unit
30	$150
45	$125
20	$175

Total sales:

$13625

As a different example, let's say that you had sliders that were named **Slider1**, **Slider2**, and **Slider3** and a label with its **Text** property set to this formula:

Sum(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the sum of all values to which the sliders were set.

Average(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the average of all values to which the sliders were set.

Max(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the maximum of all values to which the sliders were set.

Min(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the minimum of all values to which the sliders were set.

StdevP(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the standard deviation of all values to which the sliders were set.

VarP(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the variance of all values to which the sliders were set.

If and Switch functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Dataverse formula columns ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Determines whether any condition in a set is true (**If**) or the result of a formula matches any value in a set (**Switch**) and then returns a result or executes an action.

Description

The **If** function tests one or more conditions until a **true** result is found. If such a result is found, a corresponding value is returned. If no such result is found, a default value is returned. In either case, the returned value might be a string to show, a formula to evaluate, or another form of result.

The **Switch** function evaluates a formula and determines whether the result matches any value in a sequence that you specify. If a match is found, a corresponding value is returned. If no match is found, a default value is returned. In either case, the returned value might be a string to show, a formula to evaluate, or another form of result.

If and **Switch** are very similar, but you should use the best function for your situation:

- Use **If** to evaluate a single condition. The most common syntax for this function is **If**(*Condition*, *ThenResult*, *DefaultResult*), which provides the common "if ... then ... else ..." pattern seen in other programming tools.
- Use **If** to evaluate multiple unrelated conditions. In Power Apps (unlike Microsoft Excel), you can specify multiple conditions without having to nest **If** formulas.
- Use **Switch** to evaluate a single condition against multiple possible matches. You can also use **If** in this case, but you'd need to repeat the formula for each possible match.

You can use both of these functions in behavior formulas to branch between two or more actions. Only one branch will trigger an action. Conditions and matches are evaluated in order, and they stop if a condition is **true** or a match is found.

Blank is returned if no conditions are **true**, no matches are found, and you don't specify a default result.

Syntax

If(*Condition*, *ThenResult* [, *DefaultResult*])
If(*Condition1*, *ThenResult1* [, *Condition2*, *ThenResult2*, ... [, *DefaultResult*]])

- *Condition(s)* - Required. Formula(s) to test for **true**. Such formulas commonly contain comparison operators (such as <, >, and =) and test functions such as **IsBlank** and **IsEmpty**.
- *ThenResult(s)* - Required. The corresponding value to return for a condition that evaluates to **true**.
- *DefaultResult* - Optional. The value to return if no condition evaluates to **true**. If you don't specify this argument, *blank* is returned.

Switch(*Formula*, *Match1*, *Result1* [, *Match2*, *Result2*, ... [, *DefaultResult*]])

- *Formula* - Required. Formula to evaluate for matches. This formula is evaluated only once.
- *Match(s)* - Required. Values to compare with the result from *Formula*. If an exact match is found, the corresponding *Result* is returned.
- *Result(s)* - Required. The corresponding value to return when an exact match is found.
- *DefaultResult* - Optional. If an exact match isn't found, this value is returned. If you don't specify this argument, *blank* is returned.

Examples

Values in formulas

In the following examples, a **Slider** control (named **Slider1**) has a value of **25**.

Expand table

Formula	Description	Result
If(Slider1.Value = 25, "Result1")	The condition is **true**, and the corresponding result is returned.	"Result1"
If(Slider1.Value = 25, "Result1", "Result2")	The condition is **true**, and the corresponding result is returned.	"Result1"
If(Slider1.Value > 1000, "Result1")	The condition is **false**, and no *DefaultResult* was provided.	*blank*
If(Slider1.Value > 1000, "Result1", "Result2")	The condition is **false**, a *DefaultResult* was provided, and it's returned.	"Result2"

Formula	Description	Result
If(Slider1.Value = 25, "Result1", Slider1.Value > 0, "Result2")	The first condition is **true**, and the corresponding result is returned. The second condition is also **true**, but it isn't evaluated because it appears later in the argument list than a condition that evaluates to **true**.	"Result1"
If(IsBlank(Slider1.Value), "Result1", IsNumeric(Slider1.Value), "Result2")	The first condition is **false** because the slider isn't *blank*. The second condition is **true** because the slider's value is a number, and the corresponding result is returned.	"Result2"
If(Slider1.Value > 1000, "Result1", Slider1.Value > 50, "Result2", "Result3")	Both the first and second conditions are **false**, a *DefaultResult* was provided, and it's returned.	"Result3"
Switch(Slider1.Value, 25, "Result1")	The slider's value matches the first value to be checked, and the corresponding result is returned.	"Result1"
Switch(Slider1.Value, 20, "Result1", 25, "Result2", 30, "Result3")	The slider's value matches the second value to be checked, and the corresponding result is returned.	"Result2"
Switch(Slider1.Value, 20, "Result1", 10, "Result2", 0, "Result3", "DefaultResult")	The slider's value doesn't match any value to be checked. A *DefaultResult* was provided, so it's returned.	"DefaultResult"

Branching in behavior formulas

In these examples, a Text input control named **FirstName** has the value "John" typed into it.

Expand table

Formula	Description	Result
If(! IsBlank(FirstName.Text), Navigate(Screen1, ScreenTransition.None))	The condition is **true**, so the Navigate function runs. You can use the IsBlank function to test whether a required form field has been filled in. If **FirstName** were blank, this formula would have no effect.	**true** The display is changed to **Screen1**.
If(IsBlank(FirstName.Text), Navigate(Screen1,	Without the **!** operator, the condition is **false**, so the Navigate	**true**

Formula	Description	Result
ScreenTransition.None), Back())	function doesn't run. The **Back** function was provided as a *DefaultResult*, so it runs.	The display goes back to the screen that was previously shown.
Switch(FirstName.Text, "Carlos", Navigate(Screen1, ScreenTransition.None), "Kirstin", Navigate(Screen2, ScreenTransition.None), "John", Navigate(Screen3, ScreenTransition.None))	The value of **FirstName.Text** is compared against "Carlos", "Kirstin", and "John" in that order. A match is found with "John", so the app navigates to **Screen3**.	**true** The display is changed to **Screen3**.

Step by step

1. Add a **Text input** control, and name it **Text1** if it doesn't have that name by default.
2. In **Text1**, type **30**.
3. Add a **Label** control, and set its **Text** property to this formula:
   If(Value(Text1.Text) < 20, "Order MANY more!", Value(Text1.Text) < 40, "Order more!", Text1.Text)

   The **Label** control shows **Order more!** because the value of **Text1** is more than 20 but less than 40.
4. In **Text1**, type **15**.

   The **Label** control shows **Order MANY more!** because the value of **Text1** is less than 20.
5. In **Text1**, type **50**.

   The **Label** control shows the value that you typed because it's more than 40.

Table function

06/19/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions

Creates a temporary table.

Description

The **Table** function creates a table from an argument list of records or tables.

The result table's columns are the union of all the columns from all the argument records and tables. A *blank* value is added to any column for which a record doesn't include a value.

A table is a value in Power Apps, just like a string or a number. You can specify a table as an argument for a function, and functions can return a table as a result. **Table** doesn't create a permanent table. Instead it returns a temporary table made of its arguments. You can specify this temporary table as an argument for another function, visualize it in a gallery, or embed it in another table. Fore more information, see working with tables.

You can also create a single-column table with the **[value1, value2, ...]** syntax.

Syntax

Table(*RecordOrTable1* [, *RecordOrTable2*, ...])

- *RecordOrTable(s)* - Required. The records or table to add to the result table. If a table is provided, the records of the table are added to the resulting table as if they had been individually added.

Table(*Dynamic*)

- *Dynamic* - Required. **Dynamic** value that represents a table or array. Acceptable values are dependent on the untyped provider. For **JSON**, the dynamic value is expected to be a JSON array. Regardless of the content type of the Untyped array, the resulting table is a single-column table of dynamic values.

Examples

- Set the **Items** property of a listbox to this formula:

Power Fx

```
Table( {Color: "red"}, {Color: "green"}, {Color: "blue" } )
```

The listbox shows each color as an option.

- Add a text gallery, and set its **Items** property to this function:

  Power Fx

  ```
  Table( {Item: "Violin123", Location:"France", Owner:"Fabrikam"},
  {Item:"Violin456", Location:"Chile"} )
  ```

  The gallery shows two records, both of which contain the name and location of an item. Only one record contains the name of the owner.

- This formula combines standard sizes with extended sizes into a single table

  Power Fx

  ```
  Table( { Value: "XS" }, [ "S", "M", "L" ], { Value: "XL" } )
  ```

Acos, Acot, Asin, Atan, Atan2, Cos, Cot, Degrees, Pi, Radians, Sin, and Tan functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Calculates trigonometric values.

Description

Primary functions

The **Cos** function returns the cosine of its argument, an angle specified in radians.

The **Cot** function returns the cotangent of its argument, an angle specified in radians.

The **Sin** function returns the sine of its argument, an angle specified in radians.

The **Tan** function returns the tangent of its argument, an angle specified in radians.

Inverse functions

The **Acos** function returns the arccosine, or inverse cosine, of its argument. The arccosine is the angle whose cosine is the argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Acot** function returns the principal value of the arccotangent, or inverse cotangent, of its argument. The returned angle is given in radians in the range 0 (zero) to π.

The **Asin** function returns the arcsine, or inverse sine, of its argument. The arcsine is the angle whose sine is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan** function returns the arctangent, or inverse tangent, of its argument. The arctangent is the angle whose tangent is the argument. The returned angle is given in radians in the range -π/2 to π/2.

The **Atan2** function returns the arctangent, or inverse tangent, of the specified *x* and *y* coordinates as arguments. The arctangent is the angle from the *x*-axis to a line that contains the origin (0, 0) and a point with coordinates (*x*, *y*). The angle is given in radians between -π and π, excluding -π. A positive result represents a counterclockwise angle from the *x*-axis; a negative result represents a clockwise angle. **Atan2(*a*, *b*)** equals **Atan(*b*/*a*)**, except that ***a*** can equal 0 (zero) with the **Atan2** function.

Helper functions

The **Degrees** function converts radians to degrees. π radians equals 180 degrees.

The **Pi** function returns the transcendental number π, which begins 3.141592...

The **Radians** function converts degrees to radians.

Notes

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results with a **Value** column, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

If an argument would result in an undefined value, the result is *blank*. This can happen, for example, when using inverse functions with arguments that are out of range.

Syntax

Primary Functions

Cos(*Radians*)
Cot(*Radians*)
Sin(*Radians*)
Tan(*Radians*)

- *Radians* - Required. Angle to operate on.

Cos(*SingleColumnTable*)
Cot(*SingleColumnTable*)
Sin(*SingleColumnTable*)
Tan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of angles to operate on.

Inverse Functions

Acos(*Number*)
Acot(*Number*)
Asin(*Number*)
Atan(*Number*)

- *Number* - Required. Number to operate on.

Acos(*SingleColumnTable*)
Acot(*SingleColumnTable*)
Asin(*SingleColumnTable*)
Atan(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of numbers to operate on.

Atan2(*X*, *Y*)

- *X* - Required. *X*-axis coordinate.
- *Y* - Required. *Y*-axis coordinate.

Helper Functions

Degrees(*Radians*)

- *Radians* - Required. Angle in radians to convert to degrees.

Pi()

Radians(*Degrees*)

- *Degrees* - Required. Angle in degrees to convert to radians.

Examples

Single number

Expand table

Formula	Description	Result
Cos(1.047197)	Returns the cosine of 1.047197 radians or 60 degrees.	0.5
Cot(Pi()/4)	Returns the cotangent of 0.785398... radians or 45 degrees.	1
Sin(Pi()/2)	Returns the sine of 1.570796... radians or 90 degrees.	1
Tan(Radians(60))	Returns the tangent of 1.047197... radians or 60 degrees.	1.732050...
Acos(0.5)	Returns the arccosine of 0.5, in radians.	1.047197...
Acot(1)	Returns the arccotangent of 1, in radians.	0.785398...
Asin(1)	Returns the arcsine of 1, in radians.	1.570796...
Atan(1.732050)	Returns the arctangent of 1.732050, in radians.	1.047197...
Atan2(5, 3)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (5,3), which is approximately 31 degrees.	0.540419...
Atan2(4, 4)	Returns the arctangent of the angle from the *x*-axis of the line that contains the origin (0,0) and the coordinate (4,4), which is exactly π/4 radians or 45 degrees.	0.785398...
Degrees(1.047197)	Returns the equivalent number of degrees for 1.047197 radians.	60
Pi()	Returns the transcendental number π.	3.141592...
Radians(15)	Returns the equivalent number of radians for 15 degrees.	0.261799...

Single-column table

The examples in this section use a data source that's named **ValueTable** and that contains the following data. The last record in the table is π/2 radians or 90 degrees.

Expand table

Value
0.5
-2
1.570796...

Expand table

Formula	Description	Result
Cos(ValueTable)	Returns the cosine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.877582..., -0.416146..., 0
Cot(ValueTable)	Returns the cotangent of each number in the table.	A single-column table with a `Value` column containing the following values: 1.830487..., 0.457657..., 0
Sin(ValueTable)	Returns the sine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.479425, -0.909297..., 1
Tan(ValueTable)	Returns the tangent of each number in the table.	A single-column table with a `Value` column containing the following values: 0.546302..., 2.185039..., 3060023.306952...
Acos(ValueTable)	Returns the arccosine of each number in the table.	A single-column table with a `Value` column containing the following values: 1.047197..., Blank(), Blank()
Acot(ValueTable)	Returns the arccotangent of each number in the table.	A single-column table with a `Value` column containing the following values: 1.107138..., 2.677945..., 0.566911...
Asin(ValueTable)	Returns the arcsine of each number in the table.	A single-column table with a `Value` column containing the following values: 0.523598..., Blank(), Blank()
Atan(ValueTable)	Returns the arctangent of each number in the table.	A single-column table with a `Value` column containing the following values: 0.463647..., -1.107148..., 1.00388...
Degrees(ValueTable)	Returns the equivalent number of degrees for each number in the table, assumed to be angles in radians.	A single-column table with a `Value` column containing the following values: 28.647889..., -114.591559..., 90
Radians(ValueTable)	Returns the equivalent number of radians for each number in the table, assumed to be angles in degrees.	A single-column table with a `Value` column containing the following values: 0.008726..., -0.034906..., 0.027415...

Text function

06/18/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Converts any value and formats a number or date/time value to a string of text.

Description

The **Text** function formats a number or a date/time value based on one of these types of arguments:

- A predefined date/time format, which you specify by using the **DateTimeFormat** enumeration. For dates and times, this approach is preferred as it automatically adjusts to each user's language and region.
- A custom format, which comprises a string of placeholders that define, for example, whether numbers show a decimal separator and dates show the full name of the month, the month as an abbreviation, or the month as a number. Power Apps supports a subset of the placeholders that Microsoft Excel does. In this string, the language placeholder specifies the language in which to interpret the other placeholders. If the custom format includes a period, for example, the language-format placeholder specifies whether the period is a decimal separator (ja-JP) or a thousands separator (es-ES).

See working with dates and times for more information.

The **Text** function can also convert any data type to a text representation using a default format. Use this to pass non-text values to text-based functions such as **Len**, **Right**, and **IsMatch**.

Predefined date/time formats

For these examples, date and time used is Tuesday, April 7, 2020 8:26:59.180 PM, in the time zone UTC-7 hours.

Expand table

DateTimeFormat enum	Description	Examples (using en-US)
LongDate	Four-digit year, month name, day of the month, and day of the week. The names of the month and day of the week aren't abbreviated.	"Tuesday, April 7, 2020"
LongDateTime	Four-digit year, month name, day of the month, and day of the week, plus hour (12-hour clock), minutes, seconds, and AM/PM designation. The names of the month and day of the week aren't abbreviated.	"Tuesday, April 7, 2020 8:26:59 PM"
LongDateTime24	Four-digit year, month, day of the month, and day of the week, plus hour (24-hour clock), minutes, and seconds. The names of the month and day of the week aren't abbreviated.	"Tuesday, April 7, 2020 20:26:59"
LongTime	Hour (12-hour clock), minutes, seconds, and AM/PM designation.	"8:26:59 PM"
LongTime24	Hour (24-hour clock), minutes, seconds.	"20:26:59"
ShortDate	Four-digit year with numerical month and day of the month.	"4/7/2020"
ShortDateTime	Four-digit year with numerical month and day of the month, plus hour (12-hour clock), minutes, and AM/PM designation.	"4/7/2020 8:26 PM"
ShortDateTime24	Four-digit year with numerical month and day of the month, plus hour (24-hour clock) and minutes.	"4/7/2020 20:26"
ShortTime	Hour (12-hour clock), minutes, and AM/PM designation.	"8:26 PM"
ShortTime24	Hour (24-hour clock) and minutes.	"20:26"
UTC	The date/time value is converted to UTC based on the current user's time zone and formatted according to the ISO 8601 standard.	"2020-04-08T03:26:59.180Z"

Number placeholders

Expand table

Placeholder	Description
0 (*zero*)	Displays insignificant zeros if a number has fewer digits than there are zeros in the format. For example, use the format **#.00** if you want to display **8.9** as **8.90**.

Placeholder	Description
#	Follows the same rules as the **0** (zero). However, **Text** doesn't return extra zeros when the number has fewer digits on either side of the decimal than there are # symbols in the format. For example, **8.9** is displayed if the custom format is **#.##** and the number to format is **8.9**.
. (*period*)	Displays the decimal point in a number. Depends on the language of the custom format; see global apps for more details.
, (*comma*)	Displays the grouping separator in a number, often used for thousands. **Text** separates groups by commas if the format contains a comma that's enclosed by number signs (#) or by zeros. Depends on the language of the custom format; see global apps for more details.

If a number has more digits to the right of the decimal point than there are placeholders in the format, the number rounds to as many decimal places as there are placeholders. If there are more digits to the left of the decimal point than there are placeholders, the extra digits are displayed. If the format contains only number signs (#) to the left of the decimal point, numbers less than 1 start with a decimal point (for example, **.47**).

Date and time placeholders

Expand table

Placeholder	Description
m	Displays the month as a number without a leading zero.
mm	Displays the month as a number with a leading zero when appropriate.
mmm	Displays the month as an abbreviation (**Jan** to **Dec**).
mmmm	Displays the month as a full name (**January** to **December**).
d	Displays the day as a number without a leading zero.
dd	Displays the day as a number with a leading zero when appropriate.
ddd	Displays the day as an abbreviation (**Sun** to **Sat**).
dddd	Displays the day as a full name (**Sunday** to **Saturday**).
yy	Displays the year as a two-digit number.
yyyy	Displays the year as a four-digit number.
h	Displays the hour as a number without a leading zero.

Placeholder	Description
hh	Displays the hour as a number with a leading zero when appropriate. If the format contains **AM** or **PM**, the hour is shown based on the 12-hour clock. Otherwise, the hour is shown based on the 24-hour clock.
m	Displays the minute as a number without a leading zero. This placeholder must appear immediately after the **h** or **hh** code or immediately before the **ss** code; otherwise, **Text** returns the month instead of minutes.
mm	Displays the minute as a number with a leading zero when appropriate. This placeholder must appear immediately after the **h** or **hh** placeholder or immediately before the **ss** placeholder. Otherwise, **Text** returns the month instead of minutes.
s	Displays the second as a number without a leading zero.
ss	Displays the second as a number with a leading zero when appropriate.
f	Displays the fractions of seconds.
AM/PM, **a/p**	Displays the hour based on a 12-hour clock. **Text** returns "AM" or "a" for times from midnight until noon and "PM" or "p" for times from noon until midnight

Literal placeholders

You can include any of these characters in your format string. They will appear in the result of **Text** as is. Additional characters are reserved for future placeholders, so you shouldn't use them.

Expand table

Character	Description
Any currency symbol	Dollar sign, cents sign, euro sign, etc.
+	Plus sign
(	Left parenthesis
:	Colon
^	Circumflex accent (caret)
'	Apostrophe
{	Left curly bracket

Character	Description
<	Less-than sign
=	Equal sign
-	Minus sign
/	Slash mark
)	Right parenthesis
&	Ampersand
~	Tilde
}	Right curly bracket
>	Greater-than sign
	Space character

Global apps

The **Text** function is globally aware. For a wide array of languages, it knows how to properly write out dates, times, currencies, and numbers. To do its job, it needs two pieces of information:

- **The language of the custom format:** For makers, how should a custom format be interpreted? The separator characters (. and ,) have different meanings in different languages. If you specify a custom format, you can include a language placeholder or take the default value, which reflects the language to which your device is set. Even easier, you can use one of the predefined date/time formats, which are language agnostic.
- **The language of the result:** For users, in what language should the function result appear? Names of months and weekdays must be in the appropriate language for the user of the app, which you can specify by adding a third, optional argument to the **Text** function.

For both, you specify the language by using a language tag. To see the list of supported languages, type **Text(1234, "",)** in the formula bar or the **Advanced** tab of the right-hand pane, and then scroll through the list of locales suggested for the third argument.

Language placeholder

To specify the language of the custom format, use:

Expand table

Placeholder	Description
[$-*LanguageTag*]	*LanguageTag* is a language tag as returned from the **Language** function. It can specify just the language (such as **[$-en]** for English), or it can also specify the region (such as **[$-en-GB]** to further specify Great Britain).

The language placeholder can appear anywhere in the custom format but only once.

If you specify a custom format without a language placeholder and the format is ambiguous from a global standpoint, the language tag for your current language is inserted automatically.

[$-en-US] is assumed if this placeholder isn't present when your app is run.

> **Note**
>
> In a future version, the syntax of this placeholder may change to avoid confusion with a similar, but different, placeholder that Excel supports.

Result language tag

The result of **Text** includes translated strings for months, weekdays, and AM/PM designations, as well as the appropriate group and decimal separators.

By default, **Text** uses the language of the user running the app. The **Language** function returns the language tag for the current user. You can override this default value by supplying a language tag for the third argument to **Text**.

Syntax

Text(*NumberOrDateTime*, *DateTimeFormatEnum* [, *ResultLanguageTag*])

- *NumberOrDateTime* - Required. The number or the date/time value to format.
- *DateTimeFormat* - Required. A member of the **DateTimeFormat** enumeration.
- *ResultLanguageTag* - Optional. The language tag to use for the result text. By default, the language of the current user is used.

Text(*NumberOrDateTime*, *CustomFormat* [, *ResultLanguageTag*])

- *Number* - Required. The number or the date/time value to format.
- *CustomFormat* - Required. One or more placeholders enclosed in double quotation marks.

- *ResultLanguageTag* - Optional. The language tag to use for the result text. By default, the language of the current user is used.

Text(*AnyValue*)

- *AnyValue* - Required. Value to convert to a text representation. A default format is used.

Text (*Dynamic*)

- *Dynamic* - Required. **Dynamic** value that represents a string. Acceptable values are dependent on the untyped provider. For **JSON**, if the dynamic value is a number or boolean, it will be converted to text.

Examples

Unless otherwise specified, the user running these formulas is located in the United States and has selected English as their language. The **Language** function is returning "en-US".

Number

Expand table

Formula	Description	Result
Text(1234.59, "####.#")	Formats the number with one decimal place.	"1234.6"
Text(8.9, "#.000")	Pads the decimal portion of the number with trailing zeros, if needed.	"8.900"
Text(0.631, "0.#")	Pads the whole portion of the number with leading zeros, if needed.	"0.6"
Text(12, "#.0#") **Text(1234.568, "#.0#")**	Pads the decimal portion of the number with zeros for one decimal place, and includes a second decimal place if supplied.	"12.0" "1234.57"
Text(12000, "$ #,###") **Text(1200000, "$ #,###")**	Places a thousands separator every three digits, and includes a currency symbol.	"$ 12,000" "$ 1,200,000"

Date/Time

- At **2:37:47 PM** on **Monday, November 23, 2015**
- United States Pacific Time Zone (UTC-8)

Expand table

Formula	Description	Result
Text(Now(), DateTimeFormat.LongDate)	Formats as a long date string, in the language and locale of the current user.	"Monday, November 23, 2015"
Text(Now(), DateTimeFormat.LongDateTime)	Formats as a long date and time string, in the language and locale of the current user, using a 12-hour clock.	"Monday, November 23, 2015 2:37:47 PM"
Text(Now(), DateTimeFormat.LongTime24)	Formats as a long time string, using a 24-hour clock.	"14:37:47"
Text(Now(), DateTimeFormat.ShortDate)	Formats as a short date string, in the language and locale of the current user.	"11/23/2015"
Text(Now(), "d-mmm-yy")	Formats using placeholder characters: • **d** for a single-digit or double-digit day of the month • **-** as a literal character copied to the result • **mmm** for a three-letter abbreviation of the month • **-** as another literal character copied to the result • **yy** for a two-digit abbreviation of the year	"23-Nov-15"
Text(1448318857*1000, "mmm. dd, yyyy (hh:mm:ss AM/PM)")	Shows a Unix date-time value in human-readable format if you multiply the source value by 1,000.	"Nov. 23, 2015 (02:47:37 PM)"

Global apps

Expand table

Formula	Description	Result
Text(1234567.89, "[$-fr-FR]# ###,## €", "fr-FR")	Shows a space as a grouping separator, the comma as a decimal separator, and **€** as the currency symbol.	"1 234 567,89 €"
Text(1234567,89; "[$-fr-FR]# ###,## €")	If the source data follows the French custom of using a comma as the decimal separator, you must change your locale to French and separate the arguments with a	"1 234 567,89 €"

Formula	Description	Result
	semi-colon instead of a comma to get the same result as above.	
Text(Date(2016,1,31), "dddd mmmm d")	Returns the weekday, month, and day of the month in the language of the current user. Because none of the placeholders are language dependent, there is no need for a format text language tag.	"Sunday January 31"
Text(Date(2016,1,31), "dddd mmmm d", "es-ES")	Returns the weekday, month, and day of the month in the "es-ES" language.	"domingo enero 31"

Converting values to text

Expand table

Formula	Description	Result
Text(1234567.89)	Converts a number to a string. There are no thousands separators or control over the number of digits before or after the decimal separator; for more control, supply number placeholders as the second argument.	"1234567.89"
Text(DateTimeValue("01/04/2003"))	Converts a date/time value to a string of text. To control the conversion, provide either a member of the DateTimeFormat enumeration or a custom-format string.	"1/4/2003 12:00 AM"
Text(true)	Converts a Boolean value to a string.	"true"
Text(GUID())	Converts a generated GUID value to a string.	"f8b10550-0f12-4f08-9aa3-bb10958bc3ff"
Left(Text(GUID()), 4)	Returns the first four characters of a generated GUID.	"2d9c"

Operators and Identifiers in Power Apps

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Some of these operators are dependent on the language of the author. For more information about language support in canvas apps, see Global apps.

Expand table

Symbol	Type	Example	Description
'...'	Identifier	**'Account Name'**	Identifiers that contain special characters, including spaces, are enclosed in single quotes
"..."	Text string	**"Hello, World"**	Text strings are enclosed in double quotes
$"..."	String interpolation	**$"Dear {FirstName},"**	Formulas embedded within a text string
.	Property Selector	**Slider1.Value** **Color.Red** **Acceleration.X**	Extracts a property from a table, control, signal, or enumeration. For backward compatibility, **!** may also be used.
. [language dependent]	Decimal separator	**1.23**	Separator between whole and fractional parts of a number. The character depends on the language.
( )	Parentheses	**Filter(T, A < 10)** **(1 + 2) * 3**	Enforces precedence order, and groups subexpressions in a larger expression
+	Arithmetic operators	**1 + 2**	Addition
-		**2 - 1**	Subtraction and sign
*		**2 * 3**	Multiplication
/		**2 / 3**	Division (also see the **Mod** function)
^		**2 ^ 3**	Exponentiation, equivalent to the **Power** function

Symbol	Type	Example	Description
%		**20%**	Percentage (equivalent to "* 1/100")
=	Comparison operators	**Price = 100**	Equal to
>		**Price > 100**	Greater than
>=		**Price >= 100**	Greater than or equal to
<		**Price < 100**	Less than
<=		**Price <= 100**	Less than or equal to
<>		**Price <> 100**	Not equal to
&	String concatenation operator	**"hello" & " " & "world"**	Makes multiple strings appear continuous
&& or **And**	Logical operators	**Price < 100 && Slider1.Value = 20** or **Price < 100 And Slider1.Value = 20**	Logical conjunction, equivalent to the **And** function
|| or **Or**		**Price < 100 || Slider1.Value = 20** or **Price < 100 Or Slider1.Value = 20**	Logical disjunction, equivalent to the **Or** function
! or **Not**		**!(Price < 100)** or **Not (Price < 100)**	Logical negation, equivalent to the **Not** function
exactin	Membership operators	**Gallery1.Selected exactin SavedItems**	Belonging to a collection or a table
exactin		**"Windows" exactin "To display windows in the Windows operating system..."**	Substring test (case-sensitive)
in		**Gallery1.Selected in SavedItems**	Belonging to a collection or a table
in		**"The" in "The keyboard and the monitor..."**	Substring test (case-insensitive)
@	Disambiguation operator	**MyTable[@fieldname]**	Field disambiguation
@		**[@MyVariable]**	Global disambiguation

Symbol	Type	Example	Description
, [language dependent]	List separator	**If(X < 10, "Low", "Good")** **{ X: 12, Y: 32 }** **[1, 2, 3]**	Separates: • arguments in function calls • fields in a record • records in a table This character depends on the language.
; [language dependent]	Formula chaining	**Collect(T, A); Navigate(S1, "")**	Separate invocations of functions in behavior properties. The chaining operator depends on the language.
As	As operator	**AllCustomers As Customer**	Overrides **ThisItem** and **ThisRecord** in galleries and record scope functions. **As** is useful for providing a better, specific name and is especially important in nested scenarios.
Self	Self operator	**Self.Fill**	Access to properties of the current control
Parent	Parent operator	**Parent.Fill**	Access to properties of a control container
ThisItem	ThisItem operator	**ThisItem.FirstName**	Access to fields of a Gallery or form control
ThisRecord	ThisRecord operator	**ThisRecord.FirstName**	Access to the complete record and individual fields of the record within **ForAll**, **Sum**, **With**, and other record scope functions. Can be overridden with the **As** operator.

> ⓘ Note
>
> The @ operator can also be used to validate the type of the record object against a data source. For example, `Collect(coll,Account@{'Account Number: 1111')`

in and exactin operators

Use the **in** and **exactin** operators to find a string in a data source, such as a collection or an imported table. The **in** operator identifies matches regardless of case, and the **exactin** operator identifies matches only if they're capitalized the same way. Here's an example:

1. Create or import a collection named **Inventory**, and show it in a gallery, as the first procedure in Show images and text in a gallery describes.

2. Set the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" in ProductName)

   The gallery shows all products except Callisto because the name of that product is the only one that doesn't contain the letter you specified.

3. Change the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" exactin ProductName)

   The gallery shows only Europa because only its name contains the letter that you specified in the case that you specified.

ThisItem, ThisRecord, and As operators

A few controls and functions apply formulas to individual records of a table. To refer to the individual record in a formula, use one of the following:

Expand table

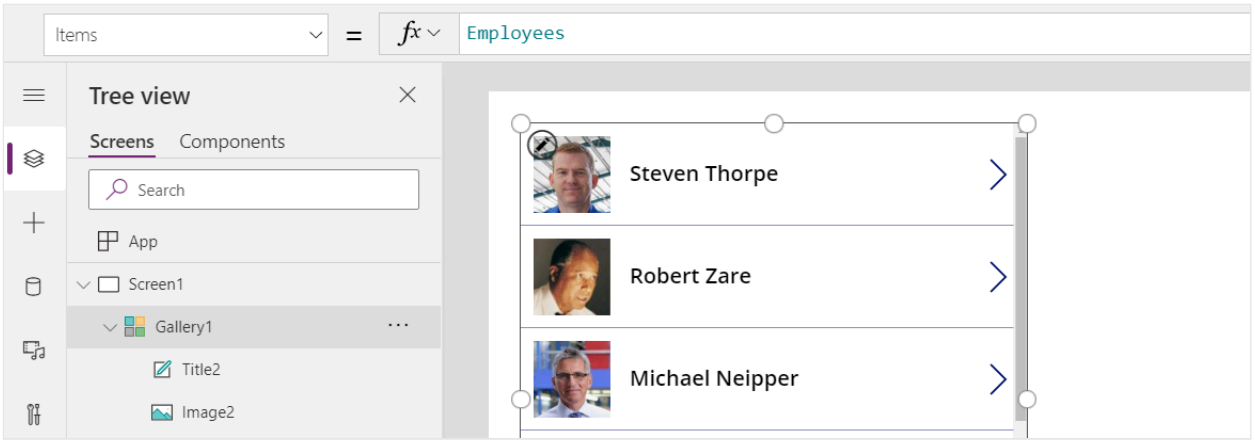
Operator	Applies to	Description
ThisItem	**Gallery** control **Edit form** control **Display form** control	The default name for the current record in a **Gallery** or form control.
ThisRecord	**ForAll**, **Filter**, **With**, **Sum** and other record scope functions	The default name for the current record in **ForAll** and other record scope functions.
As *name*	**Gallery** control **ForAll**, **Filter**, **With**, **Sum** and other record scope functions	Defines a *name* for the current record, replacing default **ThisItem** or **ThisRecord**. Use **As** to make formulas easier to understand and resolve ambiguity when nesting.

ThisItem operator

For example, in the following **Gallery** control, the **Items** property is set to the **Employees** data source (such as the **Employees** table included with the Northwind Traders sample):

Power Apps

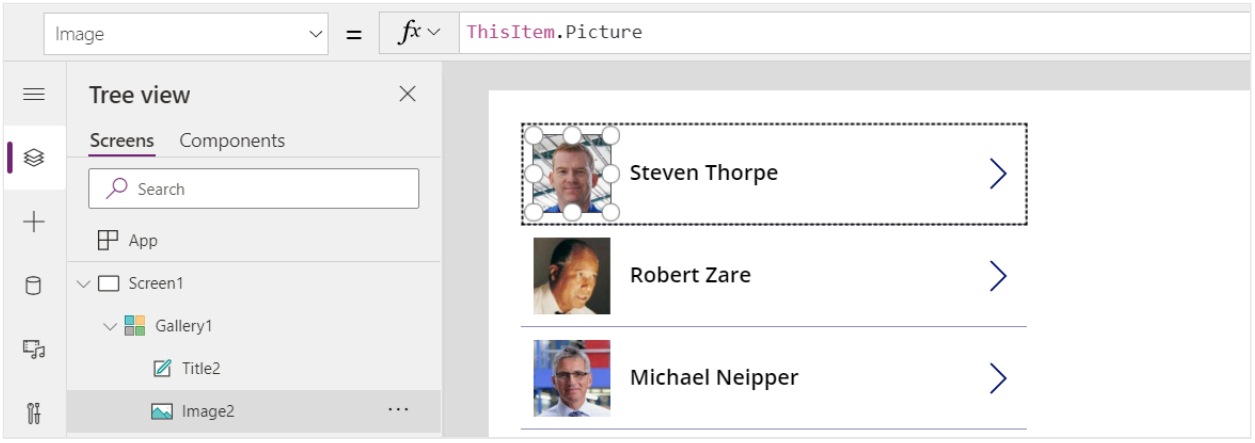
```
Employees
```



The first item in the gallery is a template that is replicated for each employee. In the template, the formula for the picture uses **ThisItem** to refer to the current item:

Power Apps

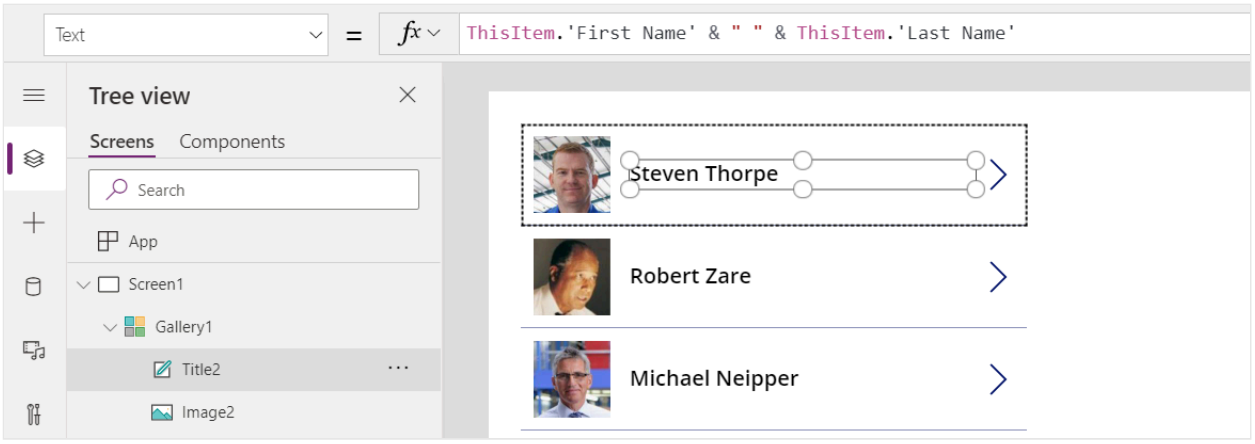
```
ThisItem.Picture
```



Likewise, the formula for the name also uses **ThisItem**:

Power Apps

```
ThisItem.'First Name' & " " & ThisItem.'Last Name'
```

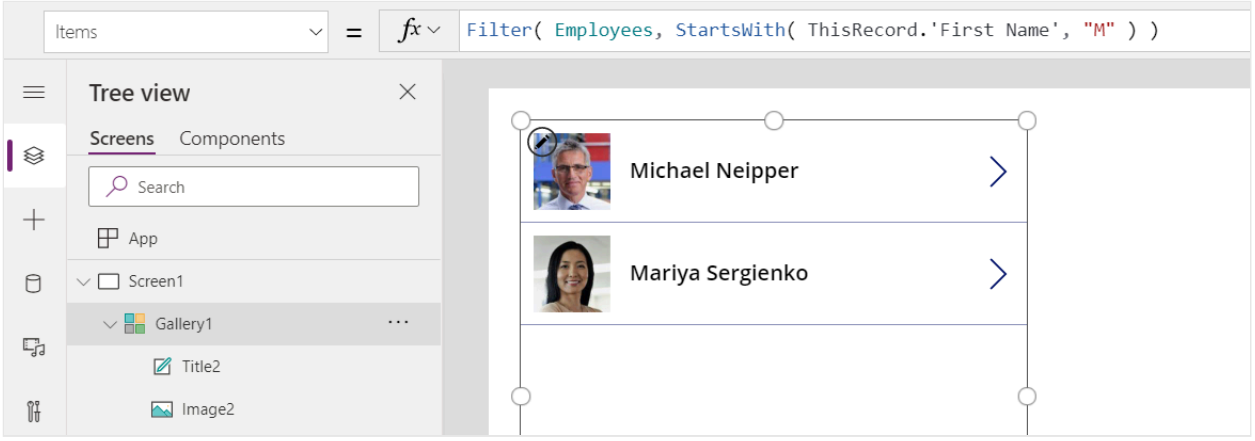


ThisRecord operator

ThisRecord is used in functions that have a record scope. For example, we can use the **Filter** function with our gallery's **Items** property to only show first names that being with *M*:

Power Apps

```
Filter( Employees, StartsWith( ThisRecord.Employee.'First Name', "M" ) )
```



ThisRecord is optional and implied by using the fields directly, for example, in this case, we could have written:

Power Apps

```
Filter( Employees, StartsWith( 'First Name', "M" ) )
```

Although optional, using **ThisRecord** can make formulas easier to understand and may be required in ambiguous situations where a field name may also be a relationship name. **ThisRecord** is optional while **ThisItem** is always required.

Use **ThisRecord** to reference the whole record with **Patch**, **Collect**, and other record scope functions. For example, the following formula sets the status for all inactive employees to active:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees,
              Patch( Employees, ThisRecord, { Status: 'Status
(Employees)'.Active } ) ) )
```

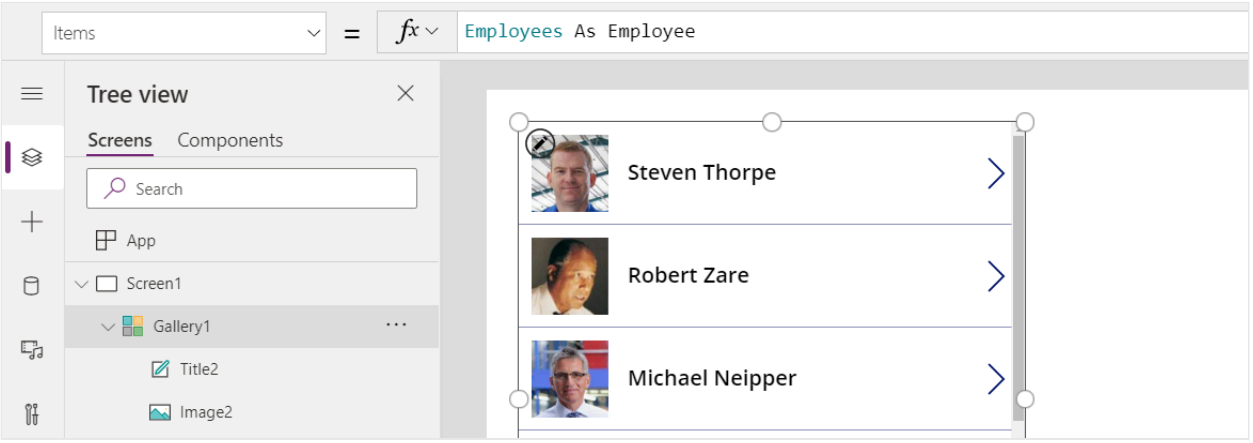
As operator

Use the **As** operator to name a record in a gallery or record scope function, overriding the default **ThisItem** or **ThisRecord**. Naming the record can make your formulas easier to understand and may be required in nested situations to access records in other scopes.

For example, you can modify the **Items** property of our gallery to use **As** to identify that we are working with an Employee:

Power Apps

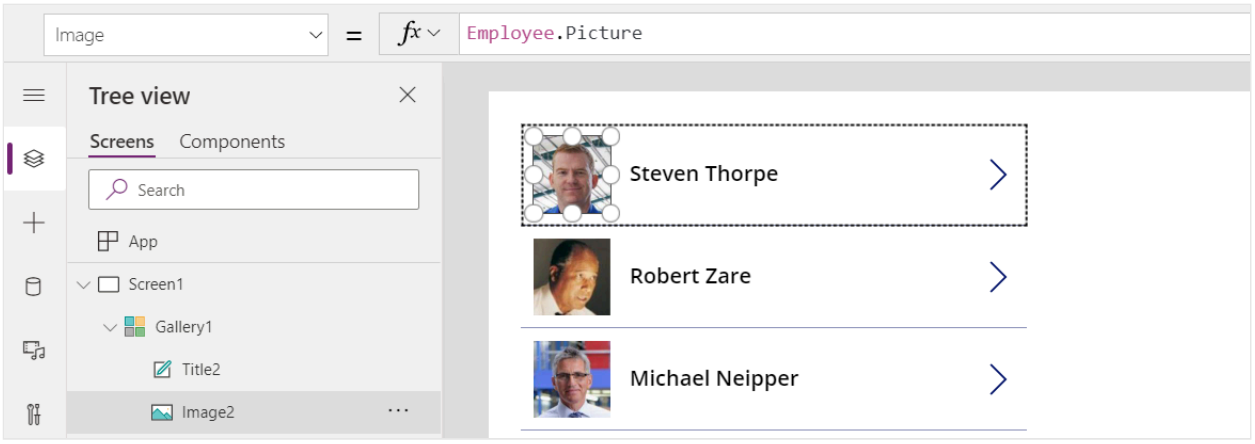
```
Employees As Employee
```



The formulas for the picture and name are adjusted to use this name for the current record:

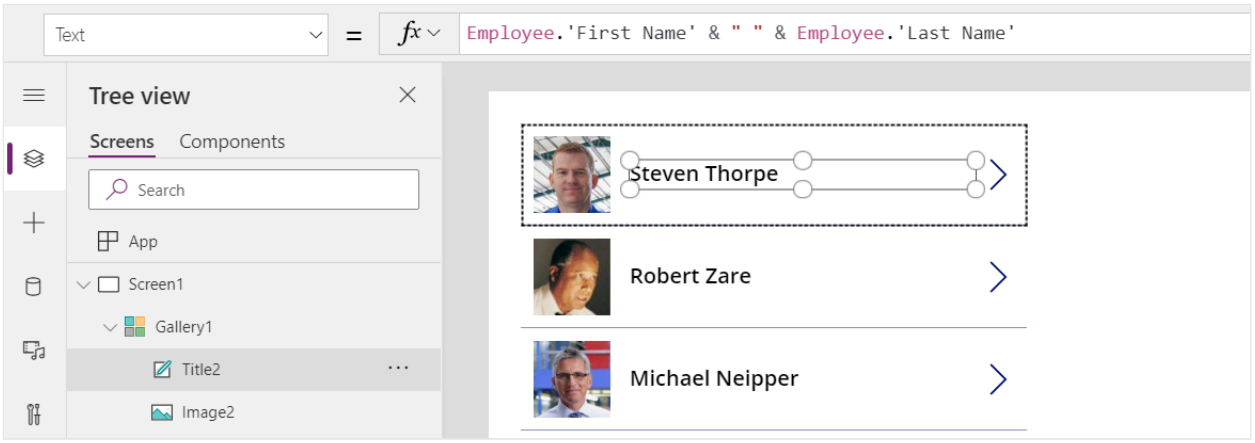
Power Apps

```
Employee.Picture
```



Power Apps

```
Employee.'First Name' & " " & Employee.'Last Name'
```



As can also be used with record scope functions to replace the default name **ThisRecord**. We can apply this to our previous example to clarify the record we're working with:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees As Employee,
              Patch( Employees, Employee, { Status: 'Status
(Employees)'.Active } ) ) )
```

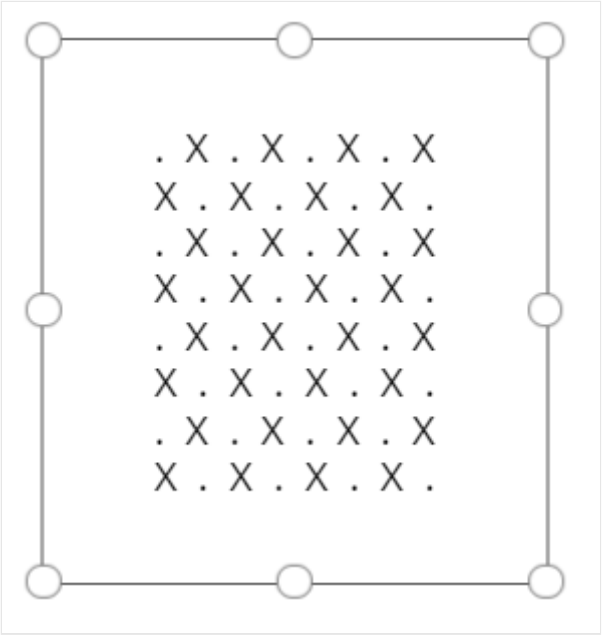
When nesting galleries and record scope functions, **ThisItem** and **ThisRecord** always refers to the inner most scope, leaving records in outer scopes unavailable. Use **As** to make all record scopes available by giving each a unique name.

For example, this formula produces a chessboard pattern as a text string by nesting two **ForAll** functions:

Power Apps

```
Concat(
    ForAll( Sequence(8) As Rank,
        Concat(
            ForAll( Sequence(8) As File,
                    If( Mod(Rank.Value + File.Value, 2) = 1, " X ", " . " )
            ),
            Value
        ) & Char(10)
    ),
    Value
)
```

Setting a **Label** control's **Text** property to this formula displays:



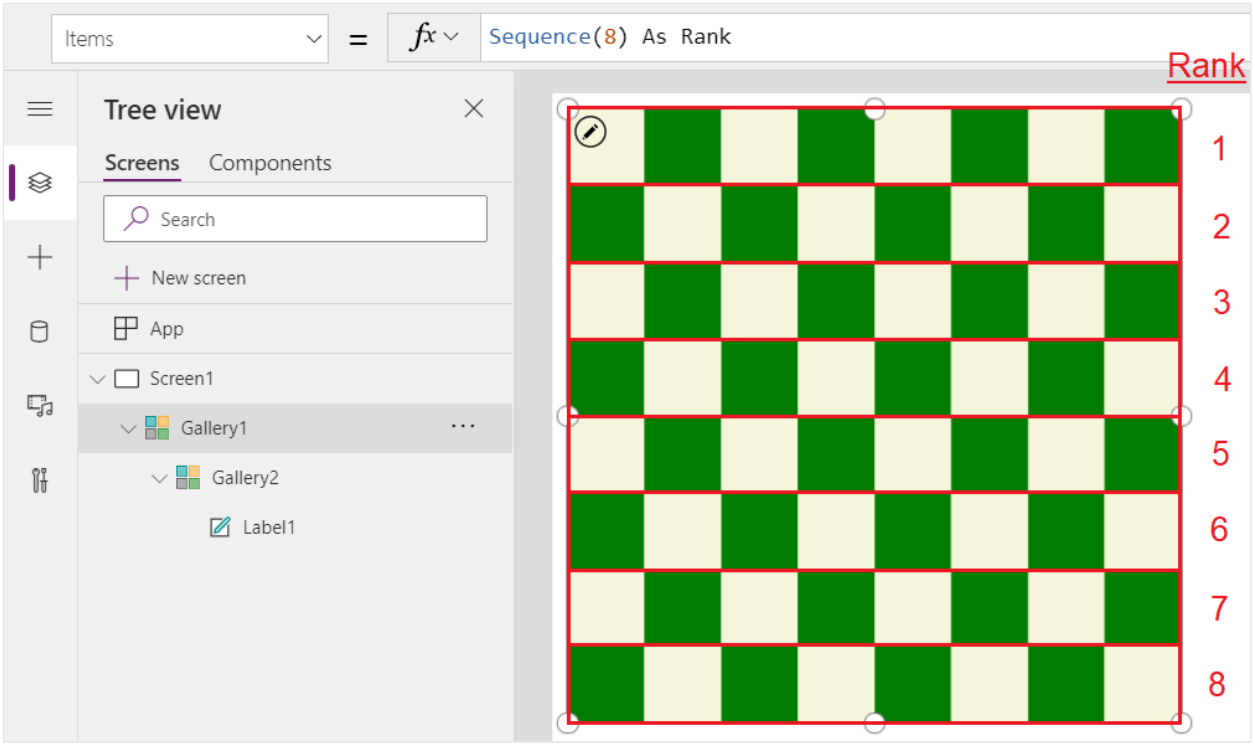
Let's unpack what is happening here:

- We start by iterating an unnamed table of 8 numbered records from the Sequence function. This loop is for each row of the board, which is commonly referred to as **Rank** and so we give it this name.
- For each row, we iterate another unnamed table of 8 columns, and we give the common name **File**.
- If **Rank.Value** + **File.Value** is an odd number, the square gets an **X**, otherwise a dot. This part of the formula is referencing both **ForAll** loops, made possible by using the **As** operator.
- Concat is used twice, first to assemble the columns and then the rows, with a Char(10) thrown in to create a new line.

A similar example is possible with nested **Gallery** controls instead of **ForAll** functions. Let's start with the vertical gallery for the **Rank**. This gallery control will have an **Items** formula of:

Power Apps

```
Sequence(8) as Rank
```



Within this gallery, we'll place a horizontal gallery for the **File**, that will be replicated for each **Rank**, with an **Items** property of:

Power Apps

```
Sequence(8) as File
```

And finally, within this gallery, we'll add a **Label** control that will be replicated for each **File** and each **Rank**. We'll size it to fill the entire space and use the **Fill** property to provide the color with this formula:

Power Apps

```
If( Mod( Rank.Value + File.Value, 2 ) = 1, Green, Beige )
```

Self and Parent operators

There are three ways to refer to a control and its properties within a formula:

Expand table

Method	Description
By control name	Any control can be referenced by name from anywhere within the app. For example, **Label1.Fill** refers to the fill property of the control who's name is **Label1**.
Self operator	It's often convenient to reference another property of the same control when writing a formula. Instead of using an absolute reference by name, it's easier and more portable to use a relative reference to one*self*. The **Self** operator provides that easy access to the current control. For example, **Self.Fill** refers to the fill color of the current control.

Method	Description
Parent operator	Some controls host other controls, such as the **Screen** and **Gallery** controls. The hosting control of the controls within it's called the *parent*. Like the **Self** operator, the **Parent** operator provides an easy relative reference to the container control. For example, **Parent.Fill** refers to the fill property of the control that is the container for the current control.

Self and **Parent** are operators and not properties on the controls themselves. Referring to **Parent.Parent**, **Self.Parent** or **Parent.Self** is not supported.

Identifier names

The names of variables, data sources, columns, and other objects can contain any Unicode.

Use single quotes around a name that contains a space or other special character. Use two single quotes together to represent one single quote in the name. Names that don't contain special characters don't require single quotes.

Here are some example column names you might encounter in a table, and how they're represented in a formula:

Expand table

Column name in a database	Column reference in a formula
SimpleName	`SimpleName`
NameWith123Numbers	`NameWith123Numbers`
Name with spaces	`'Name with spaces'`
Name with "double" quotes	`'Name with "double" quotes'`
Name with 'single' quotes	`'Name with ''single'' quotes'`
Name with an @ at sign	`'Name with an @ at sign'`

Double quotes are used to designate text strings.

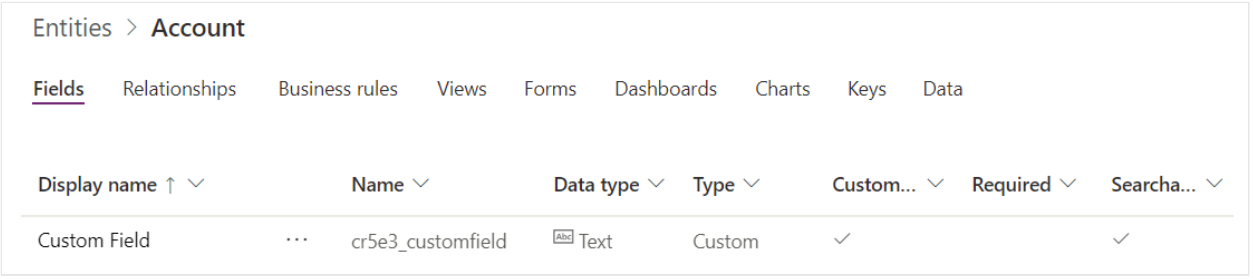
Display names and logical names

Some data sources such as SharePoint and Microsoft Dataverse have two different names to refer to the same table or column of data:

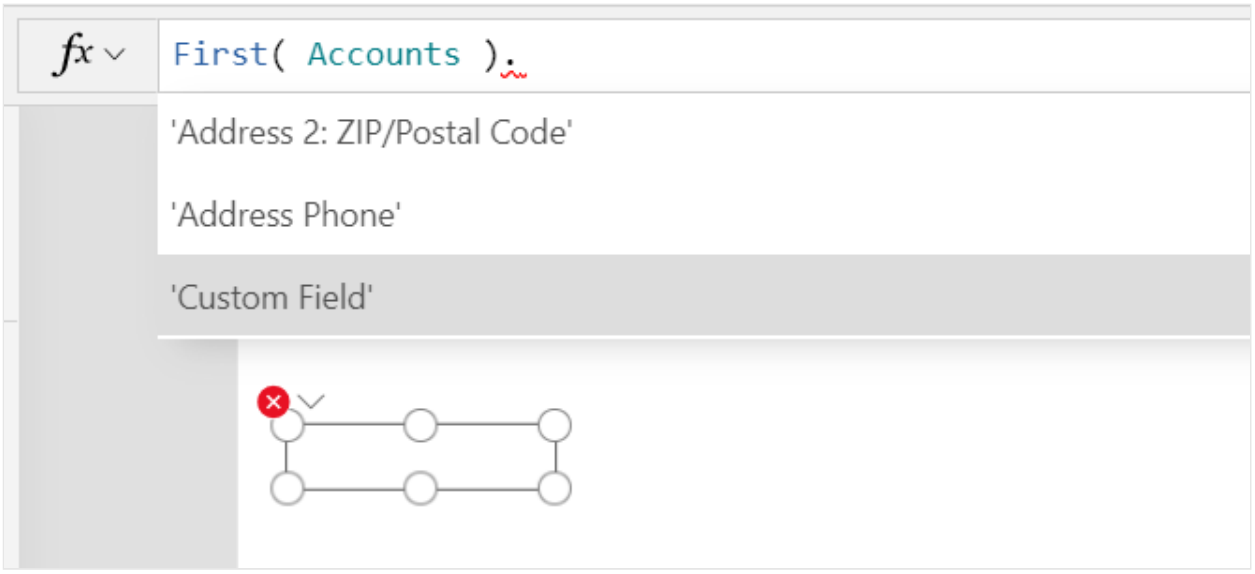
- **Logical name** - A name that is guaranteed to be unique, doesn't change after being created, usually doesn't allow spaces or other special characters, and isn't localized into different languages. As a result, the name can be cryptic. These names are used by professional developers. For example, **cra3a_customfield**. This name may also be referred to as **schema name** or just **name**.
- **Display name** - A name that is user-friendly and intended to be seen by end users. This name may not be unique, may change over time, may contain spaces and any Unicode character, and may be localized into different languages. Corresponding to the example above, the display name may be **Custom Field** with space in between the words.

Since display names are easier to understand, Canvas apps will suggest them as choices and not suggest logical names. Although logical names aren't suggested, they can still be used if typed indirectly.

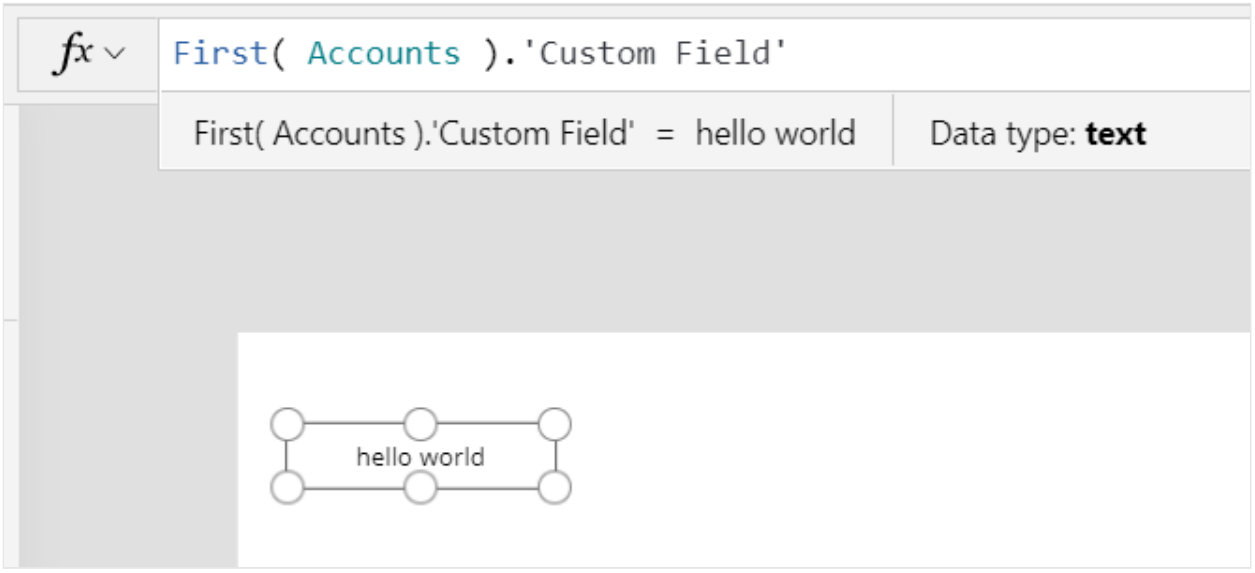
For example, imagine you've added a **Custom Field** to a table in Dataverse. A logical name will be assigned for you by the system, which you can modify only when creating the field. The result would look similar to:



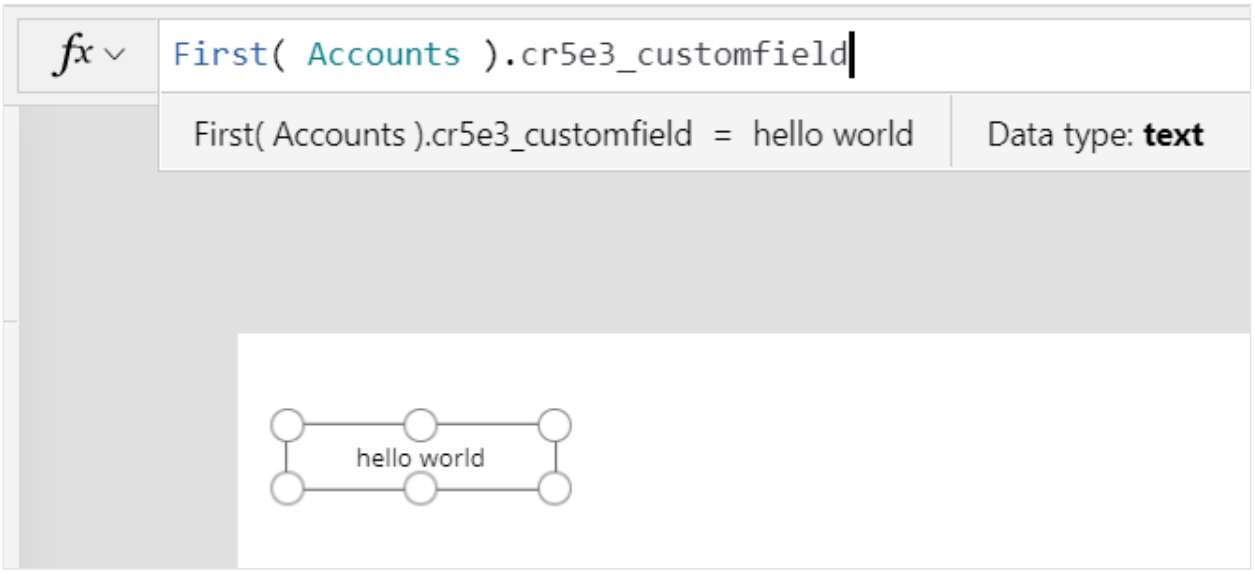
When authoring a reference to a field of Accounts, the suggestion will be made to use '**Custom Field**' since this is the display name. Single quotes must be used because this name has a space in it:



After selecting the suggestion, 'Custom Field' is shown in the formula bar and the data is retrieved:



Although it isn't suggested, we could also use the logical name for this field. This will result in the same data being retrieved. Single quotes are not required since this name doesn't contain spaces or special characters:

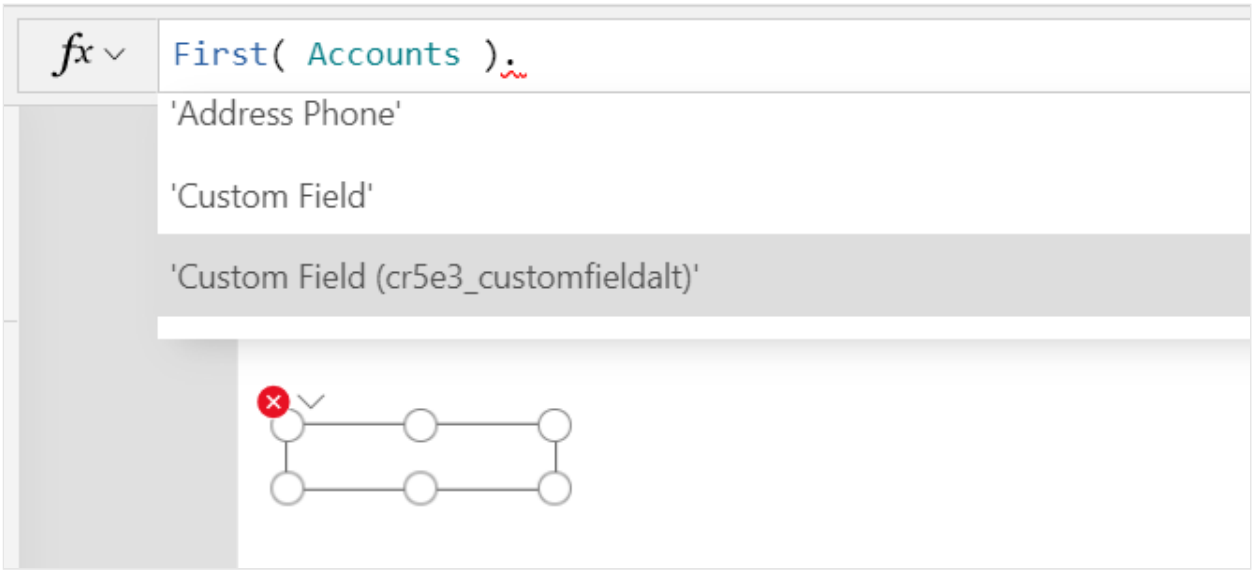


Behind the scenes, a mapping is maintained between the display names seen in formulas and the underlying logical names. Since logical names must be used to interact with the data source, this mapping is used to convert from the current display name to the logical name automatically and that is what is seen in the network traffic. This mapping is also used to convert back to logical names to switch into new display names, for example, if a display name changes or a maker in a different language edits the app.

> **Note**
>
> Logical names are not translated when moving an app between environments. For Dataverse system table and field names, this should not be a problem as logical names are consistent across environments. But any custom fields, such as **cra3a_customfield** in this example above, may have a different environment prefix (**cra3a** in this case). Display names are preferred as they can be matched against display names in the new environment.

Name disambiguation

Since display names aren't unique, the same display name may appear more than once in the same table. When this happens, the logical name will be added to the end of the display name in parentheses for one of more of the conflicting names. Building on the example above, if there was a second field with the same display name of **Custom Field** with a logical name of **cra3a_customfieldalt** then the suggestions would show:



Name disambiguation strings are added in other situations where name conflicts occur, such as the names of table, choices, and other Dataverse items.

Disambiguation operator

Some functions create record scopes for accessing the fields of table while processing each record, such as **Filter**, **AddColumns**, and **Sum**. Field names added with the record scope override the same names from elsewhere in the app. When this happens, you can still access values from outside the record scope with the @ disambiguation operator:

- To access values from nested record scopes, use the @ operator with the name of the table being operated upon using this pattern:
  Table[@*FieldName*]
- To access global values, such as data sources, collections, and context variables, use the pattern [@*ObjectName*] (without a table designation).

For more information and examples, see record scopes.

&	String concatenation operator	**"hello" & " " & "world"**	Makes multiple strings appear continuous
&& or **And**	Logical operators	**Price < 100 && Slider1.Value = 20** or **Price < 100 And Slider1.Value = 20**	Logical conjunction, equivalent to the **And** function
|| or **Or**		**Price < 100 || Slider1.Value = 20** or **Price < 100 Or Slider1.Value = 20**	Logical disjunction, equivalent to the **Or** function
! or **Not**		**!(Price < 100)** or **Not (Price < 100)**	Logical negation, equivalent to the **Not** function
exactin	Membership operators	**Gallery1.Selected exactin SavedItems**	Belonging to a collection or a table
exactin		**"Windows" exactin "To display windows in the Windows operating system..."**	Substring test (case-sensitive)
in		**Gallery1.Selected in SavedItems**	Belonging to a collection or a table
in		**"The" in "The keyboard and the monitor..."**	Substring test (case-insensitive)
@	Disambiguation operator	**MyTable[@fieldname]**	Field disambiguation
@		**[@MyVariable]**	Global disambiguation

Symbol	Type	Example	Description
, [language dependent]	List separator	**If(X < 10, "Low", "Good")** **{ X: 12, Y: 32 }** **[1, 2, 3]**	Separates: • arguments in function calls • fields in a record • records in a table This character depends on the language.
; [language dependent]	Formula chaining	**Collect(T, A); Navigate(S1, "")**	Separate invocations of functions in behavior properties. The chaining operator depends on the language.
As	As operator	**AllCustomers As Customer**	Overrides **ThisItem** and **ThisRecord** in galleries and record scope functions. **As** is useful for providing a better, specific name and is especially important in nested scenarios.
Self	Self operator	**Self.Fill**	Access to properties of the current control
Parent	Parent operator	**Parent.Fill**	Access to properties of a control container
ThisItem	ThisItem operator	**ThisItem.FirstName**	Access to fields of a Gallery or form control
ThisRecord	ThisRecord operator	**ThisRecord.FirstName**	Access to the complete record and individual fields of the record within **ForAll**, **Sum**, **With**, and other record scope functions. Can be overridden with the **As** operator.

> ⓘ Note
>
> The @ operator can also be used to validate the type of the record object against a data source. For example, `Collect(coll,Account@{'Account Number: 1111')`

in and exactin operators

Use the **in** and **exactin** operators to find a string in a data source, such as a collection or an imported table. The **in** operator identifies matches regardless of case, and the **exactin** operator identifies matches only if they're capitalized the same way. Here's an example:

1. Create or import a collection named **Inventory**, and show it in a gallery, as the first procedure in Show images and text in a gallery describes.

2. Set the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" in ProductName)

   The gallery shows all products except Callisto because the name of that product is the only one that doesn't contain the letter you specified.

3. Change the **Items** property of the gallery to this formula:
   Filter(Inventory, "E" exactin ProductName)

   The gallery shows only Europa because only its name contains the letter that you specified in the case that you specified.

ThisItem, ThisRecord, and As operators

A few controls and functions apply formulas to individual records of a table. To refer to the individual record in a formula, use one of the following:

Expand table

Operator	Applies to	Description
ThisItem	**Gallery** control **Edit form** control **Display form** control	The default name for the current record in a **Gallery** or form control.
ThisRecord	**ForAll**, **Filter**, **With**, **Sum** and other record scope functions	The default name for the current record in **ForAll** and other record scope functions.
As *name*	**Gallery** control **ForAll**, **Filter**, **With**, **Sum** and other record scope functions	Defines a *name* for the current record, replacing default **ThisItem** or **ThisRecord**. Use **As** to make formulas easier to understand and resolve ambiguity when nesting.

ThisItem operator

For example, in the following **Gallery** control, the **Items** property is set to the **Employees** data source (such as the **Employees** table included with the Northwind Traders sample):

Power Apps

```
Employees
```

The first item in the gallery is a template that is replicated for each employee. In the template, the formula for the picture uses **ThisItem** to refer to the current item:

Power Apps

```
ThisItem.Picture
```

Likewise, the formula for the name also uses **ThisItem**:

Power Apps

```
ThisItem.'First Name' & " " & ThisItem.'Last Name'
```

ThisRecord operator

ThisRecord is used in functions that have a record scope. For example, we can use the **Filter** function with our gallery's **Items** property to only show first names that being with *M*:

Power Apps

```
Filter( Employees, StartsWith( ThisRecord.Employee.'First Name', "M" ) )
```

ThisRecord is optional and implied by using the fields directly, for example, in this case, we could have written:

Power Apps

```
Filter( Employees, StartsWith( 'First Name', "M" ) )
```

Although optional, using **ThisRecord** can make formulas easier to understand and may be required in ambiguous situations where a field name may also be a relationship name. **ThisRecord** is optional while **ThisItem** is always required.

Use **ThisRecord** to reference the whole record with **Patch**, **Collect**, and other record scope functions. For example, the following formula sets the status for all inactive employees to active:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees,
              Patch( Employees, ThisRecord, { Status: 'Status
(Employees)'.Active } ) ) )
```

As operator

Use the **As** operator to name a record in a gallery or record scope function, overriding the default **ThisItem** or **ThisRecord**. Naming the record can make your formulas easier to understand and may be required in nested situations to access records in other scopes.

For example, you can modify the **Items** property of our gallery to use **As** to identify that we are working with an Employee:

Power Apps

```
Employees As Employee
```

The formulas for the picture and name are adjusted to use this name for the current record:

Power Apps

```
Employee.Picture
```

Power Apps

```
Employee.'First Name' & " " & Employee.'Last Name'
```

As can also be used with record scope functions to replace the default name **ThisRecord**. We can apply this to our previous example to clarify the record we're working with:

Power Apps

```
With( { InactiveEmployees: Filter( Employees, Status = 'Status
(Employees)'.Inactive ) },
      ForAll( InactiveEmployees As Employee,
              Patch( Employees, Employee, { Status: 'Status
(Employees)'.Active } ) ) )
```

When nesting galleries and record scope functions, **ThisItem** and **ThisRecord** always refers to the inner most scope, leaving records in outer scopes unavailable. Use **As** to make all record scopes available by giving each a unique name.

For example, this formula produces a chessboard pattern as a text string by nesting two **ForAll** functions:

Power Apps

```
Concat(
    ForAll( Sequence(8) As Rank,
        Concat(
            ForAll( Sequence(8) As File,
                    If( Mod(Rank.Value + File.Value, 2) = 1, " X ", " . " )
            ),
            Value
        ) & Char(10)
    ),
    Value
)
```

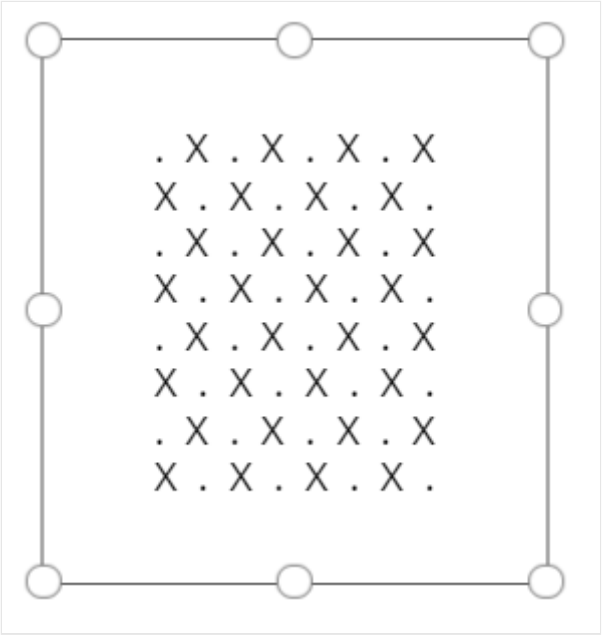
Setting a **Label** control's **Text** property to this formula displays:



Let's unpack what is happening here:

- We start by iterating an unnamed table of 8 numbered records from the Sequence function. This loop is for each row of the board, which is commonly referred to as **Rank** and so we give it this name.
- For each row, we iterate another unnamed table of 8 columns, and we give the common name **File**.
- If **Rank.Value** + **File.Value** is an odd number, the square gets an **X**, otherwise a dot. This part of the formula is referencing both **ForAll** loops, made possible by using the **As** operator.
- Concat is used twice, first to assemble the columns and then the rows, with a Char(10) thrown in to create a new line.

A similar example is possible with nested **Gallery** controls instead of **ForAll** functions. Let's start with the vertical gallery for the **Rank**. This gallery control will have an **Items** formula of:

Power Apps

```
Sequence(8) as Rank
```

Within this gallery, we'll place a horizontal gallery for the **File**, that will be replicated for each **Rank**, with an **Items** property of:

Power Apps

```
Sequence(8) as File
```

And finally, within this gallery, we'll add a **Label** control that will be replicated for each **File** and each **Rank**. We'll size it to fill the entire space and use the **Fill** property to provide the color with this formula:

Power Apps

```
If( Mod( Rank.Value + File.Value, 2 ) = 1, Green, Beige )
```

Self and Parent operators

There are three ways to refer to a control and its properties within a formula:

Expand table

Method	Description
By control name	Any control can be referenced by name from anywhere within the app. For example, **Label1.Fill** refers to the fill property of the control who's name is **Label1**.
Self operator	It's often convenient to reference another property of the same control when writing a formula. Instead of using an absolute reference by name, it's easier and more portable to use a relative reference to one*self*. The **Self** operator provides that easy access to the current control. For example, **Self.Fill** refers to the fill color of the current control.

Method	Description
Parent operator	Some controls host other controls, such as the **Screen** and **Gallery** controls. The hosting control of the controls within it's called the *parent*. Like the **Self** operator, the **Parent** operator provides an easy relative reference to the container control. For example, **Parent.Fill** refers to the fill property of the control that is the container for the current control.

Self and **Parent** are operators and not properties on the controls themselves. Referring to **Parent.Parent**, **Self.Parent** or **Parent.Self** is not supported.

Identifier names

The names of variables, data sources, columns, and other objects can contain any Unicode.

Use single quotes around a name that contains a space or other special character. Use two single quotes together to represent one single quote in the name. Names that don't contain special characters don't require single quotes.

Here are some example column names you might encounter in a table, and how they're represented in a formula:

Expand table

Column name in a database	Column reference in a formula
SimpleName	`SimpleName`
NameWith123Numbers	`NameWith123Numbers`
Name with spaces	`'Name with spaces'`
Name with "double" quotes	`'Name with "double" quotes'`
Name with 'single' quotes	`'Name with ''single'' quotes'`
Name with an @ at sign	`'Name with an @ at sign'`

Double quotes are used to designate text strings.

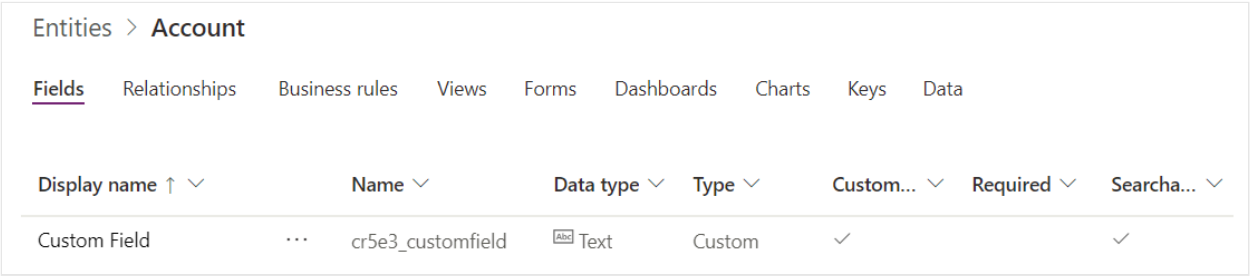
Display names and logical names

Some data sources such as SharePoint and Microsoft Dataverse have two different names to refer to the same table or column of data:

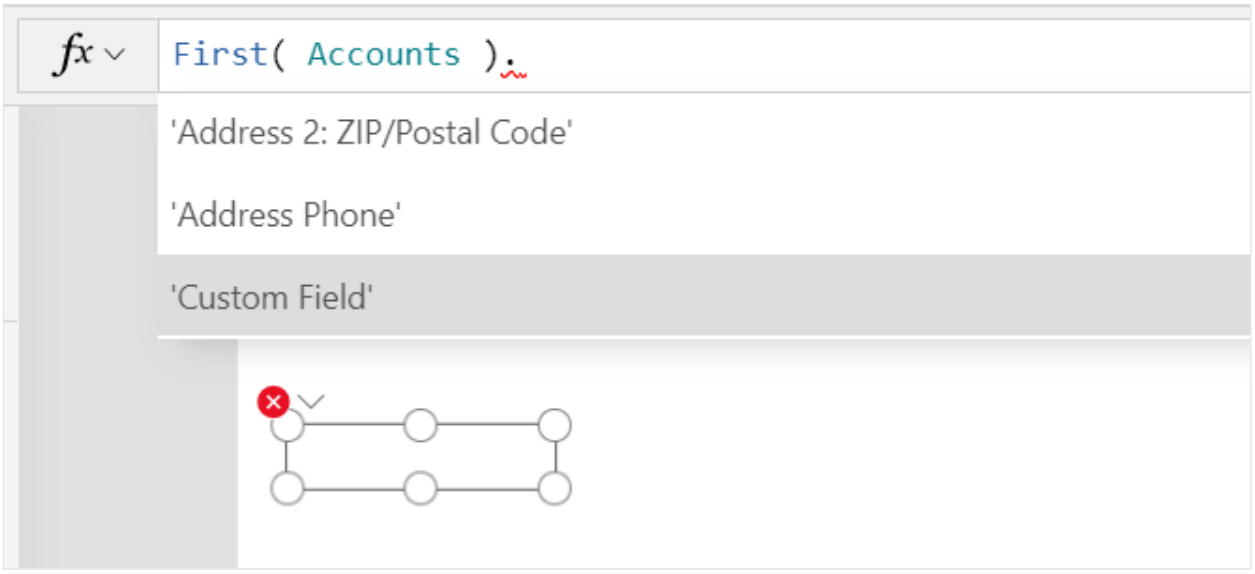
- **Logical name** - A name that is guaranteed to be unique, doesn't change after being created, usually doesn't allow spaces or other special characters, and isn't localized into different languages. As a result, the name can be cryptic. These names are used by professional developers. For example, **cra3a_customfield**. This name may also be referred to as **schema name** or just **name**.
- **Display name** - A name that is user-friendly and intended to be seen by end users. This name may not be unique, may change over time, may contain spaces and any Unicode character, and may be localized into different languages. Corresponding to the example above, the display name may be **Custom Field** with space in between the words.

Since display names are easier to understand, Canvas apps will suggest them as choices and not suggest logical names. Although logical names aren't suggested, they can still be used if typed indirectly.

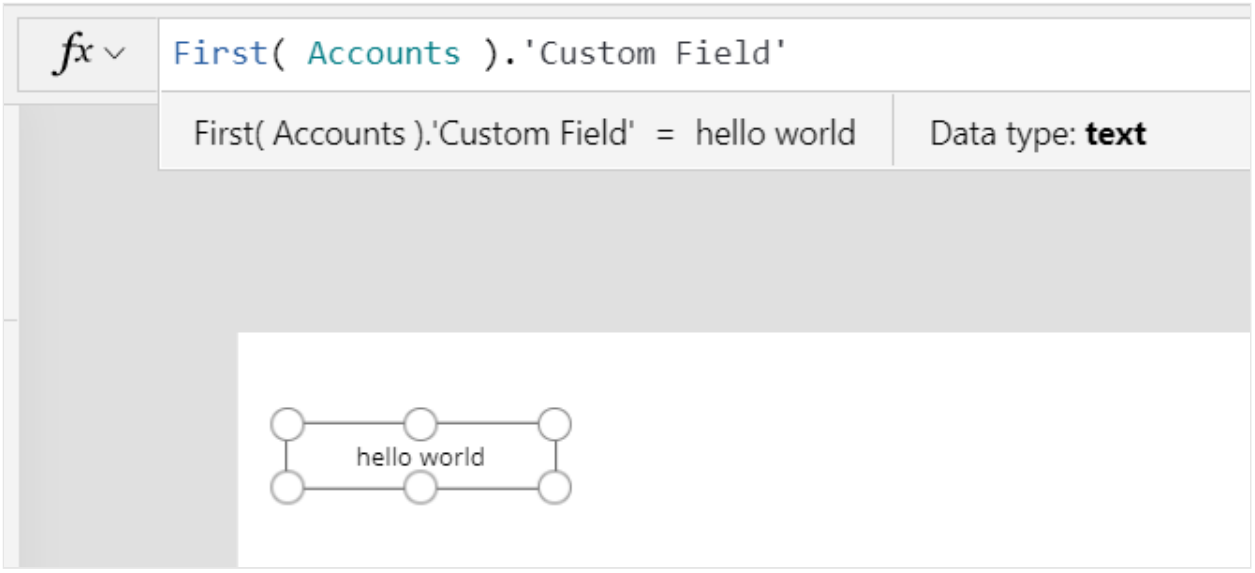
For example, imagine you've added a **Custom Field** to a table in Dataverse. A logical name will be assigned for you by the system, which you can modify only when creating the field. The result would look similar to:



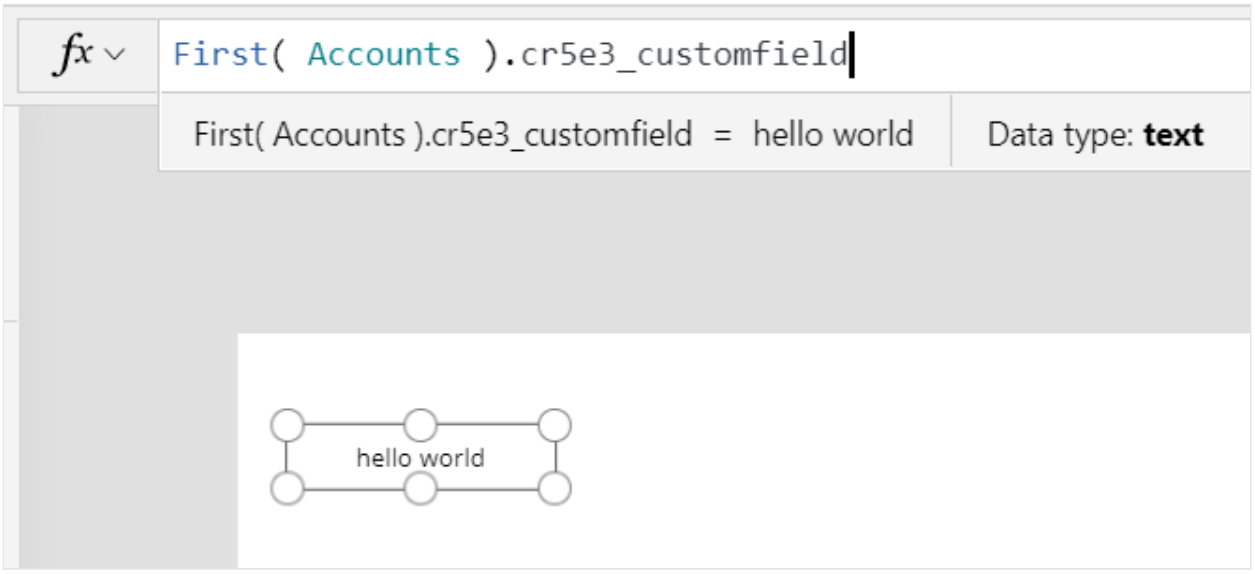
When authoring a reference to a field of Accounts, the suggestion will be made to use '**Custom Field**' since this is the display name. Single quotes must be used because this name has a space in it:



After selecting the suggestion, 'Custom Field' is shown in the formula bar and the data is retrieved:



Although it isn't suggested, we could also use the logical name for this field. This will result in the same data being retrieved. Single quotes are not required since this name doesn't contain spaces or special characters:

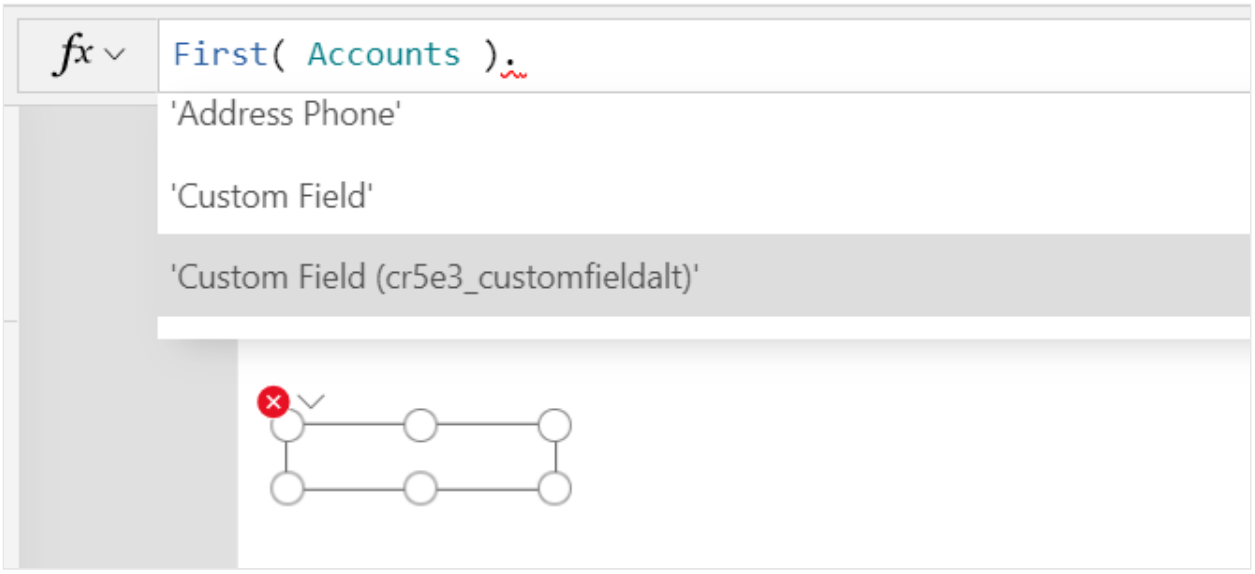


Behind the scenes, a mapping is maintained between the display names seen in formulas and the underlying logical names. Since logical names must be used to interact with the data source, this mapping is used to convert from the current display name to the logical name automatically and that is what is seen in the network traffic. This mapping is also used to convert back to logical names to switch into new display names, for example, if a display name changes or a maker in a different language edits the app.

> **Note**
>
> Logical names are not translated when moving an app between environments. For Dataverse system table and field names, this should not be a problem as logical names are consistent across environments. But any custom fields, such as **cra3a_customfield** in this example above, may have a different environment prefix (**cra3a** in this case). Display names are preferred as they can be matched against display names in the new environment.

Name disambiguation

Since display names aren't unique, the same display name may appear more than once in the same table. When this happens, the logical name will be added to the end of the display name in parentheses for one of more of the conflicting names. Building on the example above, if there was a second field with the same display name of **Custom Field** with a logical name of **cra3a_customfieldalt** then the suggestions would show:



Name disambiguation strings are added in other situations where name conflicts occur, such as the names of table, choices, and other Dataverse items.

Disambiguation operator

Some functions create record scopes for accessing the fields of table while processing each record, such as **Filter**, **AddColumns**, and **Sum**. Field names added with the record scope override the same names from elsewhere in the app. When this happens, you can still access values from outside the record scope with the @ disambiguation operator:

- To access values from nested record scopes, use the @ operator with the name of the table being operated upon using this pattern:
  Table[@*FieldName*]
- To access global values, such as data sources, collections, and context variables, use the pattern [@*ObjectName*] (without a table designation).

For more information and examples, see record scopes.

Date, DateTime, and Time functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Converts date and time components to a date/time value.

Description

The **Date** function converts individual Year, Month, and Day values to a Date/Time value. The time portion is midnight.

- If Year is between 0 and 1899 (inclusive), the function adds that value to 1900 to calculate the year. **70** becomes **1970**.
- If Month is less than 1 or more than 12, the result subtracts or adds that many months from the beginning of the specified year.
- If Day is greater than the number of days in the specified month, the function adds that many days to the first day of the month and returns the corresponding date from a subsequent month. If Day is less than 1, the function subtracts that many days, plus 1, from the first day of the specified month.

The **Time** function converts individual Hour, Minute, Second, and optionally Millisecond values to a Date/Time value. The result has no date associated with it.

The **DateTime** function combines the **Date** and **Time** functions into a single function, taking both date and time arguments and returning a Date/Time value that has both date and time components.

See the **DateValue**, **TimeValue**, and **DateTimeValue** functions for information about how to convert a string to a value.

Also see working with dates and times for more information.

Syntax

Date(*Year*, *Month*, *Day*)

- *Year* - Required. Numbers greater than 1899 are interpreted as absolute (1980 is interpreted as 1980); numbers that range from 0 to 1899 are interpreted as relative to 1900. (For example, 80 is interpreted as 1980.)

- *Month* - Required. A number that ranges from 1 to 12.
- *Day* - Required. A number that ranges from 1 to 31.

Time(*Hour*, *Minute*, *Second* [, *Milliseconds*])

- *Hour* - Required. Number of hours, usually in the range 0 (12:00 AM) to 23 (11:00 PM).
- *Minute* - Required. Number of minutes, usually in the range 0 to 59.
- *Second* - Required. Number of seconds, usually in the range 0 to 59.
- *Milliseconds* - Optional. Number of milliseconds, usually in the range 0 to 999.

DateTime(*Year*, *Month*, *Day*, *Hour*, *Minute*, *Second* [, *Milliseconds*])

- *Year* - Required. Numbers greater than 1899 are interpreted as absolute (1980 is interpreted as 1980); numbers that range from 0 to 1899 are interpreted as relative to 1900. (For example, 80 is interpreted as 1980.)
- *Month* - Required. A number that ranges from 1 to 12.
- *Day* - Required. A number that ranges from 1 to 31.
- *Hour* - Required. Number of hours, usually in the range 0 (12:00 AM) to 23 (11:00 PM)
- *Minute* - Required. Number of minutes, usually in the range 0 to 59.
- *Second* - Required. Number of seconds, usually in the range 0 to 59.
- *Milliseconds* - Optional. Number of milliseconds, usually in the range 0 to 999.

Examples

Date

If a user typed

- **1979** in a text-input control named **HireYear**
- **3** in a text-input control named **HireMonth**
- **17** in a text-input control named **HireDay**

this formula would return `3/17/1979`:

Power Apps

```
Date( Value(HireYear.Text), Value(HireMonth.Text), Value(HireDay.Text) )
```

Time

If a user typed

- **14** in a text-input control named **BirthHour**
- **50** in a text-input control named **BirthMinute**
- **24** in a text-input control named **BirthSecond**

this formula would return `02:50:24 P`:

Power Apps

```
Text(
    Time(Value(BirthHour.Text), Value(BirthMinute.Text),
Value(BirthSecond.Text)),
    "hh:mm:ss A/P"
)
```

DateTime

If a user typed

- **2023** in a text-input control named **EclipseYear**
- **10** in a text-input control named **EclipseMonth**
- **28** in a text-input control named **EclipseDate**
- **13** in a text-input control named **EclipseHour**
- **14** in a text-input control named **EclipseMinute**
- **5** in a text-input control named **EclipseSecond**
- **231** in a text-input control named **EclipseMillisecond**

this formula would return `10/28/23 01:14:05.231 PM`:

Power Apps

```
Text(
    DateTime(Value(EclipseYear.Text), Value(EclipseMonth.Text),
Value(EclipseDate.Text),
        Value(EclipseHour.Text), Value(EclipseMinute.Text),
        Value(EclipseSecond.Text), Value(EclipseSecond.Millisecond)
    ),
    "yy/mm/dd hh:mm:ss.000 AM/PM"
)
```

DateValue, TimeValue, and DateTimeValue functions

06/19/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Converts date, time, or both in a *string* to a *date/time* value.

Description

- **DateValue** function converts a *date string* (like "10/01/2014") to a *date/time* value.
- **TimeValue** function converts a *time string* (like "12:15 PM") to a *date/time* value.
- **DateTimeValue** function converts a *date and time string* (like "January 10, 2013 12:13 AM") to a *date/time* value.

DateValue function ignores any time information in the date string, and **TimeValue** function ignores any date information in the time string.

> ⓘ **Note**
>
> The DateValue, TimeValue, and DateTimeValue functions by default use the language from the current user's settings. You can override it to ensure that strings are interpreted properly. For example, "10/1/1920" is interpreted as *October 1st* in "*en*" and as *January 10th* in "*fr*".

Dates must use one of these formats:

- MM/DD/YYYY or MM-DD-YYYY
- DD/MM/YYYY or DD-MM-YYYY
- YYYY/MM/DD or YYYY-MM-DD
- MM/DD/YY or MM-DD-YY
- DD/MM/YY or DD-MM-YY
- DD Mon YYYY
- Month DD, YYYY

To convert from numeric date, month and year components, read Date.
To convert from numeric hour, minute and second components, read Time.

For more information, see:

- Working with date and time
- Date/time and data types

Syntax

DateValue(*String* [, *Language*])
DateTimeValue(*String* [, *Language*])
TimeValue(*String* [, *Language*])

- *String* - Required. A text string that contains a date, time, or combination date and time value.
- *Language* - Optional. A language string, such as would be returned by the first two characters from the Language function. If not provided, the language of the current user's settings is used.

DateValue(*Dynamic*)
DateTimeValue(*Dynamic*)
TimeValue(*Dynamic*)

- *Dynamic* - Required. **Dynamic** value that represents a date or time. Acceptable values are dependent on the untyped provider. For **JSON**, the dynamic value is expected to be a JSON string that contains a date and time in ISO 8601 format. Dates or times in other formats will result in an error. Consider converting such values to **Text** first, then to a date or time. Keep in mind that time zones and locale-related formats are important considerations when communicating with external systems.

Examples

DateValue

If you type **10/11/2014** into a text-input control named **Startdate**, and then set the Text property of a label to these formulas:

- Convert a date from a string in the user's locale and show the result as a long date.

  Power Fx

  ```
  Text( DateValue( Startdate.Text ), DateTimeFormat.LongDate )
  ```

  Device set to **en** locale shows the label as **Saturday, October 11, 2014**.

> **Note**
>
> You can use several options with the **DateTimeFormat** enum. To display a list of options, type the parameter followed by a dot or period (.) in the formula bar or check Text function reference.

- Convert date from a string in the French locale and show the result as a long date. In this example, the months and day of the month are interpreted differently from English.

  ```
  Power Fx
  Text( DateValue( Startdate.Text, "fr" ), DateTimeFormat.LongDate )
  ```

  Device set to **en** locale shows the label as **Monday, November 10, 2014**.

If you enter **October 20, 2014** instead:

- Convert a date from a string in the user's locale and calculate the difference between two days, in days

  ```
  Power Fx
  DateDiff( DateValue( Startdate.Text ), Today() )
  ```

  Device set to **en** locale shows the label as **9**, indicating the number of days between October 11 and October 20. The DateDiff function can also show the difference in months, quarters, or years.

DateTimeValue

If you typed **10/11/2014 1:50:24.765 PM** into a text-input control named **Start**, and then set the Text property of a label to the following formula:

- Convert both a date and time string in the current locale.

  ```
  Power Fx
  Text( DateTimeValue( Start.Text ), DateTimeFormat.LongDateTime )
  ```

  Device set to **en** locale shows the label as **Saturday, October 11, 2014 1:50:24 PM**.

> **Note**

You can use several options with the **DateTimeFormat** enum. To display a list of options, type the parameter followed by a dot or period (.) in the formula bar or check Text function reference.

- Convert both a date and time string in the French locale. Month and day of the month are interpreted differently.

  Power Fx

  ```
  Text( DateTimeValue( Start.Text, "fr"), DateTimeFormat.LongDateTime )
  ```

  Device set to **en** locale shows the label as **Monday, November 10, 2014 1:50:24 PM**.

- Convert both a date and time string in the user's locale, and display the result with a fractional second.

  Power Fx

  ```
  Text( DateTimeValue( Start.Text ), "dddd, mmmm dd, yyyy hh:mm:ss.fff AM/PM" )
  ```

  Device set to **en** locale shows the label as **Saturday, October 11, 2014 01:50:24.765 PM**.

  As an alternative, you can specify **hh:mm:ss.f** or **hh:mm:ss.ff** to round the time to the nearest 10th or 100th of a second.

TimeValue

Name a text-input control **FinishedAt**, and set the Text property of a label to this formula:

Power Fx

```
If( TimeValue( FinishedAt.Text ) < TimeValue( "5:00:00.000 PM" ),
    "You made it!",
    "Too late!"
)
```

- If you type **4:59:59.999 PM** in the **FinishedAt** control, the label shows "*You made it!*"
- If you type **5:00:00.000 PM** in the **FinishedAt** control, the label shows "*Too late!*"

DateAdd, DateDiff, and TimeZoneOffset functions

Article • 04/20/2025

Expand table

Functions	Applies to
DateAdd **DateDiff**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
TimeZoneOffset	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Expand table

Function	Applies to
DateAdd	
DateDiff	
TimeZoneOffset	

Adds to or finds the difference in date/time values and converts between local time and UTC.

Description

The **DateAdd** function adds a number of units to a date/time value. The result is a new date/time value. You can also subtract a number of units from a date/time value by specifying a negative value.

The **DateDiff** function returns the difference between two date/time values. The result is a whole number of units.

For both functions, units can be **TimeUnit.Milliseconds**, **TimeUnit.Seconds**, **TimeUnit.Minutes**, **TimeUnit.Hours**, **TimeUnit.Days**, **TimeUnit.Months**, **TimeUnit.Quarters**, or **TimeUnit.Years**. By default, both functions use **TimeUnit.Days** as units.

The **TimeZoneOffset** function returns the number of minutes between the user's local time and UTC (Coordinated Universal Time).

You can use **DateAdd** with the **TimeZoneOffset** to convert between the user's local time and UTC (Coordinated Universal Time). Adding **TimeZoneOffset** will convert a local time to UTC, and subtracting it (adding the negative) will convert from UTC to local time.

Also see Date, Time, and DateTime data types and working with dates and times for more information.

Syntax

DateAdd(*DateTime*, *Addition* [, *Units*])

- *DateTime* - Required. Date/time value to operate on.
- *Addition* - Required. Number, in *Units*, to add to the *DateTime*.
- *Units* - Optional. The type of *Units* to add: **TimeUnit.Milliseconds**, **TimeUnit.Seconds**, **TimeUnit.Minutes**, **TimeUnit.Hours**, **TimeUnit.Days**, **TimeUnit.Months**, **TimeUnit.Quarters**, or **TimeUnit.Years**. If not specified, **TimeUnit.Days** are used.

DateDiff(*StartDateTime*, *EndDateTime* [, *Units*])

- *StartDateTime* - Required. Starting date/time value.
- *EndDateTime* - Required. Ending date/time value.
- *Units* - Optional. The type of *Units* to subtract: **TimeUnit.Milliseconds**, **TimeUnit.Seconds**, **TimeUnit.Minutes**, **TimeUnit.Hours**, **TimeUnit.Days**, **TimeUnit.Months**, **TimeUnit.Quarters**, or **TimeUnit.Years**. If not specified, **TimeUnit.Days** are used.

TimeZoneOffset([*DateTime*])

- *DateTime* - Optional. Date/time value for which to return the offset. By default, the current date/time is used.

Examples

In all of these examples, assume that the current date and time is **July 15, 2013, 1:02 PM**.

Simple DateAdd

Expand table

Formula	Description	Result
Text(DateAdd(Now(), 3), "dd-mm-yyyy hh:mm")	Adds three days (default units) to the current date and time.	"18-07-2013 13:02"

Formula	Description	Result
Text(DateAdd(Now(), 4, TimeUnit.Hours), "dd-mm-yyyy hh:mm")	Add four hours to the current date and time.	"15-07-2013 17:02"
Text(DateAdd(Today(), 1, TimeUnit.Months), "dd-mm-yyyy hh:mm")	Adds one month to the current date, without time as **Today** doesn't return a time component.	"15-08-2013 00:00"
Text(DateAdd(Now(), -30, TimeUnit.Minutes), "dd-mm-yyyy hh:mm")	Subtracts 30 minutes from the current date and time.	"15-07-2013 12:32"

Simple DateDiff

Expand table

Formula	Description	Result
DateDiff(Now(), DateValue("1/1/2014"))	Returns the difference between the two units in the default units of **TimeUnit.Days**	170
DateDiff(Now(), DateValue("1/1/2014"), TimeUnit.Months)	Returns the difference between the two values in **TimeUnit.Months**	6
DateDiff(Now(), Today(), TimeUnit.Minutes)	Returns the difference between the current date/time and the current date only (no time) in minutes. Since the **Now** is later than **Today** the result will be negative.	-782

Difference of dates with fractional results

The function DateDiff only returns a whole number of the units being subtracted, and the precision is given in the unit specified. To calculate the difference with a higher precision, use a smaller unit, and convert the result appropriately, like in the examples below.

Expand table

Formula	Description	Result
DateDiff(TimeValue("09:45:00"), TimeValue("10:15:36"), TimeUnit.Hours)	The minutes/seconds are ignored, the difference is based on the time up to the hour.	1
DateDiff(TimeValue("09:45:00"), TimeValue("10:15:36"), TimeUnit.Minutes	The minutes are used in the difference, and the result is divided by 60 to have the difference in	0.5

Formula	Description	Result
)/60	hours.	
DateDiff(TimeValue("09:45:00"), TimeValue("10:15:36"), TimeUnit.Seconds)/3600	The minutes and seconds are used in the difference; the result is divided by 3600 to have the difference in hours.	0.51

Converting to UTC

To convert to UTC (Coordinated Universal Time), add the **TimeZoneOffset** for the given time.

For example, imagine the current date and time is **July 15, 2013, 1:02 PM** in Pacific Daylight Time (PDT, UTC-7). To determine the current time in UTC, use:

- **DateAdd(Now(), TimeZoneOffset(), TimeUnit.Minutes)**

TimeZoneOffset defaults to the current time, so you don't need to pass it an argument.

To see the result, use the **Text** function with the format *dd-mm-yyyy hh:mm*, which will return **15-07-2013 20:02**.

Converting from UTC

To convert from UTC, subtract the **TimeZoneOffset** (by adding the negative) for the given time.

For example, imagine the UTC date and time **July 15, 2013, 8:02 PM** is stored in a variable named **StartTime**. To adjust the time for the user's time zone, use:

- **DateAdd(StartTime, -TimeZoneOffset(StartTime), TimeUnit.Minutes)**

Note the negative sign before **TimeZoneOffset** to subtract the offset rather than add it.

To see the result, use the **Text** function with the format *dd-mm-yyyy hh:mm*, which will result in **15-07-2013 13:02** if you're in Pacific Daylight Time.

Now, Today, IsToday, UTCNow, UTCToday, IsUTCToday functions

Article • 04/20/2025

Expand table

Functions	Applies to
Now	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Today **IsToday**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
UTCNow **UTCToday**	✅ Dataverse formula columns ✅ Power Pages

Returns the current date and time, and tests whether a date/time value is today.

> ⓘ Note
>
> PAC CLI pac power-fx commands do not support the **UTCNow**, **UTCToday**, and **IsUTCToday** functions.

Description

The **Now** function returns the current date and time as a date/time value.

The **Today** function returns the current date as a date/time value. The time portion is midnight. **Today** has the same value throughout a day, from midnight today to midnight tomorrow.

The **IsToday** function tests whether a date/time value is between midnight today and midnight tomorrow. This function returns a Boolean (**true** or **false**) value.

Now, **Today**, and **IsToday** functions work with the local time of the current user.

UTCNow, **UTCToday**, and **IsUTCToday** functions are the same as their non-UTC counterparts but work with time zone independent values and use Coordinated Universal Time (UTC).

> ⓘ Note

- **UTCNow**, **UTCToday**, and **IsUTCToday** are only available in Microsoft Dataverse for Teams formula columns, and only for time-independent fields and values.
- **Now**, **Today**, and **IsToday** are not available in Dataverse for Teams formula columns as evaluations are done without the knowledge of the current user's local time zone. More information: Work with formula table columns in Dataverse for Teams

See Date, Time, and DateTime in the data types documentation and working with dates and times for more information.

Volatile Functions

Now, **Today**, **UTCNow**, and **UTCToday** are volatile functions. These functions return a different value for each evaluation.

When used in a data flow formula, a volatile function will only return a different value if the formula in which it appears is reevaluated. If nothing else changes in the formula then it will have the same value throughout the execution of your app.

For example, a label control with **Label1.Text = Now()** will not change while your app is active. Only closing and reopening the app will result in a new value.

The function will be reevaluated if it is part of a formula in which something else has changed. For example, if we change our example to involve a slider control with **Label1.Text = DateAdd(Now(), Slider1.Value, Minutes)** then the current time is retrieved each time the Slider control's value changes and the label's text property is reevaluated.

When used in a behavior formula, volatile functions will be evaluated each time the behavior formula is evaluated. See below for an example.

Syntax

Using the user's local time

Now()

Today()

IsToday(*DateTime*)

- *DateTime* - Required. The date/time value to test.

Using Coordinated Universal Time (UTC)

UTCNow()

UTCToday()

IsUTCToday(*TimeZoneIndependentTime*)

- *TimeZoneIndependentDateTime* - Required. The time zone independent date/time value to test.

Examples

For the examples in this section, the current time is **8:58 PM** on **July 11, 2021** in the Pacific Time Zone (UTC-8) and the language is **en-us**.

Expand table

Formula	Description	Result
Text(Now(), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date and time in the user's time zone, and displays it as a string.	"07/11/2021 20:58:00"
Text(Today(), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date only, leaving the time portion as midnight, and displays it as a string.	"07/12/2021 00:00:00"
IsToday(Now())	Tests whether the current date and time is between midnight today and midnight tomorrow.	**true**
IsToday(Today())	Tests whether the current date is between midnight today and midnight tomorrow.	**true**
Text(DateAdd(Now(), 12), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date and time, adds 12 days to the result, and displays it as a string.	"07/23/2021 20:58:00"
Text(DateAdd(Today(), 12), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date, adds 12 days to the result, and displays it as a string.	"07/23/2021 00:00:00"
IsToday(DateAdd(Now(), 12))	Tests whether the current date and time, plus 12 days, is between midnight today and midnight tomorrow.	**false**
IsToday(DateAdd(Today(), 12))	Tests whether the current date, plus 12 days, is between midnight today and midnight tomorrow.	**false**
Hour(UTCNow())	Retrieves the current date and time in UTC and extracts the hour only, which is 8 hours ahead of local time.	4

Formula	Description	Result
Day(UTCToday())	Retrieves the current date only in UTC and extracts the day, which is 1 day ahead of local time.	12
IsUTCToday(UTCNow())	Tests whether the current date and time is between midnight today and midnight tomorrow, all in UTC time.	**true**
IsUTCToday(UTCToday())	Tests whether the current date is between midnight today and midnight tomorrow, all in UTC time.	**true**

Display a clock that updates in real time

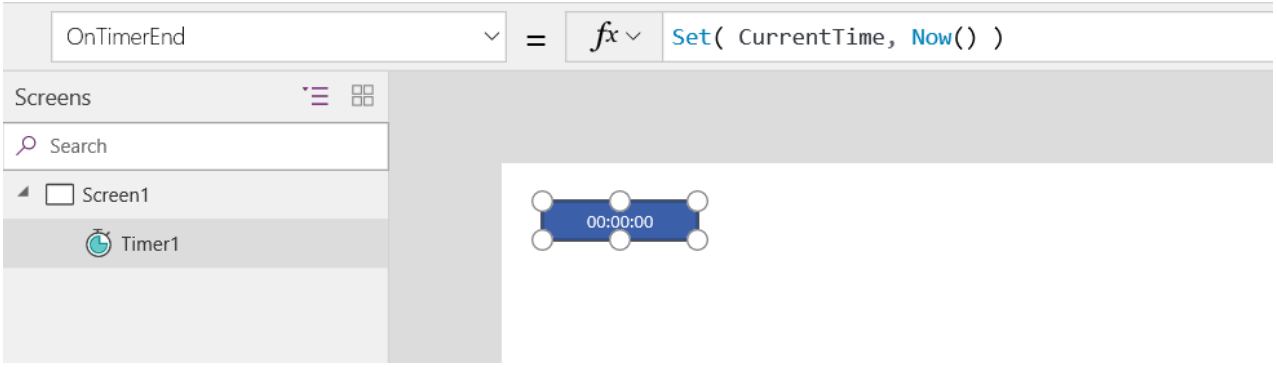
1. Add a Timer control, set its **Duration** property to **1000**, and set its **Repeat** property to **true**.

   The timer will run for one second, automatically start over, and continue that pattern.

2. Set the control's **OnTimerEnd** property to this formula:

   Set(CurrentTime, Now())

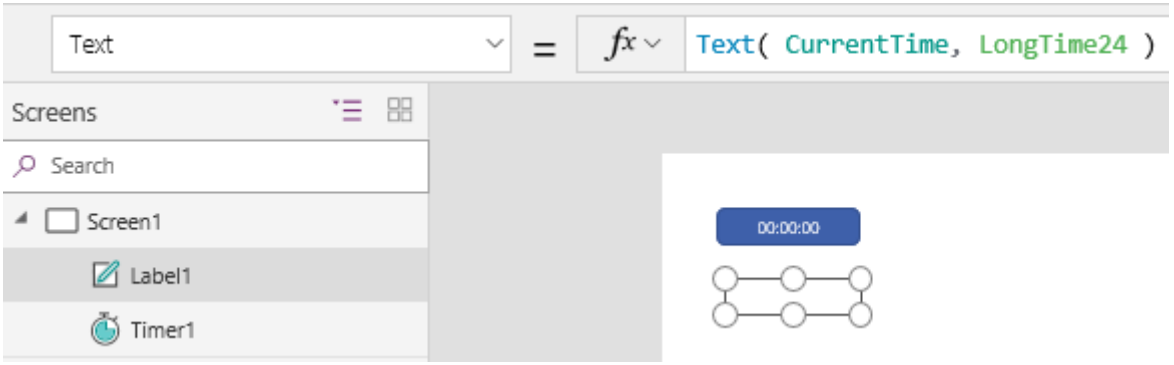
   Whenever the timer starts over (after each second), this formula sets the **CurrentTime** global variable to the current value of the **Now** function.

3. Add a Label control, and set its **Text** property to this formula:

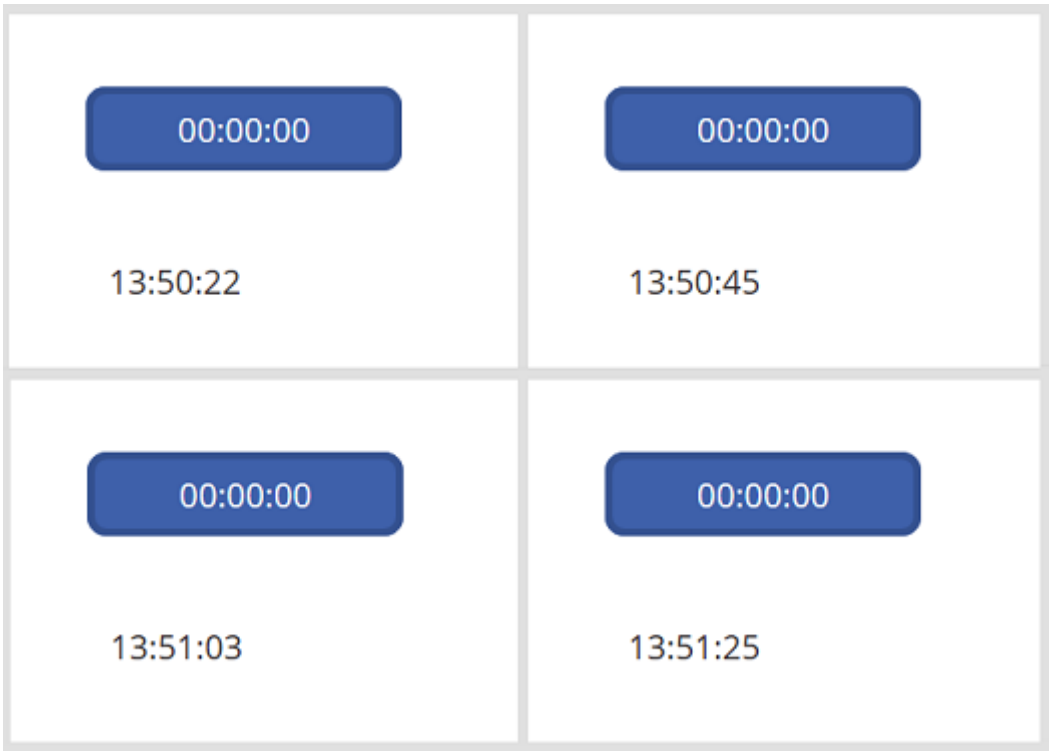
   Text(CurrentTime, LongTime24)

   Use the Text function to format the date and time however you want, or set this property to just **CurrentTime** to show hours and minutes but not seconds.



4. Preview the app by pressing F5, and then start the timer by clicking or tapping it.

   The label continually shows the current time, down to the second.



5. Set the timer's **AutoStart** property to **true** and its **Visible** property to **false**.

   The timer is invisible and starts automatically.

6. Set the screen's OnStart property so that the **CurrentTime** variable has a valid value, as in this example:

   Set(CurrentTime, Now())

   The label appears as soon as the app starts (before the timer runs for a full second).

Trace function

Applies to: ✅ Canvas apps ✅ Copilot Studio ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions

Often there is a lot of logic working behind the scenes in an app. Sometimes the impact is obvious, for example, a control's value or color changes, confirming the logic operated correctly. However, sometimes it isn't obvious and it can be difficult to visualize and understand what is happening inside the app. Use the **Trace** function to record diagnostic information from behind the scenes, creating a timeline of what actually happened, to better understand how your app is operating and to help debug issues.

When used in Power Apps, the output from **Trace** appears in the Power Apps Live Monitor tool along with other app activities. If you allowed your app to send telemetry data to Azure Application Insights, the **Trace** function can also be used to send information to your Application Insights resource. **Trace** can only be used in behavior formulas - to trace values from data properties, you need to use alternatives such as debug buttons.

When used with Test Studio, **Trace** is an optional expression that can be used to provide additional information in your test results from the **OnTestCaseComplete** event. **Trace** event messages are combined with passed and failed assertion messages in the **Traces** table of the **TestCaseResult** record. The **Traces** table has two properties, **Message** and **Timestamp**. Trace information used in tests will also be recorded in Application Insights. Test trace information isn't be available in the Live Monitor tool as the Live Monitor is connected to the app when played from the Power Apps Studio.

Syntax

Trace(*Message* [, *TraceSeverity* [, *CustomRecord* [, *TraceOptions*]]])

- *Message* – Required. The information to be traced. Numbers, Dates, Booleans, and any other data type that can be coerced to Text.
- *TraceSeverity* – Optional. The severity level of the Trace recorded in Live Monitor and Application Insights. Options are **TraceSeverity.Information** (default), **TraceSeverity.Warning**, **TraceSeverity.Error**, or **TraceSeverity.Critical**.
- *CustomRecord* – Optional. A record containing custom data that is recorded in Live Monitor or Application Insights.
- *TraceOptions* – Optional. Options are **TraceOptions.None** (default) and **TraceOptions.IgnoreUnsupportedTypes** which ignores data types in *CustomRecord* that can't be serialized.

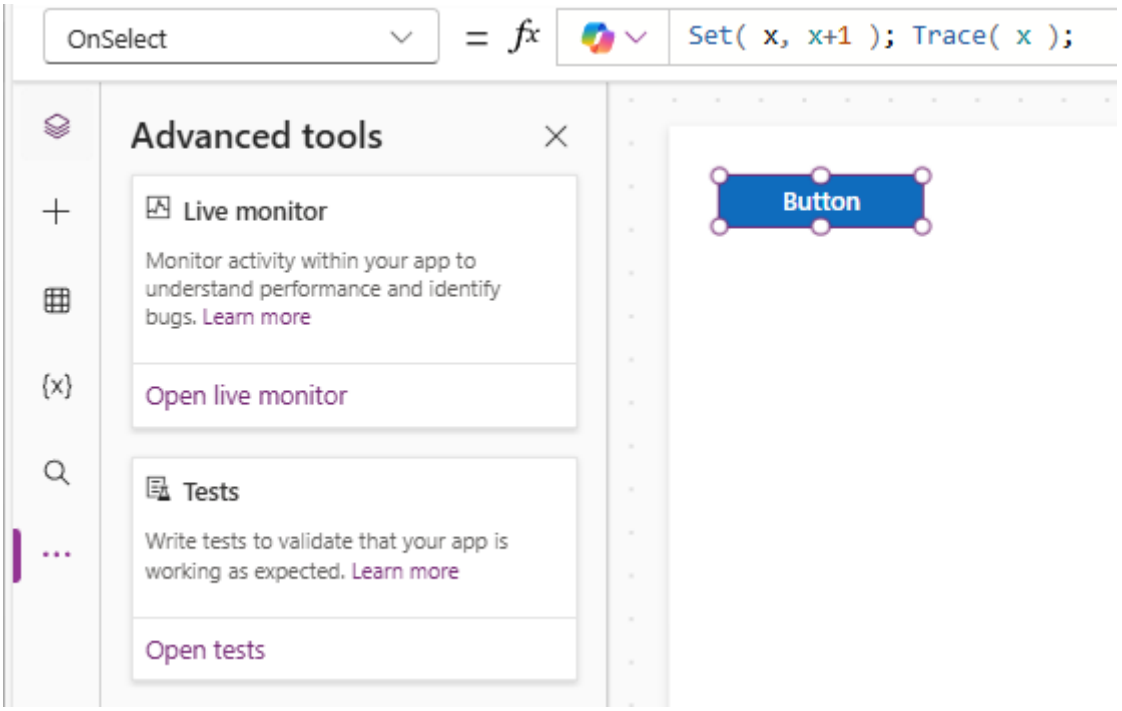
Example

1. Create a button control in Power Apps Studio.
2. Set the **OnSelect** formula to the formula:

Power Fx

```
Set( x, x+1 );
Trace( x );
```

3. Open the Power Apps Live Monitor in another browser window by selecting the "Advanced tools" icon in the left hand pane and select "Open live monitor":



4. Return to the original Studio browser window and select your button four times. Use **Alt-click** on your mouse if in design mode.
5. View the Power Apps Live Monitor.
6. The Live Monitor's grid will contain an event for each button click and for each **Trace** call, which will show the value of the variable after each increment. Drill into a Trace event to see where the **Trace** was initiated, and the expression used for the message, in the right

hand panel:

Trim and TrimEnds functions

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Dataverse formula columns ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Removes extra spaces from a string of text.

Description

The **Trim** function removes all spaces from a string of text except for single spaces between words.

The **TrimEnds** function removes all spaces from the start and end of a string of text but leaves spaces between words intact.

If you specify a single string of text, the return value for either function is the string with any extra spaces removed. If you specify a single-column table that contains strings, the return value is a single-column table of trimmed strings. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

By trimming spaces between words, **Trim** is consistent with the function of the same name in Microsoft Excel. However, **TrimEnds** is consistent with programming tools that trim spaces only from the start and end of each string.

Syntax

Trim(*String*)
TrimEnds(*String*)

- *String* - Required. The string of text to remove spaces from.

Trim(*SingleColumnTable*)
TrimEnds(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of strings to remove spaces from.

Example

Expand table

Formula	Description	Result
Trim(" Hello World ")	Removes all spaces from the start and end of a string and extra spaces from within the string.	"Hello World"
TrimEnds(" Hello World ")	Removes all spaces from the start and end of a string.	"Hello World"

The following examples use a single-column collection, named **Spaces**, that contains these strings:

Expand table

Value
" Jane Doe "
" Jack and Jill"
"Already trimmed"
" Venus, Earth, Mars "
"Oil and Water "

To create this collection, set the **OnSelect** property of a **Button** control to this formula, open Preview mode, and then click or tap the button:
ClearCollect(Spaces, [" Jane Doe ", " Jack and Jill", "Already trimmed", " Venus, Earth, Mars ", "Oil and Water "])

Expand table

Formula	Description	Result
Trim(Spaces)	Trims all spaces from the start and end of each string and extra spaces from within each string in the **Spaces** collection.	A single-column table with a `Value` column containing the following values: "Jane Doe", "Jack and Jill", "Already trimmed", "Venus, Earth, Mars", "Oil and Water"
TrimEnds(Spaces)	Trims all spaces from the start and end of each string in the **Spaces** collection.	A single-column table with a `Value` column containing the following values: "Jane Doe", "Jack and Jill", "Already trimmed", "Venus, Earth, Mars", "Oil and Water"

> **Note**
>
> Extra spaces don't appear if you display a collection by clicking or tapping **Collections** on the **File** menu. To verify string length, use the Len function.

Int, Round, RoundDown, RoundUp, and Trunc functions

Article • 04/20/2025

Applies to: ✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Rounds a number.

Round, RoundDown, and RoundUp

The **Round**, **RoundDown**, and **RoundUp** functions round a number to the specified number of decimal places:

- **Round** rounds up if the next digit is 5 or higher. Otherwise, this function rounds down.
- **RoundDown** always rounds down to the previous lower number, towards zero.
- **RoundUp** always rounds up to the next higher number, away from zero.

The number of decimal places can be specified for these functions:

Expand table

Decimal places	Description	Example
Greater than 0	The number is rounded to the right of the decimal separator.	`Round( 12.37, 1 )` returns 12.4.
0	The number is rounded to the nearest integer.	`Round( 12.37, 0 )` returns 12.
Less than 0	The number is rounded to the left of the decimal separator.	`Round( 12.37, -1 )` returns 10.

Int and Trunc

The **Int** and **Trunc** functions round a number to an integer (whole number without a decimal):

- **Int** rounds down to the nearest integer.
- **Trunc** truncates the number to just the integer portion by removing any decimal portion.

The difference between **Int** and **Trunc** is in the handling of negative numbers. For example, for an argument of `-4.3`, **Int** will return the integer further away from zero, `-5`, while **Trunc** will return the integer closer to zero, `-4`. **Int** returns values that are unique amongst the five rounding functions, while **Trunc** returns the same values as **RoundDown**.

Use **Trunc** to extract the decimal portion of a number by subtracting it from the original, for example `X - Trunc(X)`.

Decimal places cannot be specified with **Trunc** as it can with Microsoft Excel. Use **RoundDown** instead when this is needed.

Single-column tables

These functions support single-column tables. If you pass a single number, the return value is the rounded version of that number. If you pass a single-column table that contains numbers, the return value is a single-column table of rounded numbers. The *DecimalPlaces* parameter can be a single value or a single-column table. If the single-column table has less values that the *Number*, zero is used for the remaining values. Use **ShowColumns** and other table shaping functions to extract a single-column table from a larger table.

Syntax

Round(*Number*, *DecimalPlaces*)
RoundDown(*Number*, *DecimalPlaces*)
RoundUp(*Number*, *DecimalPlaces*)

- *Number* - Required. The number to round.
- *DecimalPlaces* - Required. Number of decimal places to round to. Use a positive value to indicate decimal places right of the decimal separator, a negative value to the left, and zero for a whole number.

Int(*Number*)
Trunc(*Number*)

- *Number* - Required. The number to be rounded to an integer.

Examples

Rounding to a whole number.

Expand table

X	Round(X, 0)	RoundUp(X, 0)	RoundDown(X, 0)	Int(X)	Trunc(X)
7.9	8	8	7	7	7
-7.9	-8	-8	-7	-8	-7
7.5	8	8	7	7	7
-7.5	-8	-8	-7	-8	-7
7.1	7	8	7	7	7
-7.1	-7	-8	-7	-8	-7

Rounding to two decimal places to the right of the decimal separator (0.01).

Expand table

X	Round(X, 2)	RoundUp(X, 2)	RoundDown(X, 2)
430.123	430.12	430.13	430.12
430.125	430.13	430.13	430.12
430.128	430.13	430.13	430.12

Rounding to two decimal places to the left of the decimal separator (100).

Expand table

X	Round(X, -2)	RoundUp(X, -2)	RoundDown(X, -2)
430.123	400	500	400
449.942	400	500	400
450.000	500	500	400
450.124	500	500	400
479.128	500	500	400

Rounding a single-column table of values.

Expand table

`X`	`Int( X )`	`Round( X, 2 )`	`RoundDown( X, [ 0, 1, 2 ] )`	`RoundUp( X, [ 2 ] )`
[123.456, 987.593, 542.639]	[123, 987, 542]	[123.46, 987.59, 542.64]	[123, 987.5, 542.63]	[123.46, 988, 543]

GroupBy and Ungroup functions

Article • 06/10/2024

Applies to: Canvas apps Model-driven apps Power Pages

Groups and ungroups records of a table.

Description

The **GroupBy** function returns a table with records grouped together based on the values in one or more columns. Records in the same group are placed into a single record, with a column added that holds a nested table of the remaining columns.

The **Ungroup** function reverses the **GroupBy** process. This function returns a table, breaking into separate records any records that were grouped together.

You can group records by using **GroupBy**, modify the table that it returns, and then ungroup records in the modified table by using **Ungroup**. For example, you can remove a group of records by following this approach:

- Use the **GroupBy** function.
- Use the **Filter** function to remove the entire group of records.
- Use the **Ungroup** function.

You can also aggregate results based on a grouping:

- Use the **GroupBy** function.
- Use the **AddColumns** function with **Sum**, **Average**, and other aggregate functions to add a new column, which is an aggregate of the group tables.
- Use the **DropColumns** function to drop the group table.

Ungroup tries to preserve the original order of the records that were fed to **GroupBy**. This isn't always possible (for example, if the original table contains *blank* records).

A table is a value in Power Apps, just like a string or a number. You can specify a table as an argument for a function, and a function can return a table. **GroupBy** and **Ungroup** don't modify a table; instead they take a table as an argument and return a different table. See working with tables for more details.

> **Note**

In Power Apps prior to version 3.24042, column names were specified with a text string using double quotes, and if connected to a data source they also needed to be logical names. For example, the logical name **"cr43e_name"** with double quotes was used instead of the display name **Name** without quotes. For SharePoint and Excel data sources that contain column names with spaces, each space was specified with **"_x0020_"**, for example **"Column Name"** as **"Column_x0020_Name"**. After this version, all apps were automatically updated to the new syntax described in this article.

Syntax

GroupBy(*Table*, *ColumnName1* [, *ColumnName2*, ...], *GroupColumnName*)

- *Table* - Required. Table to be grouped.
- *ColumnName(s)* - Required. The column names in *Table* by which to group records. These columns become columns in the resulting table.
- *GroupColumnName* - Required. The column name for the storage of record data not in the *ColumnName(s)*.

Ungroup(*Table*, *GroupColumnName*)

- *Table* - Required. Table to be ungrouped.
- *GroupColumnName* - Required. The column that contains the record data setup with the **GroupBy** function.

Examples

Create a collection

1. Add a button, and set its **Text** property so that the button shows **Original**.
2. Set the **OnSelect** property of the **Original** button to this formula:

Power Apps

```
ClearCollect( CityPopulations,
    { City: "London",    Country: "United Kingdom", Population: 8615000},
    { City: "Berlin",    Country: "Germany",        Population: 3562000},
    { City: "Madrid",    Country: "Spain",          Population: 3165000},
    { City: "Rome",      Country: "Italy",          Population: 2874000},
    { City: "Paris",     Country: "France",         Population: 2273000},
    { City: "Hamburg",   Country: "Germany",        Population: 1760000},
    { City: "Barcelona", Country: "Spain",          Population: 1602000},
    { City: "Munich",    Country: "Germany",        Population: 1494000},
```

```
    { City: "Milan",     Country: "Italy",          Population: 1344000}
)
```

3. While holding down the Alt key, select the **Original** button.

   You just created a collection, named **CityPopulations**, that contains this data:

City	Country	Population
"London"	"United Kingdom"	8,615,000
"Berlin"	"Germany"	3,562,000
"Madrid"	"Spain"	3,165,000
"Rome"	"Italy"	2,874,000
"Paris"	"France"	2,273,000
"Hamburg"	"Germany"	1,760,000
"Barcelona"	"Spain"	1,602,000
"Munich"	"Germany"	1,494,000
"Milan"	"Italy"	1,344,000

4. To display this collection, select **Collections** on the **File** menu and then select the **CityPopulations** collection. The first five records in the collection appear:

Group records

1. Add another button, and set its **Text** property to "**Group**".

2. Set the **OnSelect** property of this button to this formula:

ClearCollect(CitiesByCountry, GroupBy(CityPopulations, Country, Cities))

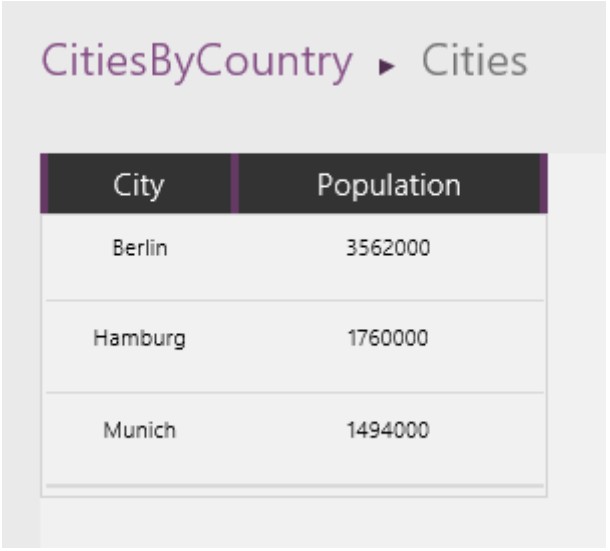
3. While holding down the Alt key, select the **Group** button.

   You just created a collection, named **CitiesByCountry**, in which the records of the previous collection are grouped by the **Country** column.

Cities	Country
City / **Population** "London" / 8,615,000	"United Kingdom"
City / **Population** "Berlin" / 3,562,000 "Hamburg" / 1,760,000 "Munich" / 1,494,000	"Germany"
City / **Population** "Madrid" / 3,165,000 "Barcelona" / 1,602,000	"Spain"
City / **Population** "Rome" / 2,874,000 "Milan" / 1,344,000	"Italy"
City / **Population** "Paris" / 2,273,000	"France"

4. To display the first five records in this collection, select **Collections** on the **File** menu.

5. To display the populations of cities in a country/region, select the table icon in the **Cities** column for that country/region (for example, Germany):



Filter and ungroup records

1. Add another button, and set its **Text** property so that the button shows **"Filter"**.

2. Set the **OnSelect** property of this button to this formula:

   ClearCollect(CitiesByCountryFiltered, Filter(CitiesByCountry, "e" in Country))

3. While holding down the Alt key, select the button that you added.

   You just created a third collection, named **CitiesByCountryFiltered**, that includes only those countries that have an "e" in their names (that is, not Spain or Italy).

Cities	Country
City / Population "London" / 8,615,000	"United Kingdom"
City / Population "Berlin" / 3,562,000 "Hamburg" / 1,760,000 "Munich" / 1,494,000	"Germany"
City / Population "Paris" / 2,273,000	"France"

4. Add one more button, and set its **Text** property so that the button shows **"Ungroup"**.

5. Set the **OnSelect** property of this button to this formula:

   ClearCollect(CityPopulationsUngrouped, Ungroup(CitiesByCountryFiltered, Cities))

   Which results in:

City	Country	Population
"London"	"United Kingdom"	8,615,000
"Berlin"	"Germany"	3,562,000
"Paris"	"France"	2,273,000
"Hamburg"	"Germany"	1,760,000
"Munich"	"Germany"	1,494,000

Aggregate results

Another operation we can perform on a grouped table is to compile the results. In this example, we'll sum the population of the major cities in each country/region.

1. Add another button, and set its **Text** property so that the button shows **"Sum"**.

2. Set the **OnSelect** property of the **"Sum"** button to this formula:

   ClearCollect(CityPopulationsSum, AddColumns(CitiesByCountry, 'Sum of City Populations', Sum(Cities, Population)))

   Which results in:

Cities	Country	Sum of City Populations
City: "London", Population: 8,615,000	"United Kingdom"	8,615,000
City: "Berlin", Population: 3,562,000 City: "Hamburg", Population: 1,760,000 City: "Munich", Population: 1,494,000	"Germany"	6,816,000
City: "Madrid", Population: 3,165,000 City: "Barcelona", Population: 1,602,000	"Spain"	4,767,000
City: "Rome", Population: 2,874,000 City: "Milan", Population: 1,344,000	"Italy"	4,218,000
City: "Paris", Population: 2,273,000	"France"	2,273,000

AddColumns starts with the base **CitiesByCountry** collection and adds a new column **Sum of City Populations**. This column's values are calculated row-by-row, based on the formula **Sum(Cities, Population)**. **AddColumns** provides the value of the **Cities** column (a table) for each row, and Sum adds up the **Population** for each row of this sub table.

Now that we have the sum that we want, we can use DropColumns to remove the sub tables.

3. Add another button, and set its Text property so that the button shows **"SumOnly"**.

4. Set the OnSelect property of the **"SumOnly"** button to this formula:

   ClearCollect(CityPopulationsSumOnly, DropColumns(CityPopulationsSum, Cities))

   Which results in:

Country	Sum of City Populations
"United Kingdom"	8,615,000
"Germany"	6,816,000
"Spain"	4,767,000
"Italy"	4,218,000
"France"	2,273,000

Note that we didn't need to ungroup this table.

Relate and Unrelate functions

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

Relate and unrelate records of two tables through a one-to-many or many-to-many relationship.

Description

The **Relate** function links two records through a one-to-many or many-to-many relationship in Microsoft Dataverse. The **Unrelate** function reverses the process and removes the link.

For one-to-many relationships, the Many table has a foreign-key field that points to a record of the One table. **Relate** sets this field to point to a specific record of the One table, while **Unrelate** sets this field to *blank*. If the field is already set when **Relate** is called, the existing link is lost in favor of the new link. You can also set this field by using the **Patch** function or an **Edit form** control; you need not use the **Relate** function.

For many-to-many relationships, the system that links the records maintains a hidden join table. You can't access this join table directly; it can be read only through a one-to-many projection and set through the **Relate** and **Unrelate** functions. Neither related table has a foreign key.

The data for the table that you specify in the first argument will be refreshed to reflect the change, but the data for the table that you specify in the second argument won't. That data must be manually refreshed with the **Refresh** function to show the result of the operation.

These functions never create or delete a record. They only relate or unrelate two records that already exist.

You can use these functions only in behavior formulas.

> **Note**
>
> These functions are part of a preview feature, and their behavior is available only when the **Relational data, option sets, and other new features for CDS** feature is enabled. This is an app-level setting that's enabled by default for new apps. To find this feature switch, select **Settings**, and then select **Upcoming features**. Your

feedback is very valuable to us - please let us know what you think in the Power Apps community forums.

Syntax

Relate(*Table1RelatedTable*, *Table2Record*)

- *Table1RelatedTable* - Required. For a record of *Table1*, the table of *Table2* records related through a one-to-many or many-to-many relationship.
- *Table2Record* - Required. The *Table2* record to add to the relationship.

Unrelate(*Table1RelatedTable*, *Table2Record*)

- *Table1RelatedTable* - Required. For a record of *Table1*, the table of *Table2* records related through a one-to-many or many-to-many relationship.
- *Table2Record* - Required. The *Table2* record to remove from the relationship.

Examples

Consider a **Products** table with the following relationships as seen in the Power Apps portal's table viewer:

Expand table

Relationship display name	Related table	Relationship type
Product Reservation	Reservation	One-to-many
Product ↔ Contact	Contact	Many-to-many

Products and **Reservations** are related through a One-to-Many relationship. To relate the first record of the **Reservations** table with the first record of the **Products** table:

```
Relate( First( Products ).Reservations, First( Reservations ) )
```

To remove the relationship between these records:

```
Unrelate( First( Products ).Reservations, First( Reservations ) )
```

At no time did we create or remove or a record, only the relationship between records was modified.

Products and **Contacts** are related through a Many-to-Many relationship. To relate the first record of the **Contacts** table with the first record of the **Products** table:

```
Relate( First( Products ).Contacts, First( Contacts ) )
```

As Many-to-Many relationships are symmetric, we could also have done this in the opposite direction:

```
Relate( First( Contacts ).Products, First( Products ) )
```

To remove the relationship between these records:

```
Unrelate( First( Products ).Contacts, First( Contacts ) )
```

or:

```
Unrelate( First( Contacts ).Products, First( Products ) )
```

The walk through that follows does exactly these operations on these tables using an app with **Gallery** and **Combo box** controls for selecting the records involved.

These examples depend on the sample data being installed in your environment. Either create a trial environment including sample data or add sample data to an existing environment.

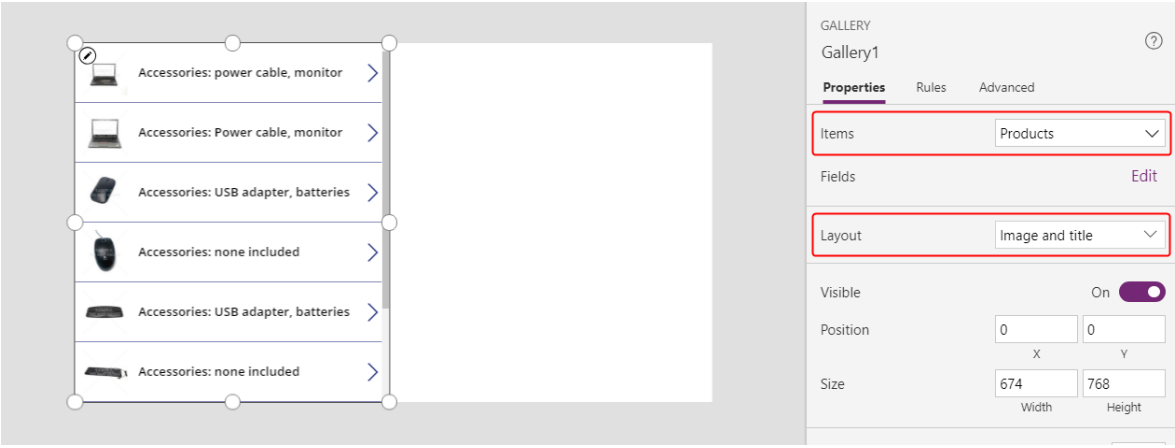
One-to-many

Relate function

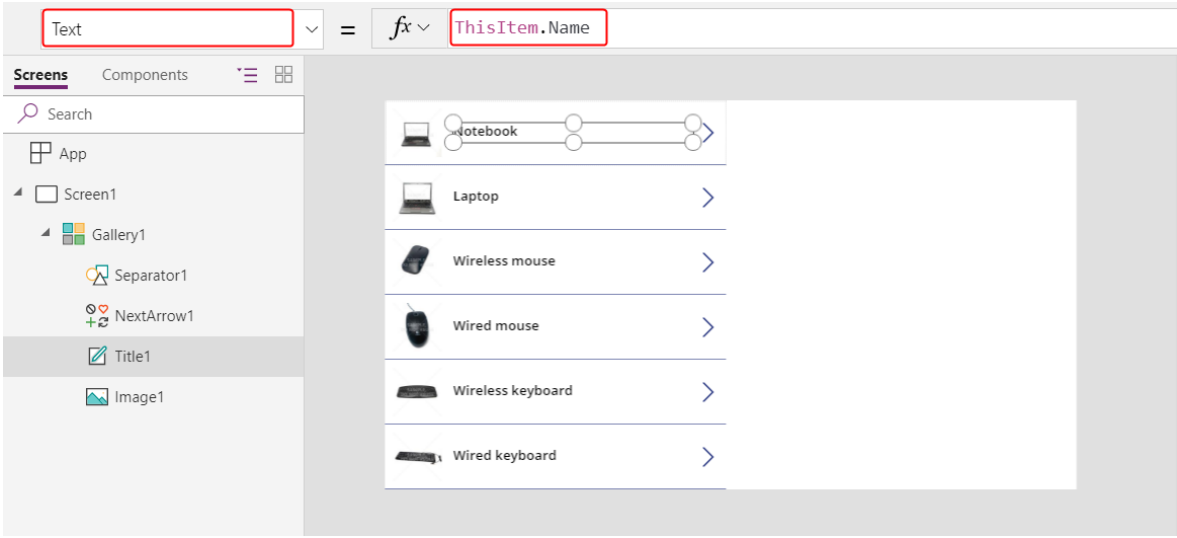
You'll first create a simple app to view and reassign the reservations that are associated with a product.

1. Create a tablet app from blank.
2. On the **View** tab, select **Data sources**.
3. In the **Data** pane, select **Add data** > select **Products**.
   The Products table is part of the sample data loaded above.
4. On the **Insert** tab, add a blank vertical **Gallery** control.
5. Ensure that the control that you just added is named **Gallery1**, and then move and resize it to fill the left-hand side of the screen.

6. On the **Properties** tab, set **Gallery1**'s **Items** property to **Products** and its **Layout** to **Image and title**.



7. In **Gallery1**, ensure that the **Label** control is named **Title1**, and then set its **Text** property to **ThisItem.Name**.



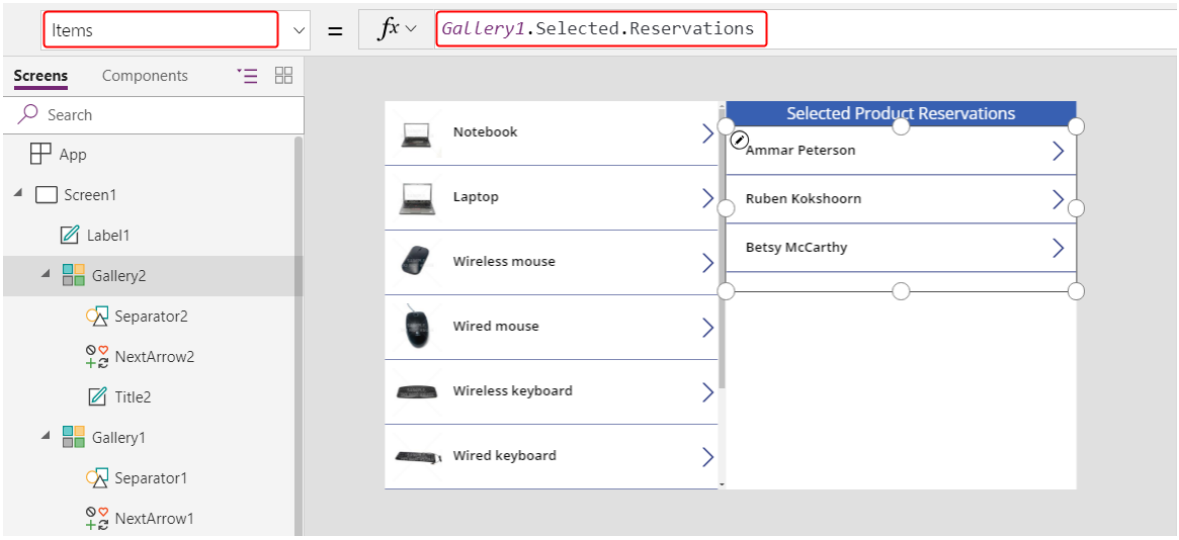
8. Select the screen to avoid inserting the next item into **Gallery1**. Add a second blank vertical **Gallery** control, and ensure that it's named **Gallery2**.

   Gallery2 will show the reservations for whatever product the user selects in **Gallery1**.

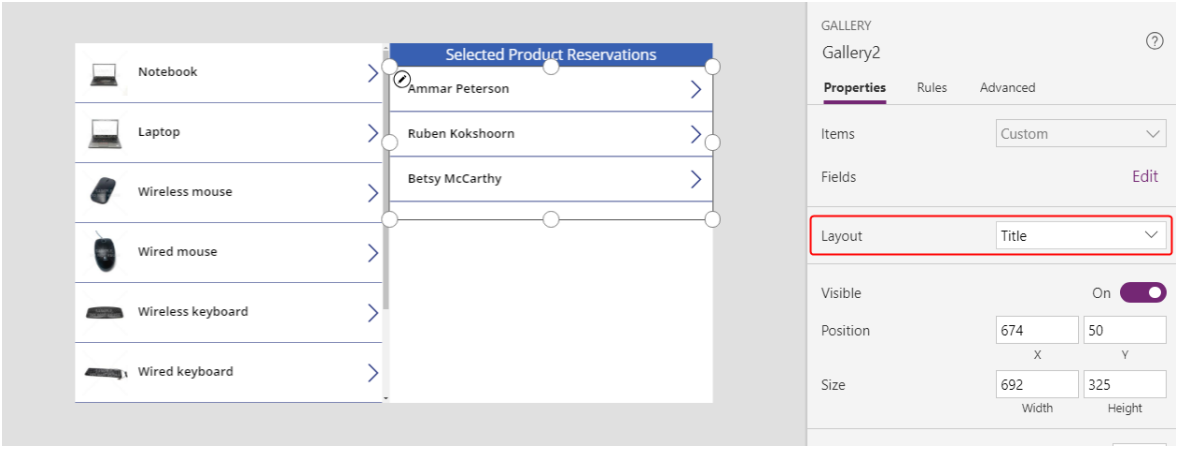
9. Move and resize **Gallery2** to fill the upper-right quadrant of the screen.

10. (optional) Add the blue **Label** control above **Gallery2**, as the next graphic shows.

11. In the formula bar, set the **Items** property of **Gallery2** to **Gallery1.Selected.Reservations**.



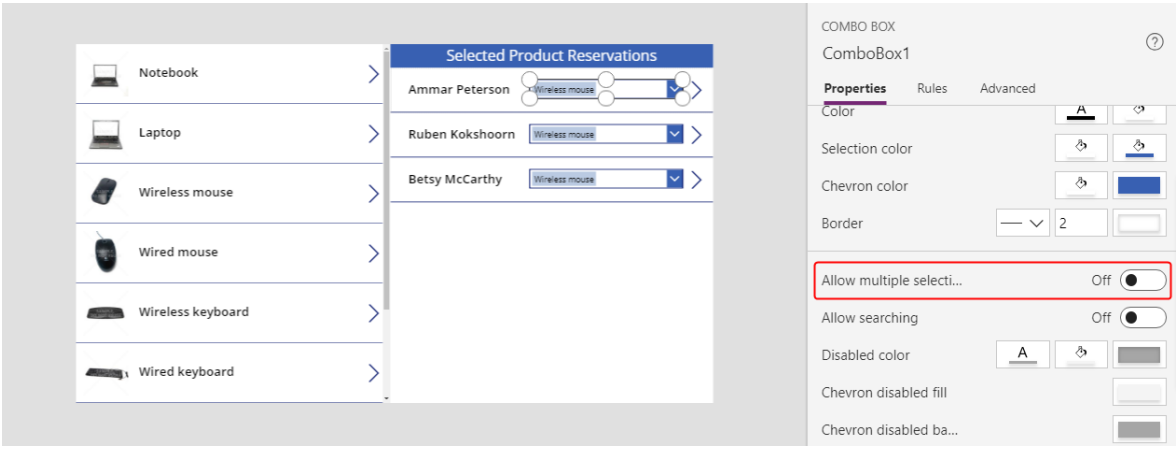
12. In the properties pane, set **Gallery2**'s **Layout** to **Title**.



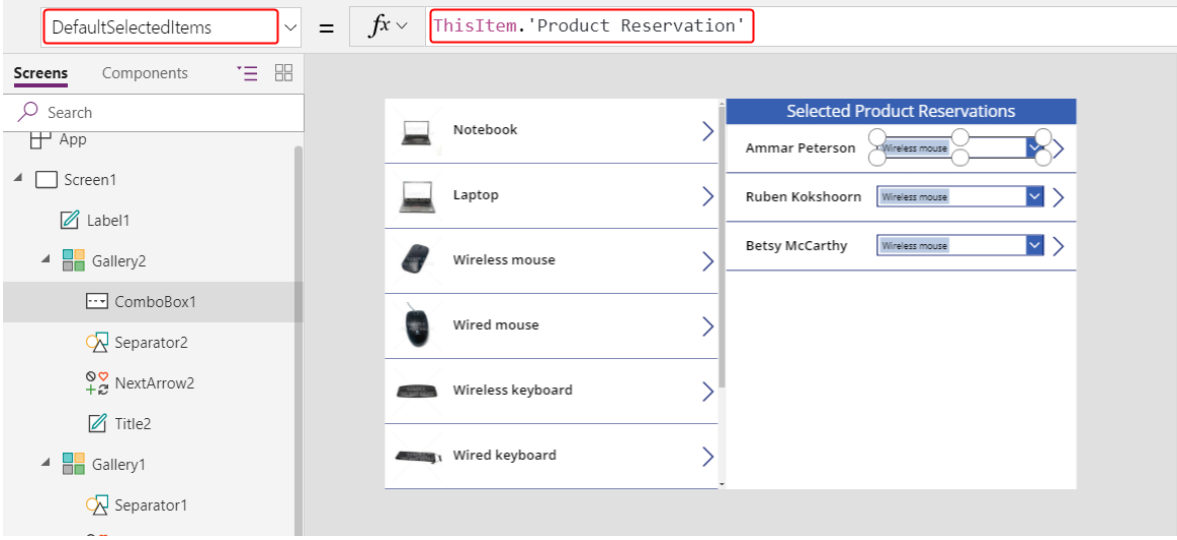
13. In **Gallery2**, add a Combo box control, ensure that it's named **ComboBox1**, and then move and resize it to avoid blocking the other controls in **Gallery2**.

14. On the **Properties** tab, set **ComboBox1**'s **Items** property to **Products**.

15. Scroll down in the **Properties** tab and set **ComboBox1**'s **Allow multiple selection** property to **Off**.



16. In the formula bar, set **ComboBox1**'s **DefaultSelectedItems** property to **ThisItem.'Product Reservation'**.

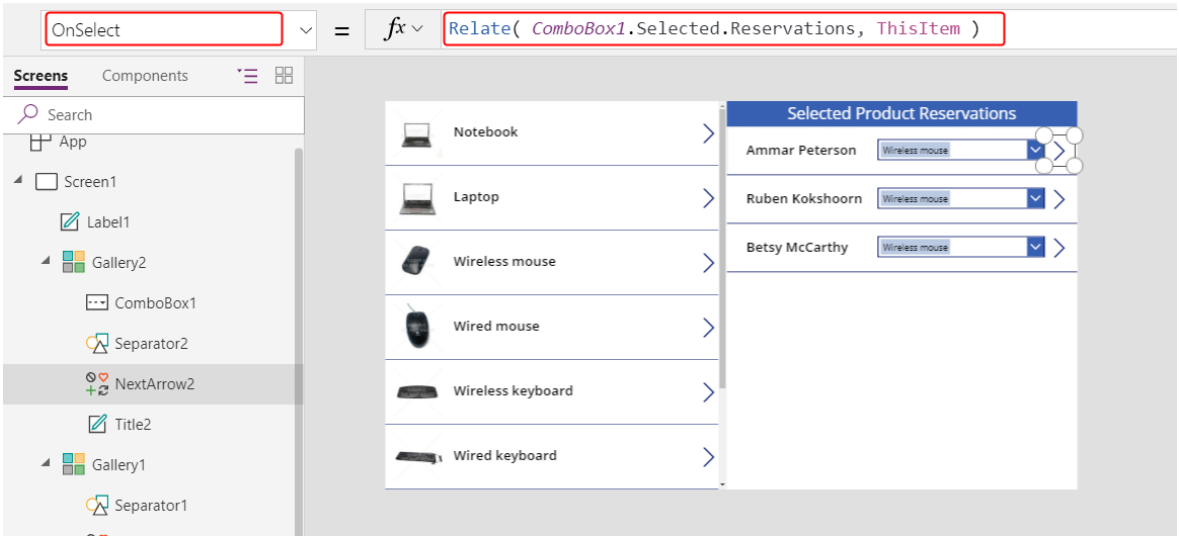


17. In **Gallery2**, set **NextArrow2**'s **OnSelect** property to this formula:

Power Apps

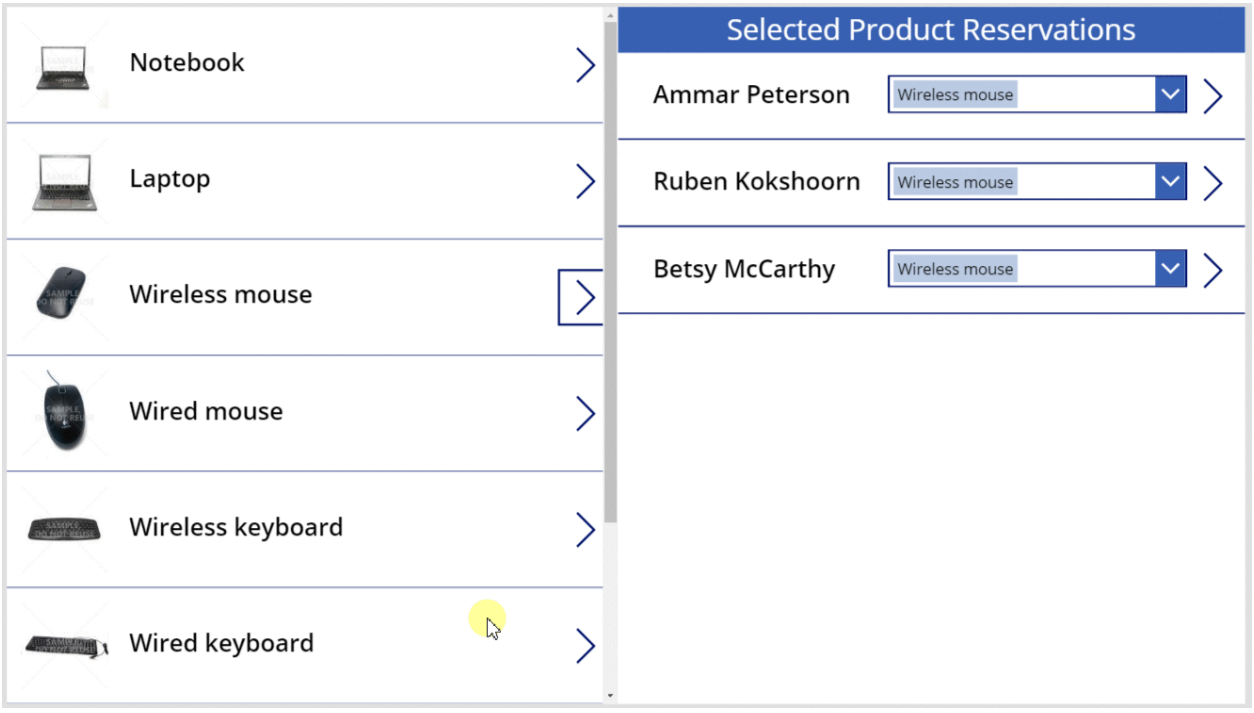
```
Relate( ComboBox1.Selected.Reservations, ThisItem )
```

When the user selects this icon, the current reservation changes to the product that the user selected in **ComboBox1**.



18. Press F5 to test the app in Preview mode.

With this app, the user can move a reservation from one product to another. For a reservation on one product, the user can select a different product in **ComboBox1** and then select **NextArrow2** to change that reservation.



Unrelate function

At this point, you can move the relationship from one record to another, but you can't remove the relationship altogether. You can use the **Unrelate** function to disconnect a reservation record from any product.

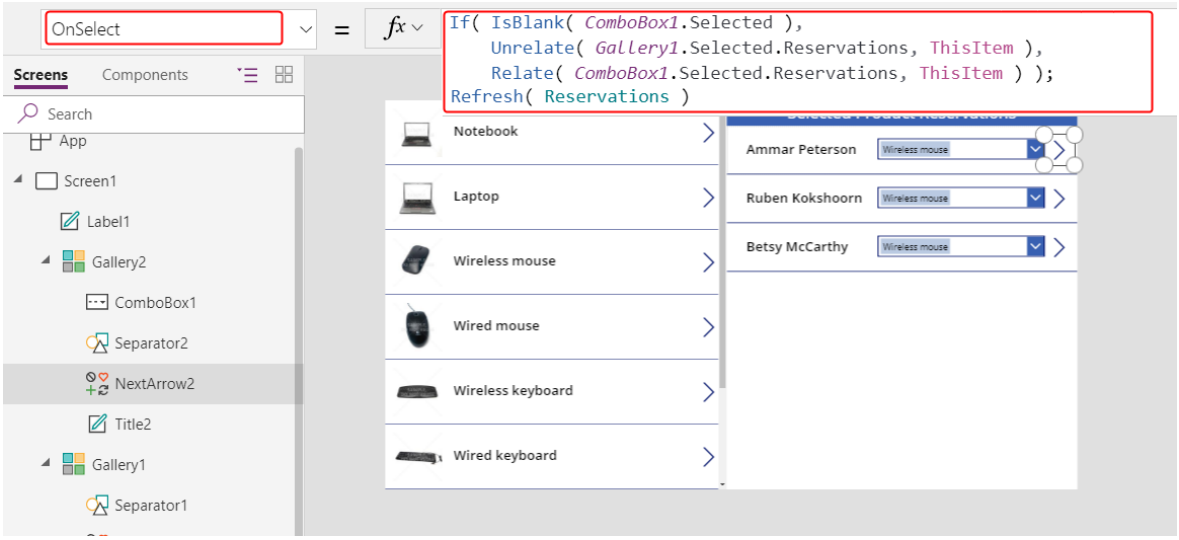
1. On the **View** tab, select **Data sources**.

2. In the **Data** pane, select **Add data source** > **Microsoft Dataverse** > **Reservations** > **Connect**.

3. In **Gallery2**, set the **OnSelect** formula for **NextArrow2** to this formula:

```
Power Apps

If( IsBlank( ComboBox1.Selected ),
    Unrelate( Gallery1.Selected.Reservations, ThisItem ),
    Relate( ComboBox1.Selected.Reservations, ThisItem )
);
Refresh( Reservations )
```



4. Copy **Gallery2** to the Clipboard by selecting it and then pressing Ctrl-C.

5. Paste a duplicate of **Gallery2** to the same screen by pressing Ctrl-V, and then move it to the lower-right quadrant of the screen.

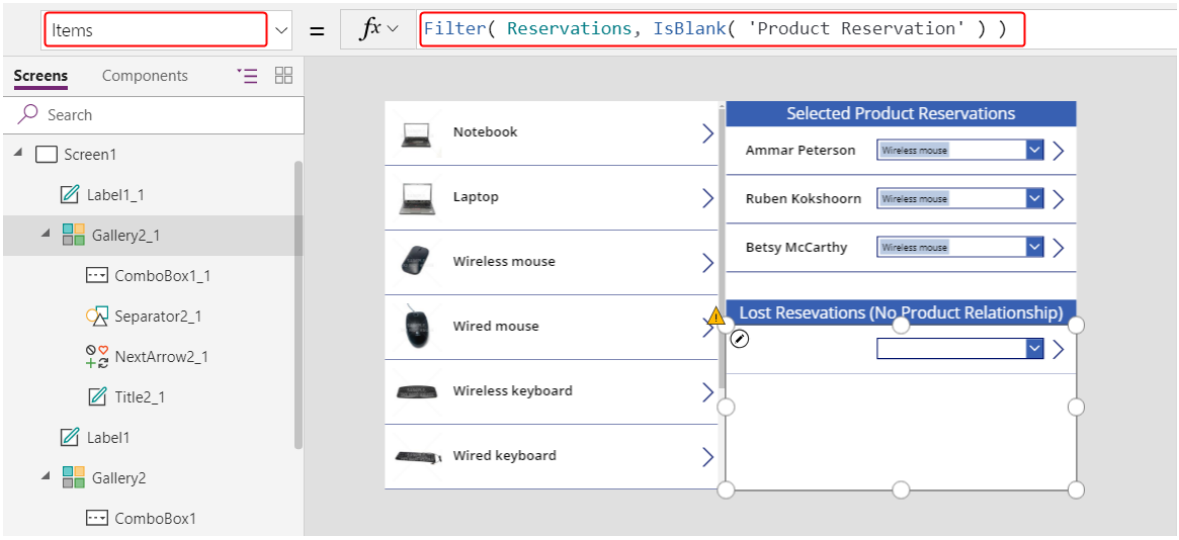
6. (optional) If you added a label above **Gallery2**, repeat the previous two steps for that label.

7. Ensure that the duplicate of **Gallery2** is named **Gallery2_1**, and then set its **Items** property to this formula:

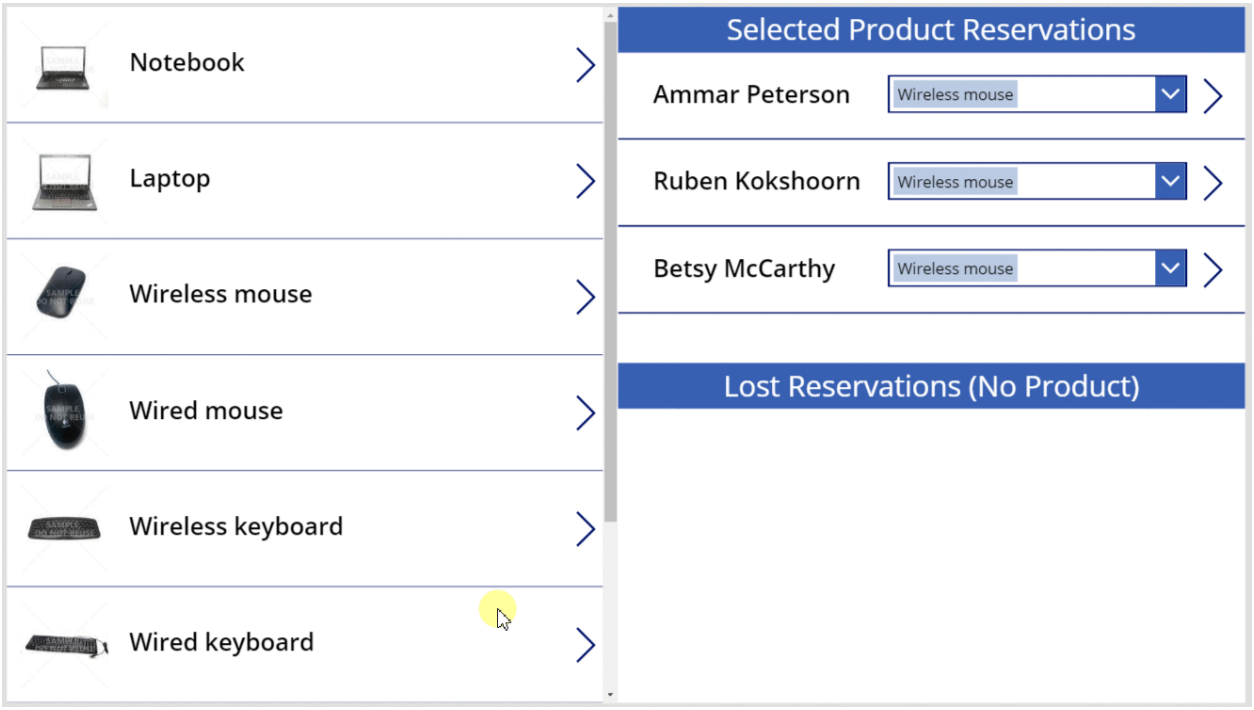
```
Power Apps

Filter( Reservations, IsBlank( 'Product Reservation' ) )
```

   A delegation warning appears, but it won't matter with the small amount of data in this example.



With these changes, users can clear the selection in **ComboBox1** for a contact if that person hasn't reserved a product. Contacts who haven't reserved a product appear in **Gallery2_1** where users can assign each contact to a product.

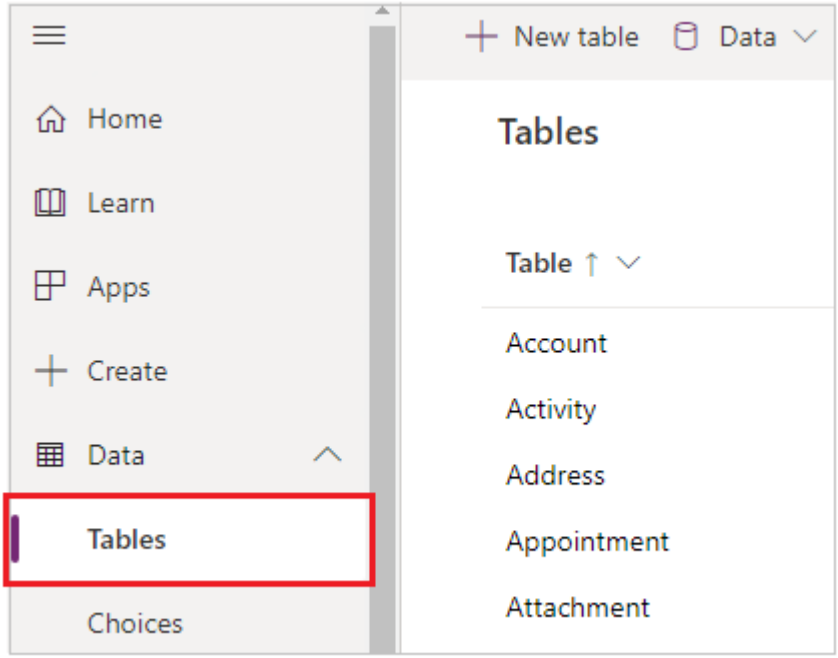


Many-to-many

Create a many-to-many relationship

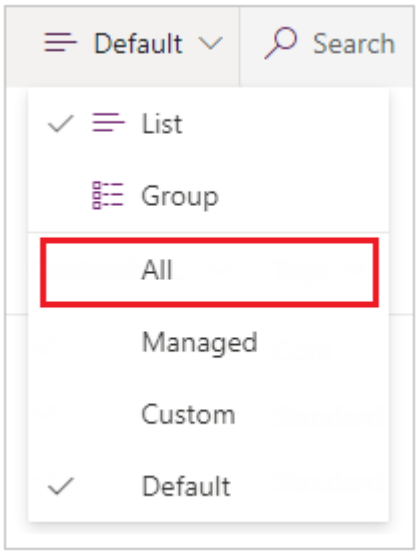
The sample data doesn't include a many-to-many relationship, but you'll create one between the Products table and the Contacts table. Users can relate each product to more than one contact and each contact to more than one product.

1. From this page, select **Data** in the left navigation bar, and then select **Tables**.



2. Change the table filter to include all tables.

   By default, sample tables don't appear.



3. Scroll down, open the **Product** table, and select **Relationships**.

4. Select **Add relationship** > **Many-to-many**.

5. Select the **Contact** table for the relationship.

6. Select **Done** > **Save table**.

Relate and unrelate contacts with one or more products

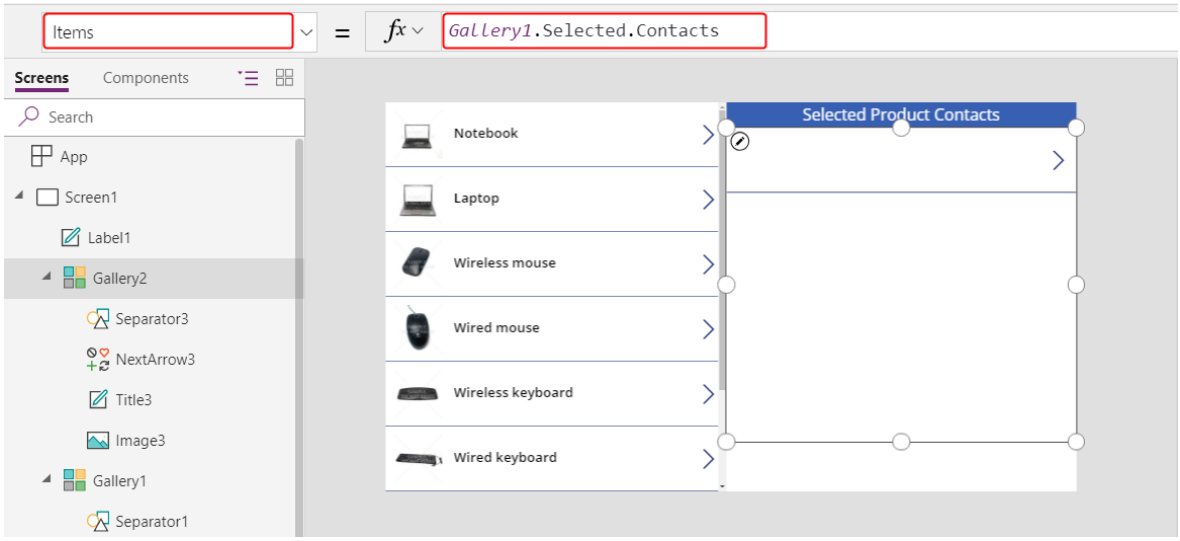
You'll create another app that resembles the one you created earlier in this topic, but the new app will offer a many-to-many relationship. Each contact will be able to reserve multiple products instead of only one.

1. In a blank app for tablets, create **Gallery1** as the first procedure in this topic describes.

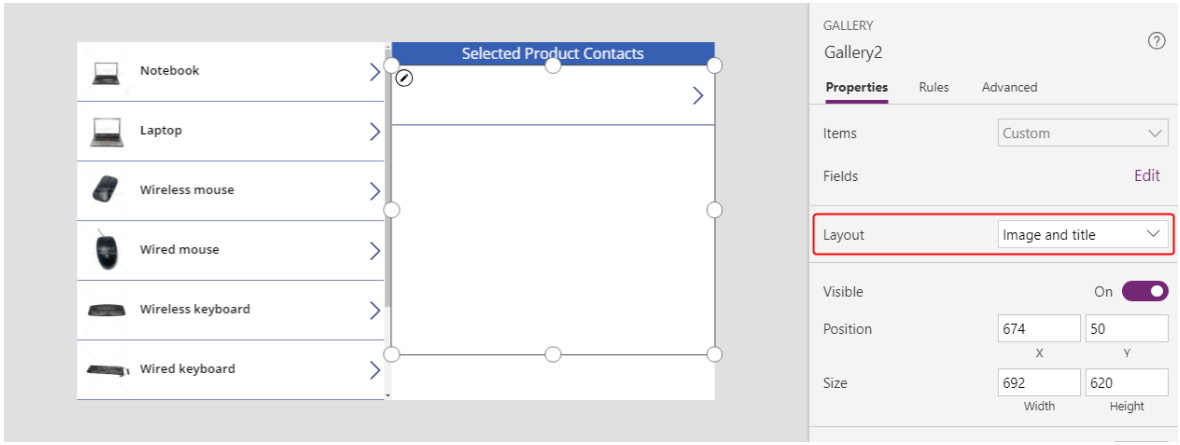
2. Add another blank vertical **Gallery** control, ensure that it's named **Gallery2**, and then move it into the upper-right corner of the screen.

   Later in this topic, you'll add a **Combo box** control under **Gallery2**.

3. In the formula bar, set **Gallery2**'s **Items** property to **Gallery1.Selected.Contacts**.

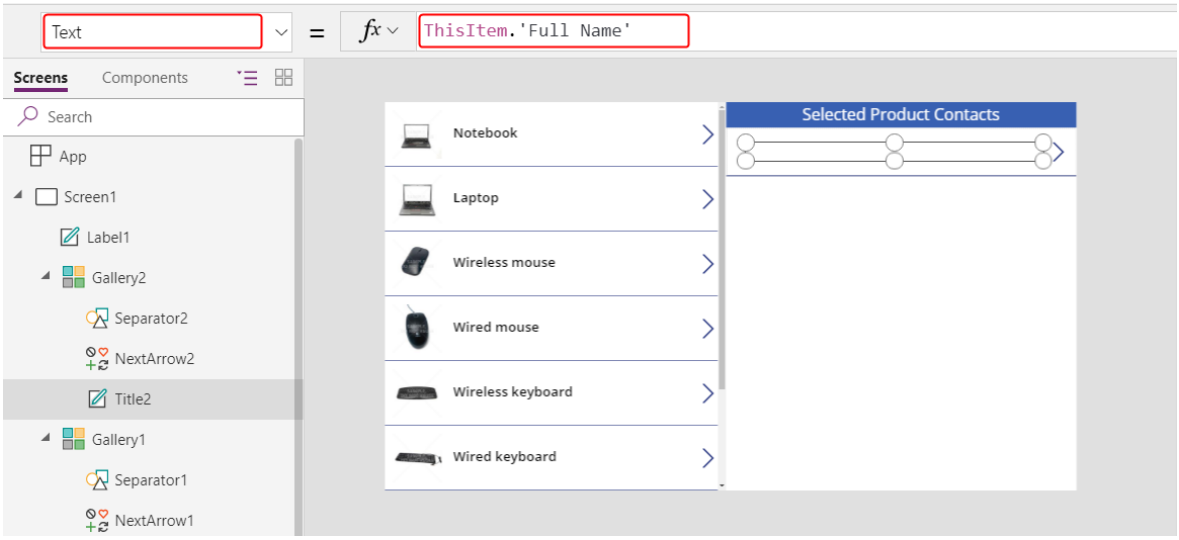


4. On the **Properties** tab, set **Layout** to **Image and title**.



5. In **Gallery2**, ensure that the **Label** control is named **Title2**, and then set its **Text** property to **ThisItem.'Full Name'**.

   No text will appear in that control until you finish this procedure and assign a contact to a product.

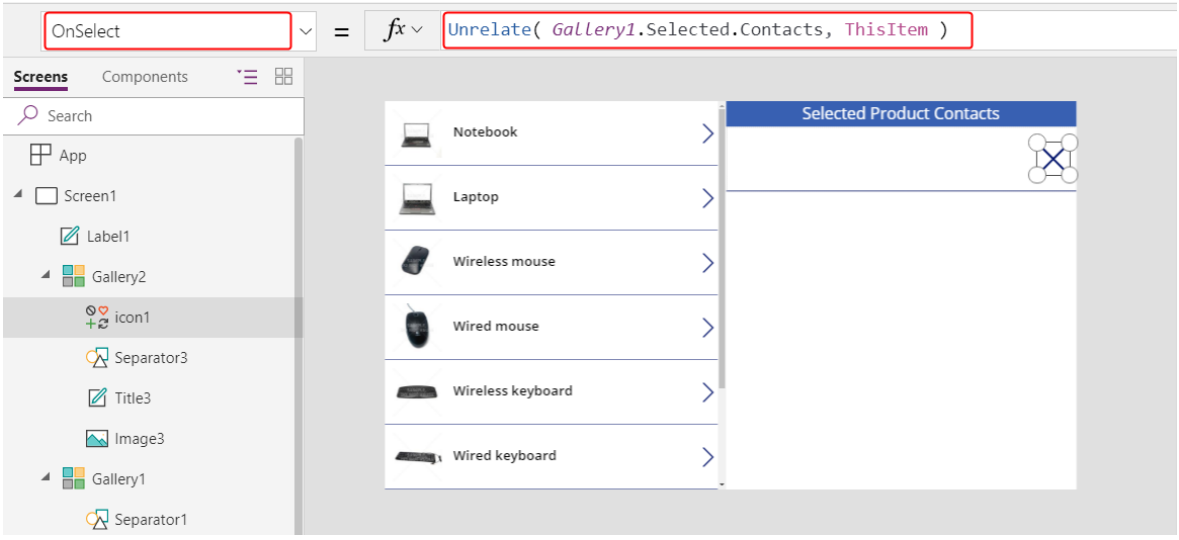


6. Delete **NextArrow2**, insert a **Cancel** icon, and ensure that it's named **icon1**.

7. Set the **Cancel** icon's **OnSelect** property to this formula:

```
Power Apps

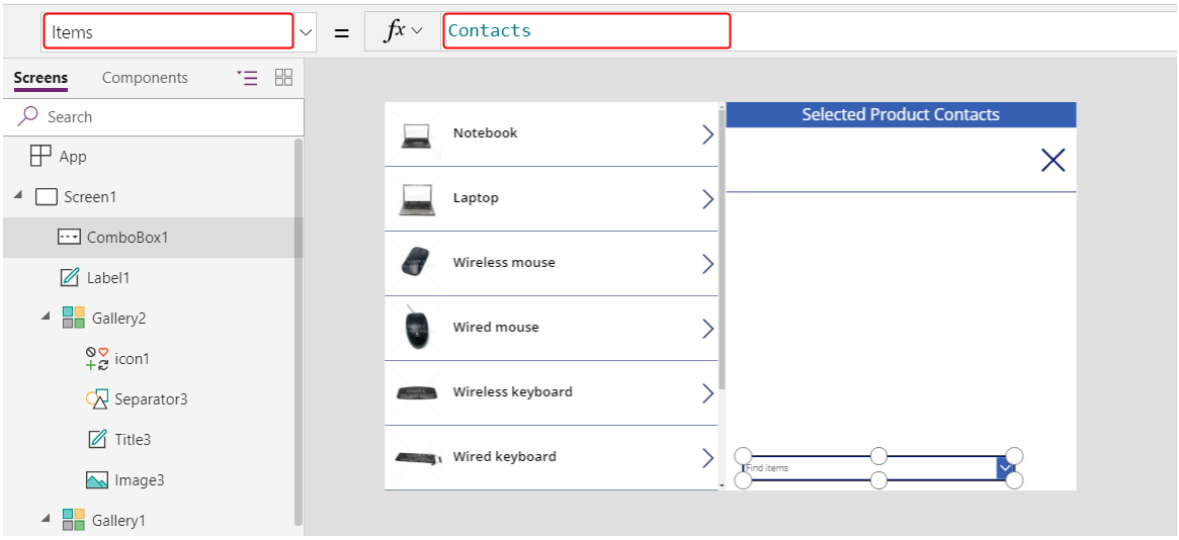
Unrelate( Gallery1.Selected.Contacts, ThisItem )
```



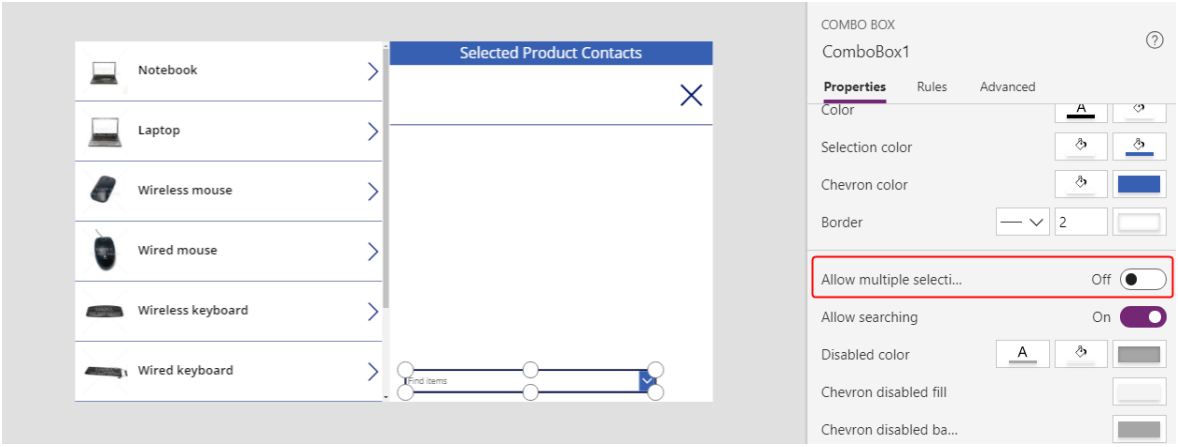
8. On the **View** tab, select **Data sources**.

9. In the **Data** pane, select **Add data source** > **Microsoft Dataverse** > **Contacts** > **Connect**.

10. Under **Gallery2**, add a **Combo box** control, ensure that it's named **ComboBox1**, and then set its **Items** property to **Contacts**.



11. On the **Properties** tab, set **Allow multiple selection** to **Off**.



12. Insert an **Add** icon, and set its **OnSelect** property to this formula:

Power Apps

```
Relate( Gallery1.Selected.Contacts, ComboBox1.Selected )
```

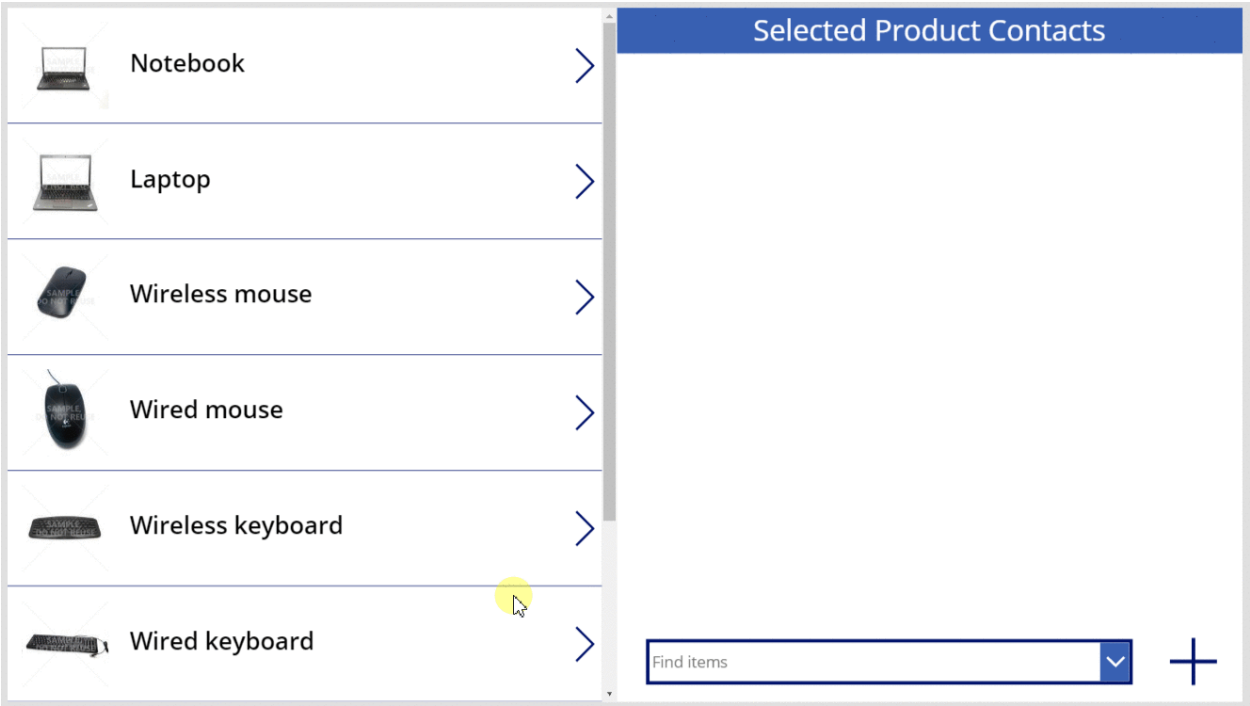
With this app, users can now freely relate and unrelate a set of contacts to each product.

- To add a contact to a product, select the contact in the combo box at the bottom of the screen, and then select the **Add** icon.
- To remove a contact from a product, select the **Cancel** icon for that contact.

  Unlike one-to-many, a many-to-many relationship allows users to associate the same contact with multiple products.

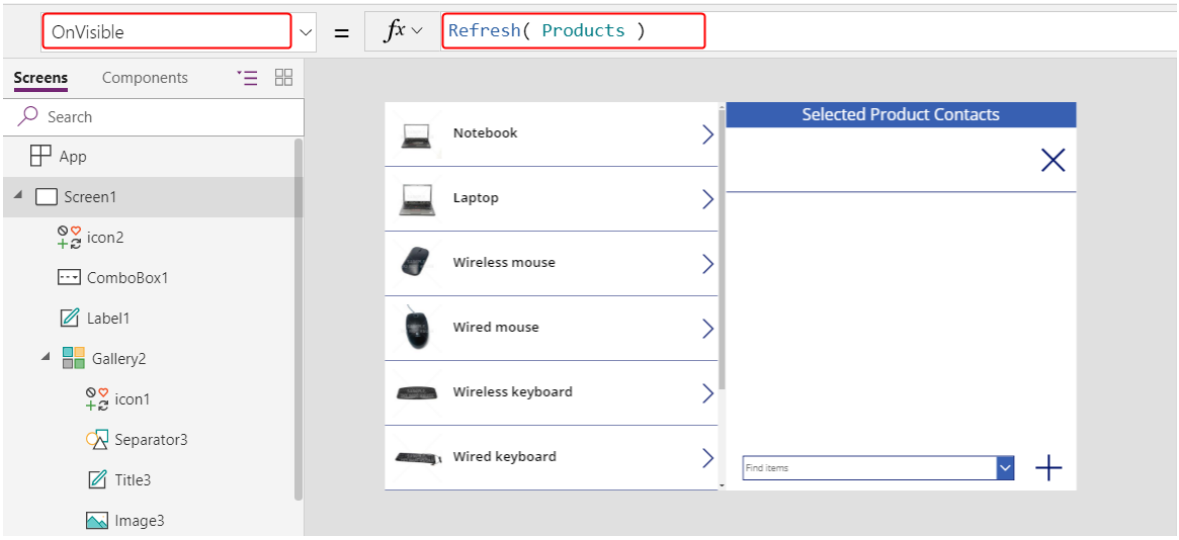


In reverse: relate and unrelate products with multiple contacts

Many-to-many relationships are symmetric. You can extend the example to add products to a contact and then flip between the two screens to show how the relationship appears from either direction.

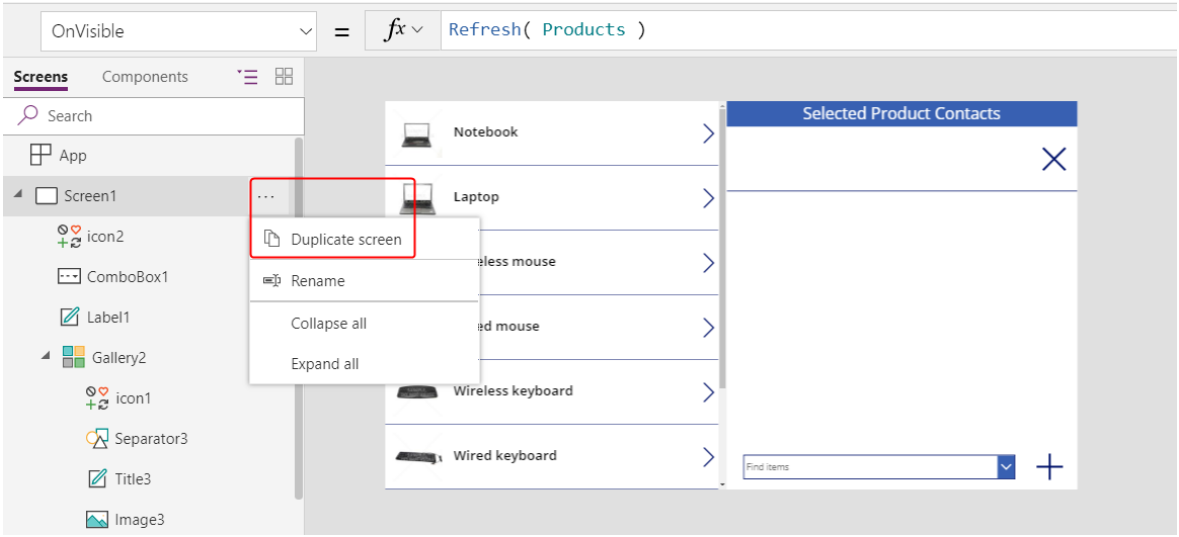
1. Set the **OnVisible** property of **Screen1** to **Refresh(Products)**.

   When you update a one-to-many or many-to-many relationship, only the data of the first argument table of the **Relate** or **Unrelate** call is refreshed. The second must be refreshed manually if you want to flip between the screens of this app.



2. Duplicate **Screen1**.

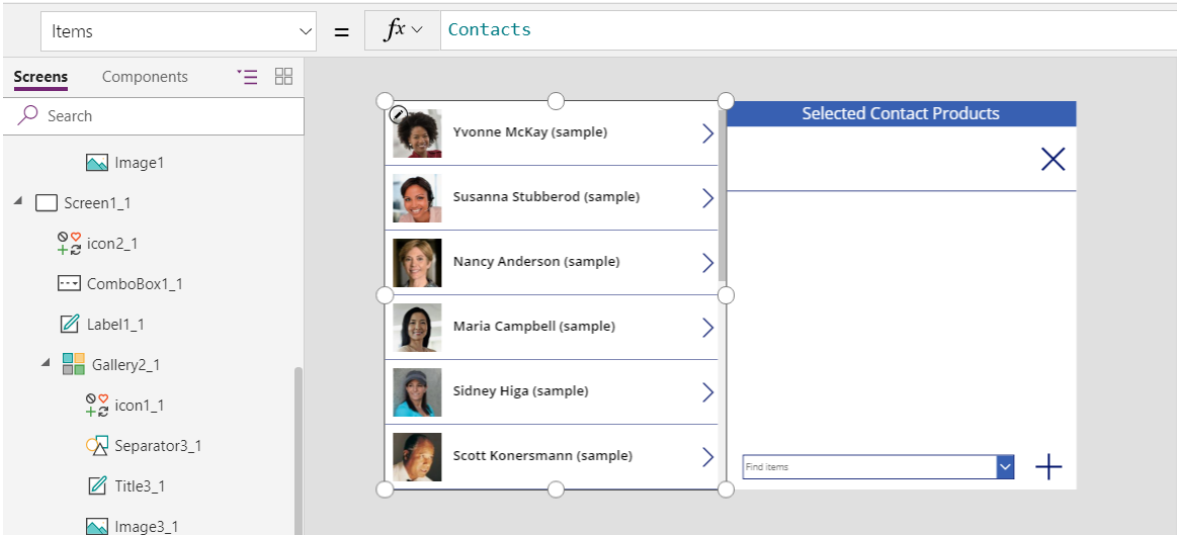
   The duplicate will be named **Screen1_1** and form the basis for looking at the relationships from the contacts side.



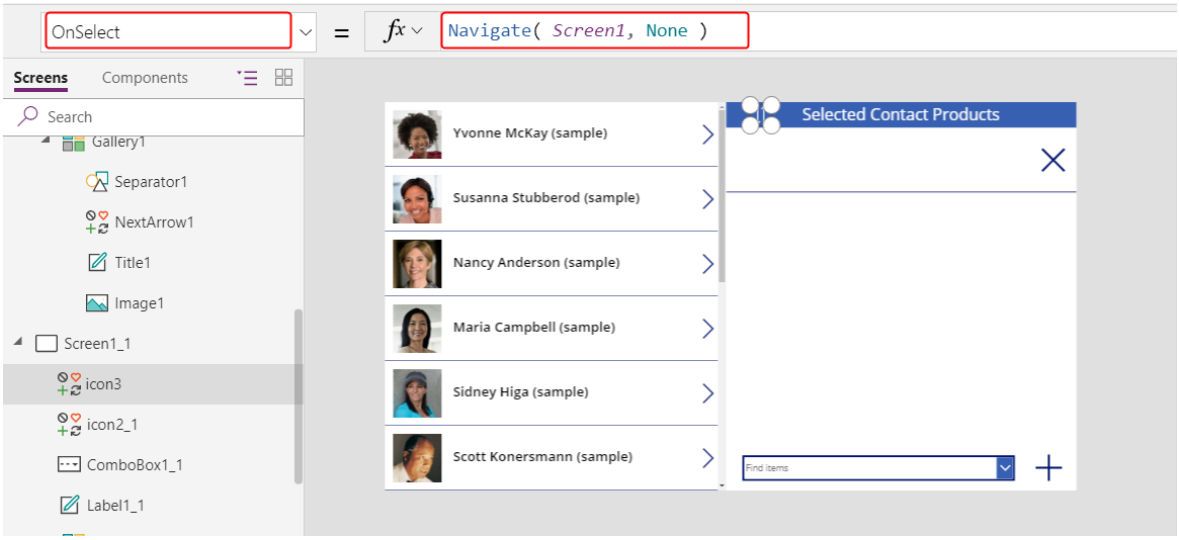
3. To create the reverse view, change these formulas on the controls of **Screen1_1**:

   - Screen1_1.OnVisible = `Refresh( Contacts )`
   - Gallery1_1.Items = `Contacts`
   - Title1_1.Text = `ThisItem.'Full Name'`
   - Label1_1.Text = `"Selected Contact Products"`
   - Gallery2_1.Items = `Gallery1_1.Selected.Products`
   - Title2_1.Text = `ThisItem.Name`
   - Icon1_1.OnSelect = `Unrelate( Gallery1_1.Selected.Products, ThisItem )`
   - ComboBox1_1.Items = `Products`
   - Icon2_1.OnSelect = `Relate( Gallery1_1.Selected.Products, ComboBox1_1.Selected )`

The result will look very similar to the previous screen but comes at the relationship from the **Contacts** side.



4. Insert an **Arrows up down** icon and set its **OnSelect** property to **Navigate(Screen1, None)**. Do the same thing on **Screen1** with the formula **Navigate(Screen1_1, None)**.



With this new screen, users can add a contact to a product and then flip to a view of contacts and see the associated product. The relationships are symmetric and shared between the two screens.

Update and UpdateIf functions

06/21/2025

Applies to: ✅ Canvas apps ✅ Model-driven apps

Updates records in a data source.

Description

Update function

Use the **Update** function to replace an entire record in a data source. In contrast, the **UpdateIf** and the **Patch** functions modify one or more values in a record, leaving the other values alone.

For a collection, the entire record must match. Collections allow duplicate records, so multiple records might match. You can use the **RemoveFlags.All** argument to update all copies of a record; otherwise, only one copy of the record is updated.

If the data source generates a column's value automatically, the value of that column must be reaffirmed.

UpdateIf function

Use the **UpdateIf** function to modify one or more values in one or more records that match one or more conditions. The condition can be any formula that results in a **true** or **false** and can reference columns of the data source by name. The function evaluates the condition for each record and modifies any record for which the result is **true**.

To specify a modification, use a change record that contains new property values. If you provide this change record inline with curly braces, property formulas can reference properties of the record that's being modified. You can use this behavior to modify records based on a formula.

Similar to **UpdateIf**, you can also use the **Patch** function to change specific columns of a record without affecting other columns.

Both **Update** and **UpdateIf** return the modified data source as a table. You must use either function in a behavior formula.

Delegation

These functions do not delegate to a data source. However, **UpdateIf** and **RemoveIf** work locally to simulate delegation up to a limit of 500/2000 records. They progressively bring down records beyond the non-delegation limit of 500/2000 records. Records that meet the **If** condition are collected. Generally, a maximum of 500/2000 records are collected separately and then modified per execution. However, more records may be updated if the existing local data cache is large, as the function may have access to more records for evaluation. Only the initial portion of the data source will be retrieved, and then the function will be applied. This may not represent the complete picture. A warning may appear during authoring to remind you of this limitation.

Syntax

Update(DataSource_, *OldRecord*, *NewRecord* [, **RemoveFlags.All**])

- *DataSource* – Required. The data source that contains the record that you want to replace.
- *OldRecord* – Required. The record to replace.
- *NewRecord* – Required. The replacement record. This isn't a change record. The entire record is replaced, and missing properties contain *blank*.
- *RemoveFlags.All* – Optional. In a collection, the same record may appear more than once. Specify the **RemoveFlags.All** argument to update all copies of the record.

UpdateIf(DataSource_, *Condition1*, *ChangeRecord1* [, *Condition2*, *ChangeRecord2*, ...])

- *DataSource* – Required. The data source that contains the record or records that you want to modify.
- *Conditions* – Required. A formula that evaluates to **true** for the record or records that you want to modify. You can use column names of *DataSource* in the formula. In case multiple *Conditions* are passed, only the *ChangeRecord* related to the first *Condition* that evaluates to **true** is applied.
- *ChangeRecord(s)* - Required. For each corresponding condition, a change record of new property values to apply to records of *DataSource* that satisfy the condition. If you provide the record inline using curly braces, property values of the existing record can be used in the property formulas.

Examples

In these examples, you'll replace or modify records in a data source that's named **IceCream** and that starts with the data in this table:

ID	Flavor	Quantity
1	"Chocolate"	100
2	"Vanilla"	200
3	"Strawberry"	300

Expand table

Formula	Description	Result
Update(IceCream, LookUp(IceCream, Flavor="Chocolate"), { ID: 1, Flavor: "Mint Chocolate", Quantity:150 })	Replaces a record from the data source.	 The **IceCream** data source has been modified.
UpdateIf(IceCream, Quantity > 175, { Quantity: Quantity + 10 })	Modifies records that have a **Quantity** that is greater than **175**. The **Quantity** field is incremented by 10, and no other fields are modified.	 The **IceCream** data source has been modified.
Update(IceCream, LookUp(IceCream, Flavor="Strawberry"), { ID: 3, Flavor: "Strawberry Swirl"})	Replaces a record from the data source. The **Quantity** property hasn't been supplied in the replacement record, so that property will be *blank* in the result.	 The **IceCream** data source has been modified.
UpdateIf(IceCream, true, { Quantity: 0 })	Sets the value of the **Quantity** property for all records in the data source to 0.	 The **IceCream** data source has been modified.

Step by step

1. Import or create a collection named **Inventory**, and show it in a gallery as Show data in a gallery describes.

2. Name the gallery **ProductGallery**.

3. Add a slider named **UnitsSold**, and set its **Max** property to this expression:
   ProductGallery.Selected.UnitsInStock

4. Add a button, and set its **OnSelect** property to this formula:
   UpdateIf(Inventory, ProductName = ProductGallery.Selected.ProductName, {UnitsInStock:UnitsInStock-UnitsSold.Value})

5. Press F5, select a product in the gallery, specify a value with the slider, and then select the button.

   The number of units in stock for the product you specified decreases by the amount that you specified.

UpdateContext function

Article • 03/22/2024

Applies to: Canvas apps

Creates or updates context variables of the current screen.

Overview

Use the **UpdateContext** function to create a context variable, which temporarily holds a piece of information, such as the number of times the user has selected a button or the result of a data operation.

Context variables are scoped to a screen, which means that you can't build a formula that refers to a context variable on another screen. If you've used another programming tool, you can think of a context variable as similar to a local variable. Use the **Set** function to work with global variables that are available throughout your app.

Power Apps are based on formulas that automatically recalculate as the user interacts with an app. Context variables don't offer this benefit and can make your app harder to create and understand. Before you use a context variable, review working with variables.

Description

To create or update a context variable, pass a single record to the **UpdateContext** function. In each record, specify the name of a column, which defines or matches the name of the variable, and the value to which you want to set that variable.

- If you specify the name of a variable that you've previously defined, **UpdateContext** sets the value of the variable to the value that you specify.
- If you specify the name of a variable that doesn't yet exist, **UpdateContext** creates a variable with that name and sets the value of that variable to the value that you specify.
- If you've previously defined a variable but don't specify it in this particular **UpdateContext** formula, its value remains the same.

Context variables are implicitly created by using the **UpdateContext** or **Navigate** function. There is no explicit declaration required. If you remove all the **UpdateContext** and **Navigate** references to a context variable, then that context variable will cease to exist. To clear a variable set its value to the result of the **Blank** function.

You can see your variables' values, definitions, and uses with the Variables view under the File menu in the authoring environment.

You reference a context variable in a formula by using the variable's column name. For example, **UpdateContext({ ShowLogo: true })** creates a context variable named **ShowLogo** and sets its value to **true**. You can then use the value of this context variable by using the name **ShowLogo** in a formula. You can write **ShowLogo** as the formula for the **Visible** property of an image control and show or hide that control based on whether the value of the context variable is **true** or **false**.

As the examples later in this topic show, context variables can hold several kinds of information, including these:

- a single value
- a record
- a table
- an object reference
- any result from a formula

A context variable holds its value until the app is closed. If you define a context variable and set its value on a particular screen, that information remains intact even if the user switches to a different screen. Once the app is closed, the context variable's value will be lost and must be recreated when the app is loaded again.

Every context variable is scoped to a screen. If you want to define a context variable on one screen and modify that variable from another screen, you must build a formula that's based on the **Navigate** function. Or use a global variable.

UpdateContext has no return value, and you can use it only within a behavior formula.

Syntax

UpdateContext(*UpdateRecord*)

- *UpdateRecord* – Required. A record that contains the name of at least one column and a value for that column. A context variable is created or updated for each column and value that you specify.

UpdateContext({ *ContextVariable1*: *Value1* [, *ContextVariable2*: *Value2* [, ...]] })

- *ContextVariable1* - Required. The name of a context variable to create or update.
- *Value1* - Required. The value to assign to the context variable.
- *ContextVariable2*: *Value2*, ... - Optional. Additional context variables to create or update and their values.

Examples

Expand table

Formula	Description	Result
UpdateContext({ Counter: 1 })	Creates or modifies the context variable **Counter**, setting its value to **1**.	**Counter** has the value **1**. You can reference that variable by using the name **Counter** in a formula.
UpdateContext({ Counter: 2 })	Sets the value of the **Counter** context variable from the previous example to **2**.	**Counter** has the value **2**.
UpdateContext({ Name: "Lily", Score: 10 })	Creates or modifies the context variables **Name** and **Score**, setting their values to **Lily** and **10** respectively.	**Name** has the value **Lily**, and **Score** has the value **10**.
UpdateContext({ Person: { Name: "Milton", Address: "1 Main St" } })	Creates or modifies the context variable **Person**, setting its value to a record. The record contains two columns, named **Name** and **Address**. The value of the **Name** column is **Milton**, and the value of the **Address** column is **1 Main St**.	**Person** has the value of record **{ Name: "Milton", Address: "1 Main St" }**. Reference this record as a whole with the name **Person**, or reference an individual column of this record with **Person.Name** or **Person.Address**.
UpdateContext({ Person: Patch(Person, {Address: "2 Main St" }) })	Works with the Patch function to update the **Person** context variable by setting the value of the **Address** column to **2 Main St**.	**Person** now has the value of record **{ Name: "Milton", Address: "2 Main St" }**.

Step-by-step example 1

1. Name the default screen **Source**, add another screen, and name it **Target**.

2. On the **Source** screen, add two buttons, and set their **Text** properties so that one says **English** and the other says **Spanish**.

3. Set the **OnSelect** property of the **English** button to this expression:
   Navigate(Target, ScreenTransition.Fade, {Language:"English"})

4. Set the **OnSelect** property of the **Spanish** button to this expression:
   Navigate(Target, ScreenTransition.Fade, {Language:"Spanish"})

5. On the **Target** screen, add a label, and set its **Text** property to this expression:
   If(Language="English", "Hello!", "Hola!")

6. On the **Target** screen, select **Shapes** on the **Insert** tab, and then select the Back arrow.

7. Set the Back arrow's **OnSelect** property to this formula:
   Navigate(Source, ScreenTransition.Fade)

8. From the **Source** screen, press F5, and then select the button for either language.

   On the **Target** screen, the label appears in the language that corresponds to the button that you selected.

9. Select the Back arrow to return to the **Source** screen, and then select the button for the other language.

   On the **Target** screen, the label appears in the language that corresponds to the button that you selected.

10. Press Esc to return to the default workspace.

Step-by-step example 2

1. Open the canvas app where you want to use this formula.
2. Add a new blank screen by selecting **New screen** from the command bar.
3. Add a button, and set its **OnSelect** property to this formula:
   UpdateContext({ Name: "Lily", Score: 10 })

Update and UpdateIf functions

06/21/2025

Applies to: ✅ Canvas apps ✅ Model-driven apps

Updates records in a data source.

Description

Update function

Use the **Update** function to replace an entire record in a data source. In contrast, the **UpdateIf** and the **Patch** functions modify one or more values in a record, leaving the other values alone.

For a collection, the entire record must match. Collections allow duplicate records, so multiple records might match. You can use the **RemoveFlags.All** argument to update all copies of a record; otherwise, only one copy of the record is updated.

If the data source generates a column's value automatically, the value of that column must be reaffirmed.

UpdateIf function

Use the **UpdateIf** function to modify one or more values in one or more records that match one or more conditions. The condition can be any formula that results in a **true** or **false** and can reference columns of the data source by name. The function evaluates the condition for each record and modifies any record for which the result is **true**.

To specify a modification, use a change record that contains new property values. If you provide this change record inline with curly braces, property formulas can reference properties of the record that's being modified. You can use this behavior to modify records based on a formula.

Similar to **UpdateIf**, you can also use the **Patch** function to change specific columns of a record without affecting other columns.

Both **Update** and **UpdateIf** return the modified data source as a table. You must use either function in a behavior formula.

Delegation

These functions do not delegate to a data source. However, **UpdateIf** and **RemoveIf** work locally to simulate delegation up to a limit of 500/2000 records. They progressively bring down records beyond the non-delegation limit of 500/2000 records. Records that meet the **If** condition are collected. Generally, a maximum of 500/2000 records are collected separately and then modified per execution. However, more records may be updated if the existing local data cache is large, as the function may have access to more records for evaluation. Only the initial portion of the data source will be retrieved, and then the function will be applied. This may not represent the complete picture. A warning may appear during authoring to remind you of this limitation.

Syntax

Update(DataSource_, *OldRecord*, *NewRecord* [, **RemoveFlags.All**])

- *DataSource* – Required. The data source that contains the record that you want to replace.
- *OldRecord* – Required. The record to replace.
- *NewRecord* – Required. The replacement record. This isn't a change record. The entire record is replaced, and missing properties contain *blank*.
- *RemoveFlags.All* – Optional. In a collection, the same record may appear more than once. Specify the **RemoveFlags.All** argument to update all copies of the record.

UpdateIf(DataSource_, *Condition1*, *ChangeRecord1* [, *Condition2*, *ChangeRecord2*, ...])

- *DataSource* – Required. The data source that contains the record or records that you want to modify.
- *Conditions* – Required. A formula that evaluates to **true** for the record or records that you want to modify. You can use column names of *DataSource* in the formula. In case multiple *Conditions* are passed, only the *ChangeRecord* related to the first *Condition* that evaluates to **true** is applied.
- *ChangeRecord(s)* - Required. For each corresponding condition, a change record of new property values to apply to records of *DataSource* that satisfy the condition. If you provide the record inline using curly braces, property values of the existing record can be used in the property formulas.

Examples

In these examples, you'll replace or modify records in a data source that's named **IceCream** and that starts with the data in this table:

ID	Flavor	Quantity
1	"Chocolate"	100
2	"Vanilla"	200
3	"Strawberry"	300

Expand table

Formula	Description	Result
Update(IceCream, LookUp(IceCream, Flavor="Chocolate"), { ID: 1, Flavor: "Mint Chocolate", Quantity:150 })	Replaces a record from the data source.	 The **IceCream** data source has been modified.
UpdateIf(IceCream, Quantity > 175, { Quantity: Quantity + 10 })	Modifies records that have a **Quantity** that is greater than **175**. The **Quantity** field is incremented by 10, and no other fields are modified.	 The **IceCream** data source has been modified.
Update(IceCream, LookUp(IceCream, Flavor="Strawberry"), { ID: 3, Flavor: "Strawberry Swirl"})	Replaces a record from the data source. The **Quantity** property hasn't been supplied in the replacement record, so that property will be *blank* in the result.	 The **IceCream** data source has been modified.
UpdateIf(IceCream, true, { Quantity: 0 })	Sets the value of the **Quantity** property for all records in the data source to 0.	 The **IceCream** data source has been modified.

Step by step

1. Import or create a collection named **Inventory**, and show it in a gallery as Show data in a gallery describes.

2. Name the gallery **ProductGallery**.

3. Add a slider named **UnitsSold**, and set its **Max** property to this expression:
   ProductGallery.Selected.UnitsInStock

4. Add a button, and set its **OnSelect** property to this formula:
   UpdateIf(Inventory, ProductName = ProductGallery.Selected.ProductName, {UnitsInStock:UnitsInStock-UnitsSold.Value})

5. Press F5, select a product in the gallery, specify a value with the slider, and then select the button.

   The number of units in stock for the product you specified decreases by the amount that you specified.

Lower, Upper, and Proper functions

Article • 04/20/2025

Expand table

Functions	Applies to
Lower **Upper**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Proper	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Converts letters in a string of text to all lowercase, all uppercase, or proper case.

Description

The **Lower**, **Upper**, and **Proper** functions convert the case of letters in strings.

- **Lower** converts any uppercase letters to lowercase.
- **Upper** converts any lowercase letters to uppercase.
- **Proper** converts the first letter in each word to uppercase if it's lowercase and converts any other uppercase letters to lowercase.

All three functions ignore characters that aren't letters.

If you pass a single string, the return value is the converted version of that string. If you pass a single-column table that contains strings, the return value is a single-column table of converted strings. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

Syntax

Lower(*String*)
Upper(*String*)
Proper(*String*)

- *String* - Required. The string to convert.

Lower(*SingleColumnTable*)
Upper(*SingleColumnTable*)
Proper(*SingleColumnTable*)

- *SingleColumnTable* - Required. A single-column table of strings to convert.

Examples

Single string

The examples in this section use a text-input control, named **Author**, as their data source. The control contains the string "E. E. CummINGS".

Expand table

Formula	Description	Result
Lower(Author.Text)	Converts any uppercase letters in the string to lowercase.	"e. e. cummings"
Upper(Author.Text)	Converts any lowercase letters in the string to uppercase.	"E. E. CUMMINGS"
Proper(Author.Text)	Converts the first letter of each word to uppercase if it's lowercase, and converts any other uppercase letters to lowercase.	"E. E. Cummings"

Single-column table

The examples in this section convert strings from the **Address** column of the **People** data source, which contains this data:

Expand table

Name	Address
"Jean"	"123 Main St NE"
"Fred"	"789 SW 39th #3B"

Each formula returns a single-column table that contains the converted strings.

Expand table

Formula	Description	Result
Lower(ShowColumns(People, "Address"))	Converts any letter that's lowercase to uppercase.	A single-column table with a `Value` column containing the

Formula	Description	Result
		following values: "123 main st ne", "789 sw 39th #3b"
Upper(ShowColumns(People, "Address"))	Converts any letter that's lowercase to uppercase.	A single-column table with a `Value` column containing the following values: "123 MAIN ST NE", "789 SW 39TH #3B"
Proper(ShowColumns(People, "Address"))	Converts any first letter of a word that's lowercase to uppercase, and converts any other letter that's uppercase to lowercase.	A single-column table with a `Value` column containing the following values: "123 Main St Ne", "789 Sw 39th #3b"

Step-by-step example

1. Add a **Text input** control, and name it **Source**.
2. Add a label, and set its **Text** property to this function:
   Proper(Source.Text)
3. Press F5, and then type **WE ARE THE BEST!** into the **Source** box.
   The label shows **We Are The Best!**

User function

Article • 11/24/2024

Applies to: Canvas apps Power Pages

Returns information about the current user.

Description

The **User** function returns a record of information about the current user:

Expand table

Property	Description
User().Email	Email address of the current user. The `User().Email` function returns the user's UPN and not the SMTP email address.
User().EntraObjectId	Microsoft Entra Object ID of the current user, useful for calling APIs that use this value. This is a GUID value and unique for each user.
User().FullName	Full name of the current user, including first and last names.
User().Image	Image of the current user. This will be an image URL of the form "blob:*identifier*". Set the **Image** property of the **Image** control to this value to display the image in the app.

> **Note**
>
> The information returned is for the current Power Apps user. It will match the "Account" information that is displayed in the Power Apps players and studio, which can be found outside of any authored apps. This may not match the current user's information in Office 365 or other services.

> **Note**
>
> If you published your application with a User function prior to March 2020, you may find that it, intermittently, will not retrieve photos. The issues were fixed in the late March 2020 release. To take advantage of the updated implementation, simply re-open your application, save it, and republish it.

Syntax

User()

Examples

The current Power Apps user has the following information:

- Full Name: **"John Doe"**
- Email address: **"john.doe@contoso.com"**
- Entra Object Id: **aaaaaaaa-0000-1111-2222-bbbbbbbbbbbb** *(GUID)*
- Image: 

Expand table

Formula	Description	Result
User()	Record of all information for the current Power Apps user.	{ FullName: "John Doe", Email: "john.doe@contoso.com", Image: "blob:1234...5678", EntraObjectId: a90c6800-e58c-4495-81f7-55819b56fe2a }
User().Email	The email address of the current Power Apps user.	"john.doe@contoso.com"
User().FullName	The full name of the current Power Apps user.	"John Doe"
User().EntraObjectId	Microsoft Entra Object ID of the current user.	aaaaaaaa-0000-1111-2222-bbbbbbbbbbbb *(GUID)*
User().Image	The image URL for the current Power Apps user. Set the **Image**	"blob:1234...5678"

Formula	Description	Result
	property of the **Image** control to this value to display the image in the app.	With **ImageControl.Image**:

Now, Today, IsToday, UTCNow, UTCToday, IsUTCToday functions

Article • 04/20/2025

Expand table

Functions	Applies to
Now	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
Today **IsToday**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
UTCNow **UTCToday**	✅ Dataverse formula columns ✅ Power Pages

Returns the current date and time, and tests whether a date/time value is today.

> ⓘ Note
>
> PAC CLI pac power-fx commands do not support the **UTCNow**, **UTCToday**, and **IsUTCToday** functions.

Description

The **Now** function returns the current date and time as a date/time value.

The **Today** function returns the current date as a date/time value. The time portion is midnight. **Today** has the same value throughout a day, from midnight today to midnight tomorrow.

The **IsToday** function tests whether a date/time value is between midnight today and midnight tomorrow. This function returns a Boolean (**true** or **false**) value.

Now, **Today**, and **IsToday** functions work with the local time of the current user.

UTCNow, **UTCToday**, and **IsUTCToday** functions are the same as their non-UTC counterparts but work with time zone independent values and use Coordinated Universal Time (UTC).

> ⓘ Note

- **UTCNow**, **UTCToday**, and **IsUTCToday** are only available in Microsoft Dataverse for Teams formula columns, and only for time-independent fields and values.
- **Now**, **Today**, and **IsToday** are not available in Dataverse for Teams formula columns as evaluations are done without the knowledge of the current user's local time zone. More information: Work with formula table columns in Dataverse for Teams

See Date, Time, and DateTime in the data types documentation and working with dates and times for more information.

Volatile Functions

Now, **Today**, **UTCNow**, and **UTCToday** are volatile functions. These functions return a different value for each evaluation.

When used in a data flow formula, a volatile function will only return a different value if the formula in which it appears is reevaluated. If nothing else changes in the formula then it will have the same value throughout the execution of your app.

For example, a label control with **Label1.Text = Now()** will not change while your app is active. Only closing and reopening the app will result in a new value.

The function will be reevaluated if it is part of a formula in which something else has changed. For example, if we change our example to involve a slider control with **Label1.Text = DateAdd(Now(), Slider1.Value, Minutes)** then the current time is retrieved each time the Slider control's value changes and the label's text property is reevaluated.

When used in a behavior formula, volatile functions will be evaluated each time the behavior formula is evaluated. See below for an example.

Syntax

Using the user's local time

Now()

Today()

IsToday(*DateTime*)

- *DateTime* - Required. The date/time value to test.

Using Coordinated Universal Time (UTC)

UTCNow()

UTCToday()

IsUTCToday(*TimeZoneIndependentTime*)

- *TimeZoneIndependentDateTime* - Required. The time zone independent date/time value to test.

Examples

For the examples in this section, the current time is **8:58 PM** on **July 11, 2021** in the Pacific Time Zone (UTC-8) and the language is **en-us**.

Expand table

Formula	Description	Result
Text(Now(), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date and time in the user's time zone, and displays it as a string.	"07/11/2021 20:58:00"
Text(Today(), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date only, leaving the time portion as midnight, and displays it as a string.	"07/12/2021 00:00:00"
IsToday(Now())	Tests whether the current date and time is between midnight today and midnight tomorrow.	**true**
IsToday(Today())	Tests whether the current date is between midnight today and midnight tomorrow.	**true**
Text(DateAdd(Now(), 12), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date and time, adds 12 days to the result, and displays it as a string.	"07/23/2021 20:58:00"
Text(DateAdd(Today(), 12), "mm/dd/yyyy hh:mm:ss")	Retrieves the current date, adds 12 days to the result, and displays it as a string.	"07/23/2021 00:00:00"
IsToday(DateAdd(Now(), 12))	Tests whether the current date and time, plus 12 days, is between midnight today and midnight tomorrow.	**false**
IsToday(DateAdd(Today(), 12))	Tests whether the current date, plus 12 days, is between midnight today and midnight tomorrow.	**false**
Hour(UTCNow())	Retrieves the current date and time in UTC and extracts the hour only, which is 8 hours ahead of local time.	4

Formula	Description	Result
Day(UTCToday())	Retrieves the current date only in UTC and extracts the day, which is 1 day ahead of local time.	12
IsUTCToday(UTCNow())	Tests whether the current date and time is between midnight today and midnight tomorrow, all in UTC time.	**true**
IsUTCToday(UTCToday())	Tests whether the current date is between midnight today and midnight tomorrow, all in UTC time.	**true**

Display a clock that updates in real time

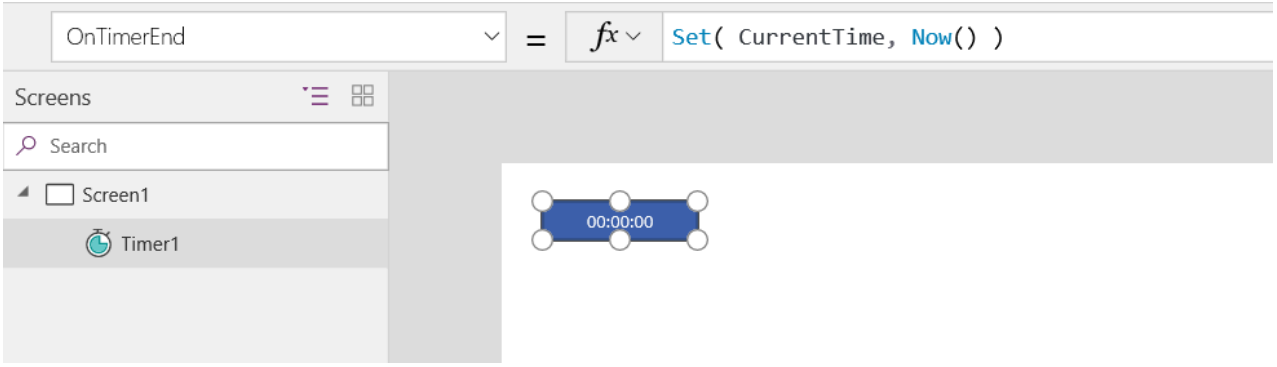
1. Add a Timer control, set its **Duration** property to **1000**, and set its **Repeat** property to **true**.

   The timer will run for one second, automatically start over, and continue that pattern.

2. Set the control's **OnTimerEnd** property to this formula:

   Set(CurrentTime, Now())

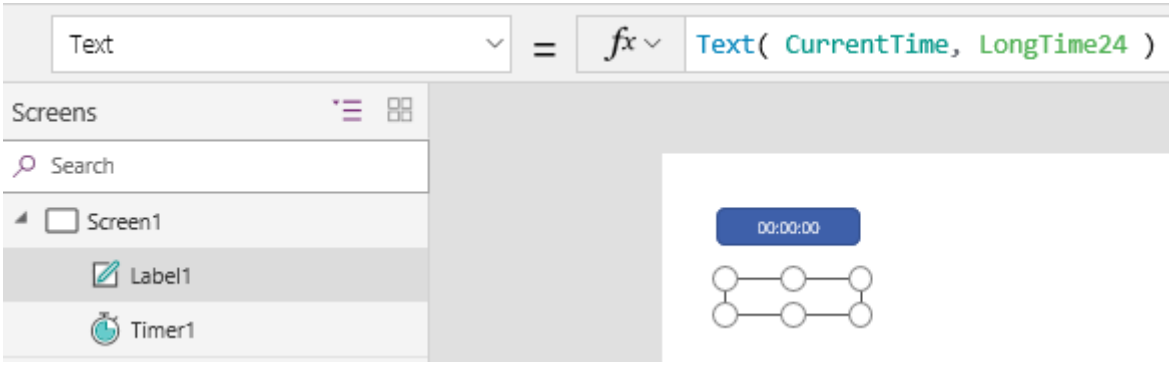
   Whenever the timer starts over (after each second), this formula sets the **CurrentTime** global variable to the current value of the **Now** function.

3. Add a Label control, and set its **Text** property to this formula:

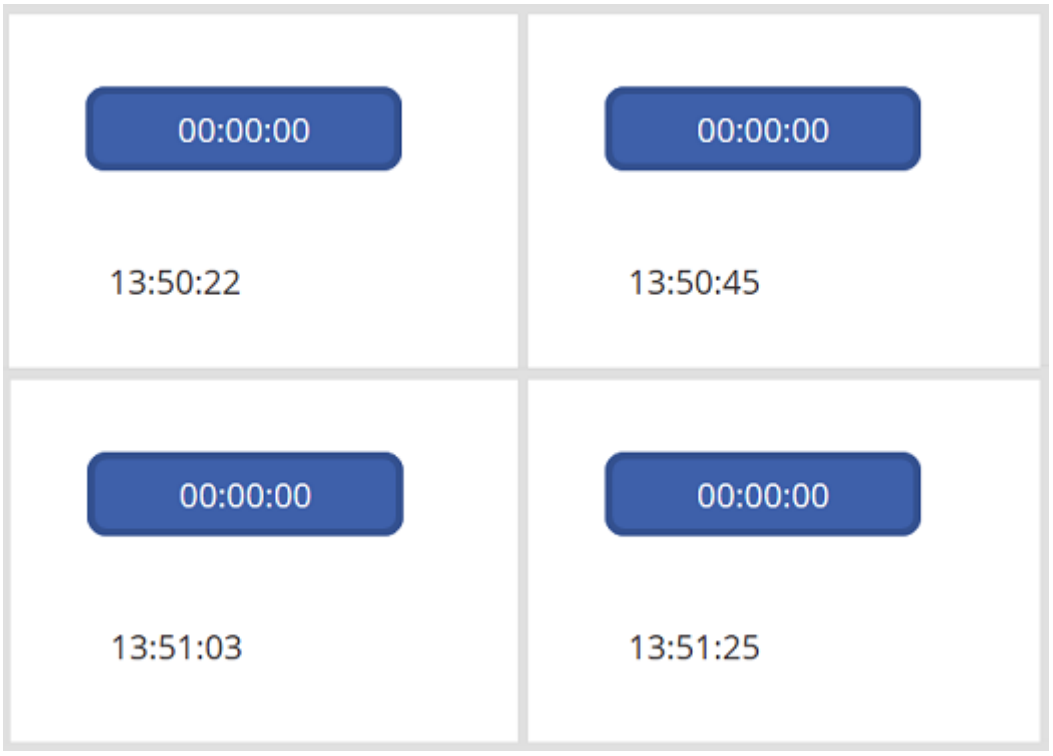
   Text(CurrentTime, LongTime24)

   Use the Text function to format the date and time however you want, or set this property to just **CurrentTime** to show hours and minutes but not seconds.



4. Preview the app by pressing F5, and then start the timer by clicking or tapping it.

   The label continually shows the current time, down to the second.



5. Set the timer's **AutoStart** property to **true** and its **Visible** property to **false**.

   The timer is invisible and starts automatically.

6. Set the screen's OnStart property so that the **CurrentTime** variable has a valid value, as in this example:

   Set(CurrentTime, Now())

   The label appears as soon as the app starts (before the timer runs for a full second).

Display a clock that updates in real time

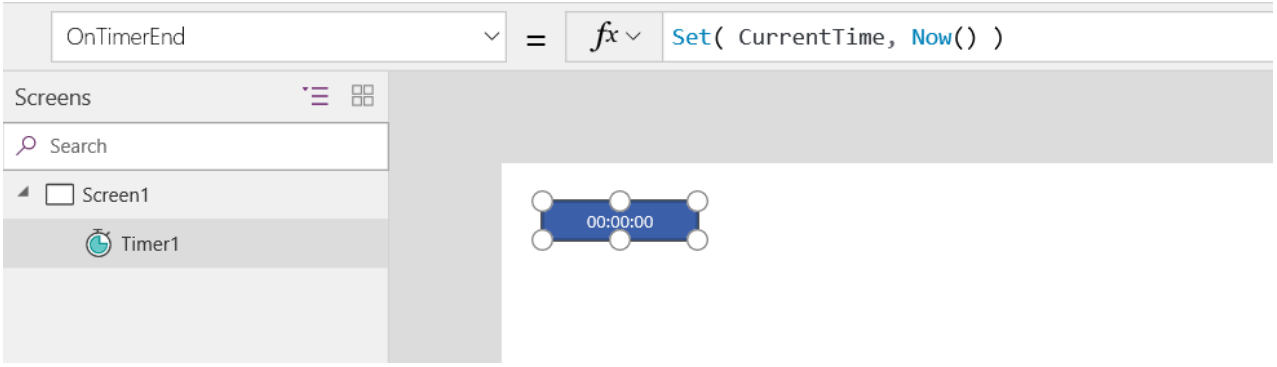
1. Add a Timer control, set its **Duration** property to **1000**, and set its **Repeat** property to **true**.

   The timer will run for one second, automatically start over, and continue that pattern.

2. Set the control's **OnTimerEnd** property to this formula:

   Set(CurrentTime, Now())

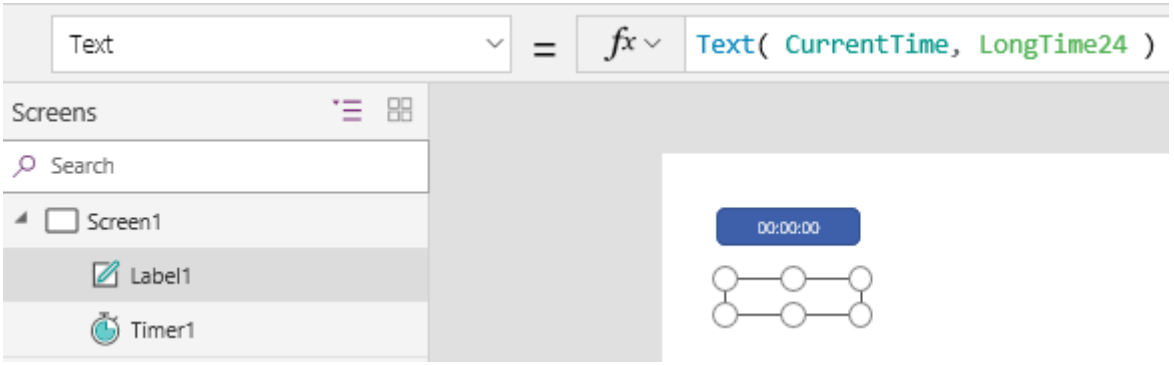
   Whenever the timer starts over (after each second), this formula sets the **CurrentTime** global variable to the current value of the **Now** function.

3. Add a Label control, and set its **Text** property to this formula:

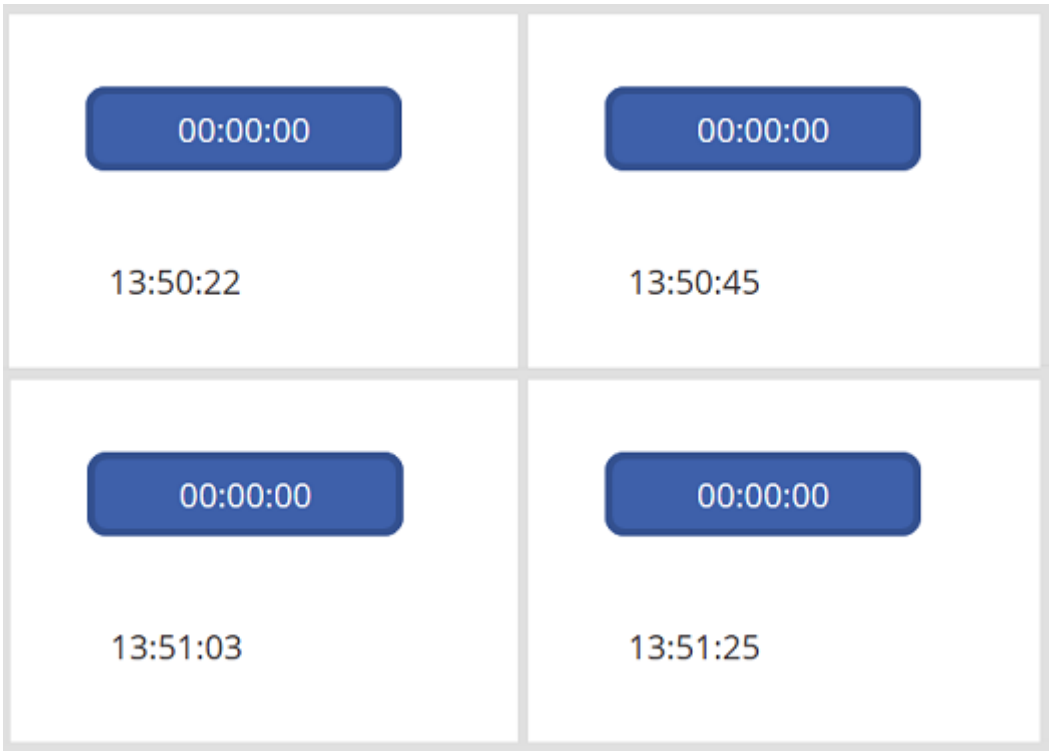
   Text(CurrentTime, LongTime24)

   Use the Text function to format the date and time however you want, or set this property to just **CurrentTime** to show hours and minutes but not seconds.



4. Preview the app by pressing F5, and then start the timer by clicking or tapping it.

   The label continually shows the current time, down to the second.



5. Set the timer's **AutoStart** property to **true** and its **Visible** property to **false**.

   The timer is invisible and starts automatically.

6. Set the screen's OnStart property so that the **CurrentTime** variable has a valid value, as in this example:

   Set(CurrentTime, Now())

   The label appears as soon as the app starts (before the timer runs for a full second).

Validate function

Article • 03/22/2024

Applies to: Canvas apps Model-driven apps

The **Validate** function checks whether the value of a single column or a complete record is valid for a data source.

Description

Before a user submits a data change, you can provide immediate feedback on the validity of that submission, resulting in a better user experience.

Data sources can provide information on what constitutes valid values within a record. This information can include many constraints, such as these examples:

- whether a column requires a value
- how long a string of text can be
- how high and low a number can be
- how early and late a date can be

The **Validate** function uses this information to determine whether a value is valid and to return an appropriate error message if not. You can use the **DataSourceInfo** function to view the same information that **Validate** uses.

Data sources vary in how much validation information they provide, including not providing any at all. **Validate** can only verify values based on this information. Even if **Validate** doesn't find a problem, applying the data change may still fail. You can use the **Errors** function to obtain information about the failure.

If **Validate** finds a problem, the function returns an error message that you can show to the user of the app. If all values are valid, **Validate** returns blank. When you work with a collection that has no validation information, values are always valid.

Syntax

Validate(*DataSource*, *Column*, *Value*)

- *DataSource* – Required. The data source to validate with.
- *Column* – Required. The column to validate.
- *Value* – Required. The value for the selected column to be validated.

Validate(*DataSource*, *OriginalRecord*, *Updates*)

- *DataSource* – Required. The data source to validate with.
- *OriginalRecord* - Required. The record to which updates are to be validated.
- *Updates* - Required. The changes to apply to the original record.

Examples

For these examples, values in the **Percentage** column of the **Scores** data source must be between 0 and 100, inclusive. If the data passes validation, the function returns *blank*. Otherwise, the function returns an error message.

Validate with a single column

Expand table

Formula	Description	Result
Validate(Scores, Percentage, 10)	Checks whether **10** is a valid value for the **Percentage** column in the **Scores** data source.	*blank*
Validate(Scores, Percentage, 120)	Checks whether **120** is a valid value for the **Percentage** column in the **Scores** data source.	"Values must be between 0 and 100."

Validate with a complete record

Expand table

Formula	Description	Result
Validate(Scores, EditRecord, Gallery.Updates)	Checks whether values in all columns are valid for the **Scores** data source. In this example, the value in the **Percentage** column is **10**.	*blank*
Validate(Scores, EditRecord, Gallery.Updates)	Checks whether values in all columns are valid for the **Scores** data source. In this example, the value in the **Percentage** column is **120**.	"Values must be between 0 and 100."

Decimal, Float, and Value functions

06/19/2025

Expand table

Functions	Applies to
Decimal **Float**	✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Power Platform CLI ✅ Dataverse functions
Value	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Converts a string of text or other types to a number.

Description

> **Note**
>
> Power Apps only supports the **Value** function and it returns a **Float** value. Support for the **Decimal** and **Float** functions will be added soon.

Use the **Decimal**, **Float**, and **Value** functions to convert a string of text that contains number characters to a numeric value. Use these function when you need to perform calculations on numbers that were entered as text by a user. These functions can also be used to convert other types to a number, such as date/time and Boolean.

The **Value** function will return the default numeric data type for the Power Fx host you are using, which is usually **Decimal** and the best choice for most situations. Use the **Decimal** and **Float** functions when you need a specific data type for a particular scenario, such as a scientific calculation with a very large number. For more details on working with these data types, see the Numbers section of Data types.

Different languages interpret **,** and **.** differently. By default, the text is interpreted in the language of the current user. You can specify the language to use with a language tag, using the same language tags that are returned by the **Language** function.

Notes on the format of the string:

- The string may be prefixed with the currency symbol for the current language. The currency symbol is ignored. Currency symbols for other languages aren't ignored.

- The string may be include a percent sign (%) at the end, indicating that it's a percentage. The number will be divided by 100 before being returned. Percentages and currency symbols can't be mixed.
- The string may be in scientific notation, with 12 x 10^3 expressed as "12e3".

If the number isn't in a proper format, these functions will return an error.

To convert date and time values, use the **DateValue**, **TimeValue**, or **DateTimeValue** functions.

Syntax

Decimal(*String* [, *LanguageTag*])
Float(*String* [, *LanguageTag*])
Value(*String* [, *LanguageTag*])

- *String* - Required. String to convert to a numeric value.
- *LanguageTag* - Optional. The language tag in which to parse the string. If not specified, the language of the current user is used.

Decimal(*Dynamic*)
Float(*Dynamic*)
Value(*Dynamic*)

- *Dynamic* - Required. **Dynamic** value that represents a number. Acceptable values are dependent on the untyped provider. For **JSON**, the dynamic value is expected to be a JSON number, boolean, or text that can be converted to a number. Keep in mind that locale-related formats are important considerations when communicating with external systems.

Examples

The user running these formulas is located in the United States and has selected English as their language. The **Language** function is returning "en-US". The Power Fx host uses **Decimal** by default.

Value and Decimal

Since we are using a host that has **Decimal** as the default, **Value** and **Decimal** will return the same results.

Expand table

Formula	Description	Result
Value("123.456") **Decimal("123.456")**	The default language of "en-US" will be used, which uses a period as the decimal separator.	123.456 (**Decimal**)
Value("123.456", "es-ES") **Decimal("123.456", "es-ES")**	"es-ES" is the language tag for Spanish in Spain. In Spain, a period is a thousands separator.	123456 (**Decimal**)
Value("123,456") **Decimal("123,456")**	The default language of "en-US" will be used, which uses a comma as a thousands separator.	123456 (**Decimal**)
Value("123,456", "es-ES") **Decimal("123,456", "es-ES")**	"es-ES" is the language tag for Spanish in Spain. In Spain, a comma is the decimal separator.	123.456 (**Decimal**)
Value("12.34%") **Decimal("12.34%")**	The percentage sign at the end of the string indicates that this is a percentage.	0.1234 (**Decimal**)
Value("$ 12.34") **Decimal("$ 12.34")**	The currency symbol for the current language is ignored.	12.34 (**Decimal**)
Value("24e3") **Decimal("24e3")**	Scientific notation for 24 x 10^3.	24000 (**Decimal**)
Value(true) **Decimal(true)**	Converts a Boolean to a number, 0 for *false* and 1 for *true*	1 **Decimal**

Float

The **Float** function will have very close to the same results as above. Since 123.456 cannot be precisely represented in **Float**, the result is an approximation that is very close (123.456000000000003069544618484E2) and compounding rounding errors calculations could result in an unexpected result. The resulting type will be **Float** instead.

Where things diverge is if larger or smaller numbers are used.

Expand table

Formula	Description	Result
Float(1e100)	Because the literal number `1e100` is beyond the range of a **Decimal**, this results in an error before ever calling the **Float** function.	*error (overflow)*
Decimal(1e100)	Same problem as with the **Float** function.	*error (overflow)*

Formula	Description	Result
Float("1e100")	The number in the text string is within the range of **Float** numbers.	1e100 **Float**
Decimal("1e100")	The number in the text string is beyond the range of **Decimal** numbers.	*error (overflow)*
Float("10000000000.0000000001")	The number in the text string is within the range of **Float** numbers. However, the number requires more precision than a **Float** can provide and will be truncated.	1 (**Float**)
Decimal("10000000000.0000000001")	The number in the text string is within both the range and precision of a **Decimal** numbers.	10000000000.0000000001 (**Decimal**)

Average, Max, Min, StdevP, Sum, and VarP functions

Article • 04/20/2025

Expand table

Functions	Applies to
Average **Max** **Min** **Sum**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages
StdevP **VarP**	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Aggregate functions that summarize a set of numbers.

Description

The **Average** function calculates the average, or arithmetic mean, of its arguments.

The **Max** function finds the maximum value.

The **Min** function finds the minimum value.

The **Sum** function calculates the sum of its arguments.

The **StdevP** function calculates the standard deviation of its arguments.

The **VarP** function calculates the variance of its arguments.

You can supply the values for these functions as:

- Separate arguments. For example, **Sum(1, 2, 3)** returns 6.
- A table and a formula to operate over that table. The aggregate will be calculated on the values of the formula for each record.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

These functions operate on numeric values only. Other types of values, such as strings or records, are ignored. Use the **Value** function to convert a string into a number.

The **Average**, **Max**, **Min**, and **Sum** functions can be delegated when used with a data source that supports delegation for these functions. However, **StdevP** and **VarP** can't be delegated for any data sources. If delegation is not supported, only the first portion of the data will be retrieved and then the function applied locally. The result may not represent the complete story. A delegation warning will appear at authoring time to remind you of this limitation and to suggest switching to delegable alternatives where possible. For more information, see the delegation overview.

Syntax

Average(*NumericalFormula1*, [*NumericalFormula2*, ...])
Max(*NumericalFormula1*, [*NumericalFormula2*, ...])
Min(*NumericalFormula1*, [*NumericalFormula2*, ...])
Sum(*NumericalFormula1*, [*NumericalFormula2*, ...])
StdevP(*NumericalFormula1*, [*NumericalFormula2*, ...])
VarP(*NumericalFormula1*, [*NumericalFormula2*, ...])

- *NumericalFormula(s)* - Required. Numeric values to operate on.

Average(*Table*, *NumericalFormula*)
Max(*Table*, *NumericalFormula*)
Min(*Table*, *NumericalFormula*)
Sum(*Table*, *NumericalFormula*)
StdevP(*Table*, *NumericalFormula*)
VarP(*Table*, *NumericalFormula*)

- *Table* - Required. Table to operate on.
- *NumericalFormula* - Required. Formula to evaluate for each record. The result of this formula is used for the aggregation. You can use columns of the table in the formula.

Examples

Step by step

Let's say that you had a data source named **Sales** that contained a **CostPerUnit** column and a **UnitsSold** column, and you set the **Text** property of a label to this function:
Sum(Sales, CostPerUnit * UnitsSold)

The label would show total sales by multiplying the values in those columns for each record and then adding the results from all records together:

Units sold	Cost per unit
30	$150
45	$125
20	$175

Total sales:

$13625

As a different example, let's say that you had sliders that were named **Slider1**, **Slider2**, and **Slider3** and a label with its **Text** property set to this formula:

Sum(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the sum of all values to which the sliders were set.

Average(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the average of all values to which the sliders were set.

Max(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the maximum of all values to which the sliders were set.

Min(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the minimum of all values to which the sliders were set.

StdevP(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the standard deviation of all values to which the sliders were set.

VarP(Slider1.Value, Slider2.Value, Slider3.Value): The label would show the variance of all values to which the sliders were set.

EditForm, NewForm, SubmitForm, ResetForm, and ViewForm functions

Article • 03/22/2024

Applies to: Canvas apps

View, edit, or create an item, save the contents, and reset the controls in an **Edit form** control.

Overview

These functions change the state of the **Edit form** control. The form control can be in one of these modes:

Expand table

Mode	Description
FormMode.Edit	The form is populated with an existing record and the user can modify the values of the fields. Once complete, the user can save the changes to the record.
FormMode.New	The form is populated with default values and the user can modify the values of the fields. Once complete, the user can add the record to the data source.
FormMode.View	The form is populated with an existing record but the user cannot modify the values of the fields.

Description

These functions are often invoked from the **OnSelect** formula of a **Button** or **Image** control so that the user can save edits, abandon edits, or create a record. You can use controls and these functions together to create a complete solution.

These functions return no values.

You can use these functions only in behavior formulas.

SubmitForm

Use the **SubmitForm** function in the **OnSelect** property of a Button control to save any changes in a Form control to the data source.

Before submitting any changes, this function checks for validation issues with any field that's marked as required or that has one or more constraints on its value. This behavior matches that of the **Validate** function.

SubmitForm also checks the **Valid** property of the Form, which is an aggregation of all the **Valid** properties of the **Card** controls that the Form control contains. If a problem occurs, the data isn't submitted, and the **Error** and **ErrorKind** properties of the Form control are set accordingly.

If validation passes, **SubmitForm** submits the change to the data source.

- If successful, the Form's **OnSuccess** behavior runs, and the **Error** and **ErrorKind** properties are cleared. If the form was in **FormMode.New** mode, it is returned to **FormMode.Edit** mode.
- If unsuccessful, the Form's **OnFailure** behavior runs, and the **Error** and **ErrorKind** properties are set accordingly. The mode of the form is unchanged.

EditForm

The **EditForm** function changes the Form control's mode to **FormMode.Edit**. In this mode, the contents of the Form control's **Item** property are used to populate the form. If the **SubmitForm** function runs when the form is in this mode, a record is changed, not created. **FormMode.Edit** is the default for the Form control.

> ⓘ **Note**
>
> When the form is in edit mode and Item is null, data card properties are not evaluated and will return default values.

NewForm

The **NewForm** function changes the Form control's mode to **FormMode.New**. In this mode, the contents of the Form control's **Item** property are ignored, and the default values of the Form's **DataSource** property populate the form. If the **SubmitForm** function runs when the form is in this mode, a record is created, not changed.

ResetForm

The **ResetForm** function resets the contents of a form to their initial values, before the user made any changes. If the form is in **FormMode.New** mode, the form is reset to **FormMode.Edit** mode. The **OnReset** behavior of the form control also runs. You can also reset individual controls with the **Reset** function but only from within the form.

ViewForm

The **ViewForm** function changes the Form control's mode to **FormMode.View**. In this mode, the contents of the Form control's **Item** property are used to populate the form. The **SubmitForm** and **ResetForm** functions have no effect when in this mode.

DisplayMode Property

The current mode can be read through the **Mode** property. The mode also determines the value of the **DisplayMode** property, which can be used by data cards and controls within the form control. Often, the data card's **DisplayMode** property will be set to **Parent.DisplayMode** (referencing the form) as will the control's **DisplayMode** property (referencing the data card):

Expand table

Mode	DisplayMode	Description
FormMode.Edit	**DisplayMode.Edit**	Data cards and controls are editable, ready to accept changes to a record.
FormMode.New	**DisplayMode.Edit**	Data cards and controls are editable, ready to accept a new record.
FormMode.View	**DisplayMode.View**	Data cards and controls are not editable and optimized for viewing.

Syntax

SubmitForm(*FormName*)

- *FormName* - Required. Form control to submit to the data source.

EditForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.Edit** mode.

NewForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.New** mode.

ResetForm(*FormName*)

- *FormName* - Required. Form control to reset to initial values. Also switches the form from **FormMode.New** mode to **FormMode.Edit** mode.

ViewForm(*FormName*)

- *FormName* - Required. Form control to switch to **FormMode.View** mode.

Examples

See Understand data forms for complete examples.

1. Add a Button control, set its **Text** property to show **Save**, and set its **OnSelect** property to this formula:

   SubmitForm(EditForm)

2. Set the **OnFailure** property of a Form control to blank and its **OnSuccess** property to this formula:

   Back()

3. Name a **Label** control **ErrorText**, and set its **Text** property to this formula:

   EditForm.Error

   When the user selects the **Save** button, any changes in the Form control are submitted to the underlying data source.

   - If the submission succeeds, any changes are saved or, if the Form control is in **New** mode, a record is created. **ErrorText** is *blank* and the previous screen reappears.
   - If the submission fails, **ErrorText** shows a user-friendly error message, and the current screen remains visible so that the user can correct the problem and try again.

4. Add a Button control, set its **Text** property to show **Cancel**, and set its **OnSelect** property to this formula:

   ResetForm(EditForm); Back()

   When the user selects the **Cancel** button, the values in the Form control are reset to what they were before the user started to edit it, the previous screen reappears,

and the Form control is returned to **Edit** mode if it was in **New** mode.

5. Add a Button control, set its Text property to show **New**, and set its OnSelect property to this formula:

   NewForm(EditForm); Navigate(EditScreen, None)

   When the user selects the **New** button, the Form control switches to **New** mode, the default values for the Form control's data source populate that control, and the screen that contains the Form control appears. When the **SubmitForm** function runs, a record is created instead of updated.

Day, Month, Year, Hour, Minute, Second, and Weekday functions

Article • 06/10/2024

Applies to: Canvas apps Dataverse formula columns Desktop flows Model-driven apps Power Pages Power Platform CLI

Returns individual components of a Date/Time value.

Description

The **Day** function returns the day component of a Date/Time value, ranging from 1 to 31.

The **Month** function returns the month component of a Date/Time value, ranging from 1 to 12.

The **Year** function returns the year component of a Date/Time value, starting with 1900.

The **Hour** function returns the hour component of a Date/Time value, ranging from 0 (12:00 AM) to 23 (11:00 PM).

The **Minute** function returns the minute component of a Date/Time value, ranging from 0 to 59.

The **Second** function returns the second component of a Date/Time value, ranging from 0 to 59.

The **Weekday** function returns the weekday of a Date/Time value. By default, the result ranges from 1 (Sunday) to 7 (Saturday). You can specify a different range with a Microsoft Excel Weekday function code or a StartOfWeek enumeration value:

Expand table

Excel code	StartOfWeek enumeration	Description
1, 17	StartOfWeek.Sunday	Numbers 1 (Sunday) through 7 (Saturday). Default.
2, 11	StartOfWeek.Monday	Numbers 1 (Monday) through 7 (Sunday).
3	StartOfWeek.MondayZero	Numbers 0 (Monday) through 6 (Sunday).
12	StartOfWeek.Tuesday	Numbers 1 (Tuesday) through 7 (Monday).

Excel code	StartOfWeek enumeration	Description
13	**StartOfWeek.Wednesday**	Numbers 1 (Wednesday) through 7 (Tuesday).
14	**StartOfWeek.Thursday**	Numbers 1 (Thursday) through 7 (Wednesday).
15	**StartOfWeek.Friday**	Numbers 1 (Friday) through 7 (Thursday).
16	**StartOfWeek.Saturday**	Numbers 1 (Saturday) through 7 (Friday).

All functions return a number.

See working with dates and times for more information.

Syntax

Day(*DateTime*)
Month(*DateTime*)
Year(*DateTime*)
Hour(*DateTime*)
Minute(*DateTime*)
Second(*DateTime*)

- *DateTime* - Required. Date/Time value to operate on.

Weekday(*DateTime* [, *WeekdayFirst*])

- *DateTime* - Required. Date/Time value to operate on.
- *WeekdayFirst* - Optional. Excel code specifying which day starts the week. If not supplied, 1 (Sunday first) is used.

Examples

For the following example, the current time is **3:59:37 PM** on **Thursday, April 9, 2015**.

Expand table

Formula	Description	Result
Year(Now())	Returns the year component of the current time and date.	2015
Month(Now())	Returns the month component of the current time and date.	4

Formula	Description	Result
Day(Now())	Returns the day component of the current time and date.	9
Hour(Now())	Returns the hour component of the current time and date.	15
Minute(Now())	Returns the minute component of the current time and date.	59
Second(Now())	Returns the second component of the current time and date.	37
Weekday(Now())	Returns the weekday component of the current time and date, using the default start of the week as Sunday.	5
Weekday(Now(), 14)	Returns the weekday component of the current time and date, using an Excel code to specify the start of the week as Thursday.	1
Weekday(Now(), StartOfWeek.Wednesday)	Returns the weekday component of the current time and date, using a **StartOfWeek** enumeration to specify the start of the week as Wednesday.	2

WeekNum and ISOWeekNum functions

Article • 04/20/2025

Expand table

Function	Applies to
ISOWeekNum	✅ Canvas apps ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Pages
WeekNum	✅ Canvas apps ✅ Cards ✅ Copilot Studio ✅ Desktop flows ✅ Dataverse formula columns ✅ Model-driven apps ✅ Power Platform CLI ✅ Dataverse functions ✅ Power Pages

Returns the week number of a specific date.

Description

Use the **WeekNum** and **ISOWeekNum** functions to determine the week number of a date.

These functions differ in how they determine the first week of the year (week 1):

- **WeekNum** uses the week containing January 1 as the first week of the year. The result from this function can range from 1 to 54.
- **ISOWeekNum** uses the week containing the first Thursday of the year as the first week of the year. This follows the ISO 8601 date and time standard definition for week numbering. The result from this function can range from 1 to 53. It is possible that 52 or 53 may be returned for the first days of January since the dates could belong to the last week of the previous year.

Use the second parameter to **WeekNum** to specify which day begins a week. You can provide either an Excel code number or use the StartOfWeek enumeration:

Expand table

Excel code	StartOfWeek enumeration	Description
1, 17	**StartOfWeek.Sunday**	Week begins on Sunday. Default.
2, 11	**StartOfWeek.Monday**	Week begins on Monday.
12	**StartOfWeek.Tuesday**	Week begins on Tuesday.
13	**StartOfWeek.Wednesday**	Week begins on Wednesday.

Excel code	StartOfWeek enumeration	Description
14	**StartOfWeek.Thursday**	Week begins on Thursday.
15	**StartOfWeek.Friday**	Week begins on Friday.
16	**StartOfWeek.Saturday**	Week begins on Saturday.

ISOWeekNum always uses Monday as the start of the week. In Excel, the **WeekNum** function supports an addition code **21** that is not supported here; use **ISOWeekNum** instead.

If you pass a single number to these functions, the return value is a single result. If you pass a single-column table that contains numbers, the return value is a single-column table of results, one result for each record in the argument's table. If you have a multi-column table, you can shape it into a single-column table, as working with tables describes.

Syntax

WeekNum(*DateTime* [, *StartOfWeek*])

- *DateTime* - Required. Date/Time value to operate on.
- *StartOfWeek* - Optional. Excel code or StartOfWeek enumeration that determines which day the week begins.

ISOWeekNum(*DateTime*)

- *DateTime* - Required. Date/Time value to operate on. The week always begins on Monday.

Examples

First and last calendar weeks of 2021

Expand table

Date	WeekNum(Date)	ISOWeekNum(Date)	WeekNum(Date, StartOfWeek.Wednesday)
Friday, January 1, 2021	1	53	1
Saturday, January 2, 2021	1	53	1
Sunday, January 3, 2021	2	53	1
Monday, January 4, 2021	2	1	1
Tuesday, January 5, 2021	2	1	1

Date	WeekNum(Date)	ISOWeekNum(Date)	WeekNum(Date, StartOfWeek.Wednesday)
Wednesday, January 6, 2021	2	1	2
Thursday, January 7, 2021	2	1	2
Saturday, December 25, 2021	52	51	52
Sunday, December 26, 2021	53	51	52
Monday, December 27, 2021	53	52	52
Tuesday, December 28, 2021	53	52	52
Wednesday, December 29, 2021	53	52	53
Thursday, December 30, 2021	53	52	53
Friday, December 31, 2021	53	52	53

With function

Article • 06/10/2024

Applies to: ✅ Canvas apps ✅ Desktop flows ✅ Model-driven apps ✅ Power Pages ✅ Power Platform CLI

Calculates values and performs actions for a single record, including inline records of named values.

Description

The **With** function evaluates a formula for a single record. The formula can calculate a value and/or perform actions, such as modifying data or working with a connection. Use the **ForAll** function to evaluate a formula for all the records in a table of records.

Fields of the record currently being processed are available within the formula. Use the **ThisRecord** operator or simply reference fields by name as you would any other value. The **As** operator can also be used to name the record being processed which can help make your formula easier to understand and make nested records accessible. For more information, see the examples below and working with record scope.

Use **With** to improve the readability of complex formulas by dividing it into smaller named sub-formulas. These named values act like simple local variables confined to the scope of the **With**. The same inline record syntax that is used with the **UpdateContext** function can be used with **With**. Using **With** is preferred over context or global variables as it is self contained, easy to understand, and can be used in any declarative formula context.

Use **With** to access the fields of the record that are returned by functions such as **Patch** or **Match**. **With** holds the value from these functions long enough to be used in further calculations or actions.

If the *Record* argument to **With** is an error, that error will be returned by the function and the *Formula* will not be evaluated.

Syntax

With(*Record*, *Formula*)

- *Record* – Required. The record to be acted upon. For names values, use the inline syntax `{ name1: value1, name2: value2, ... }`

- *Formula* – Required. The formula to evaluate for *Record*. The formula can reference any of the fields of *Record* directly as a record scope.

Examples

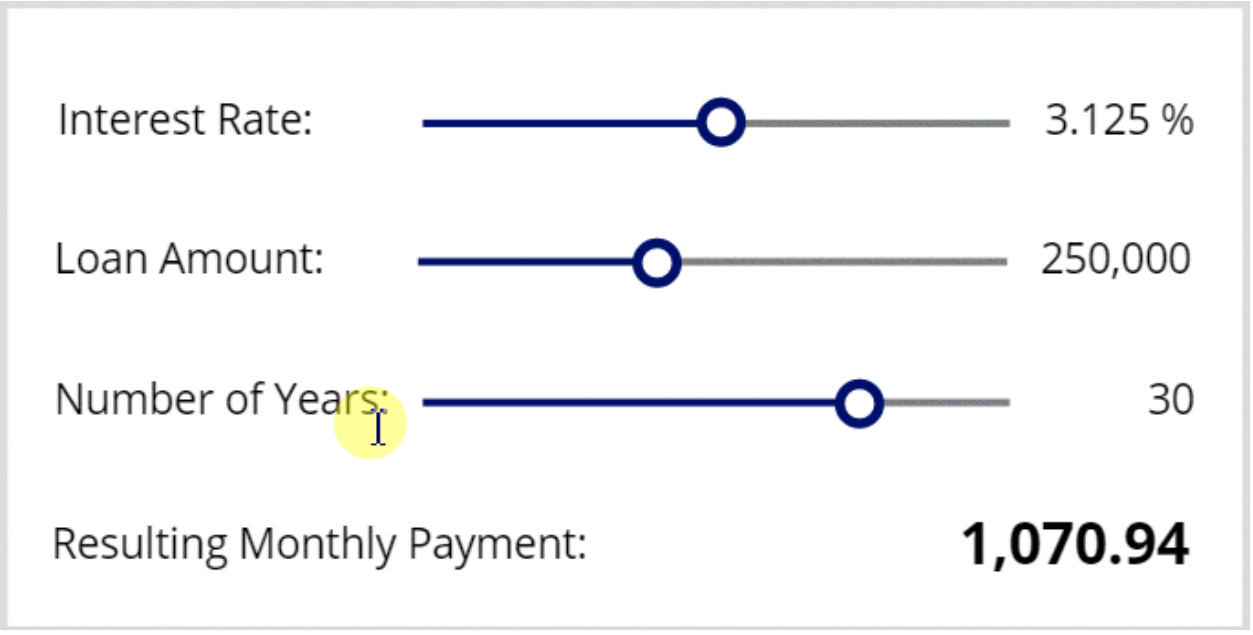
Simple named values

Power Apps

```
With( { radius: 10,
        height: 15 },
    Pi() * (radius*radius) * height
)
// Result: 4712.38898038 (as shown in a label control)
```

This example uses a record of named values to calculate the volume of a cylinder. **With** is being used to capture all the input values together, making it easy to separate them from the calculation itself.

Nested With



Power Apps

```
With( { AnnualRate: RateSlider/8/100,        // slider moves in 1/8th
increments and convert to decimal
        Amount: AmountSlider*10000,          // slider moves by 10,000
increment
        Years: YearsSlider,                  // slider moves in single year
increments, no adjustment required
```

```
        AnnualPayments: 12 },                // number of payments per year
      With( { r: AnnualRate/AnnualPayments,  // interest rate
              P: Amount,                     // loan amount
              n: Years*AnnualPayments },     // number of payments
            r*P / (1 - (1+r)^-n)             // standard interest
calculation
      )
)
```

This example nests **With** functions to create a two-tier calculation for monthly mortgage payments. As long as there is no conflict, all of the outer **With** named values are available within the inner **With**.

Since the slider controls can only move in increments of 1, the sliders are divided or multiplied to create effectively a custom increment. In the case of the interest rate, the **RateSlider** has its **Max** property set to **48**, divided by 8 for a 1/8 percentage point increment and divided by 100 to convert from a percentage to a decimal, covering the range 0.125% to 6%. In the case of of the loan amount, the **AmountSlider** has its **Max** property set to **60** and multiplied by 10,000, covering the range 10,000 to 600,000.

The **With** is automatically recalculated as the sliders move and the new loan payment displayed. No variables are used and there is no need to use the **OnChange** property of the slider controls.

Here are the detailed instructions for creating this app:

1. Create a new app.
2. Add a **Slider** control and name it **RateSlider**. Set its **Max** property to 48.
3. Add a **Label** control to the left of the slider control. Set its **Text** property to **"Interest Rate:"**.
4. Add a **Label** control to the right of the slider control. Set its **Text** property to the formula **RateSlider/8 & " %"**.
5. Add another **Slider** control and name it **AmountSlider**. Set its **Max** property to 60.
6. Add a **Label** control to the left of this slider control. Set its **Text** property to **"Loan Amount:"**.
7. Add a **Label** control to the right of this slider control. Set its **Text** property to the formula **AmountSlider/8 * 10000**.
8. Add another **Slider** control and name it **YearsSlider**. Set its **Max** property to 40.
9. Add a **Label** control to the left of this slider control. Set its **Text** property to **"Number of Years:"**.
10. Add a **Label** control to the right of this slider control. Set its **Text** property to the formula **YearsSlider**.
11. Add a **Label** control and set its **Text** property to the formula shown above.

12. Add a **Label** control to the left of the last label control. Set its **Text** property to "**Recurring Monthly Payment:**".

Primary key returned from Patch

Power Apps

```
With( Patch( Orders, Defaults( Orders ), { OrderStatus: "New" } ),
      ForAll( NewOrderDetails,
              Patch( OrderDetails, Defaults( OrderDetails ),
                     { Order: OrderID,          // from With's first
argument, primary key of Patch result
                       Quantity: Quantity,      // from ForAll's
NewOrderDetails table
                       ProductID: ProductID }   // from ForAll's
NewOrderDetails table
              )
      )
)
```

This example adds a record to the **Order** table in SQL Server. It then uses the returned primary key for the order, returned by the **Patch** function in the **OrderID** field, to create related records in the **OrderDetails** table.

Extracted values with a regular expression

Power Apps

```
With(
    Match( "PT2H1M39S", "PT(?:(?<hours>\d+)H)?(?:(?<minutes>\d+)M)?(?:(?
<seconds>\d+)S)?" ),
    Time( Value( hours ), Value( minutes ), Value( seconds ) )
)
// Result: 2:01 AM (as shown in a label control, use the Text function to
see the seconds)
```

This example extracts the hours, minutes, and seconds from an ISO 8601 duration value and then uses these sub-matches to create a Date/Time value.

Note that although the sub-matches contain numbers they are still in a text string. Use the **Value** function to convert to a number before performing mathematical operations.

Map a record in a component

See Map record.

Day, Month, Year, Hour, Minute, Second, and Weekday functions

Article • 06/10/2024

Applies to: Canvas apps Dataverse formula columns Desktop flows Model-driven apps Power Pages Power Platform CLI

Returns individual components of a Date/Time value.

Description

The **Day** function returns the day component of a Date/Time value, ranging from 1 to 31.

The **Month** function returns the month component of a Date/Time value, ranging from 1 to 12.

The **Year** function returns the year component of a Date/Time value, starting with 1900.

The **Hour** function returns the hour component of a Date/Time value, ranging from 0 (12:00 AM) to 23 (11:00 PM).

The **Minute** function returns the minute component of a Date/Time value, ranging from 0 to 59.

The **Second** function returns the second component of a Date/Time value, ranging from 0 to 59.

The **Weekday** function returns the weekday of a Date/Time value. By default, the result ranges from 1 (Sunday) to 7 (Saturday). You can specify a different range with a Microsoft Excel Weekday function code or a StartOfWeek enumeration value:

Expand table

Excel code	StartOfWeek enumeration	Description
1, 17	StartOfWeek.Sunday	Numbers 1 (Sunday) through 7 (Saturday). Default.
2, 11	StartOfWeek.Monday	Numbers 1 (Monday) through 7 (Sunday).
3	StartOfWeek.MondayZero	Numbers 0 (Monday) through 6 (Sunday).
12	StartOfWeek.Tuesday	Numbers 1 (Tuesday) through 7 (Monday).

Excel code	StartOfWeek enumeration	Description
13	**StartOfWeek.Wednesday**	Numbers 1 (Wednesday) through 7 (Tuesday).
14	**StartOfWeek.Thursday**	Numbers 1 (Thursday) through 7 (Wednesday).
15	**StartOfWeek.Friday**	Numbers 1 (Friday) through 7 (Thursday).
16	**StartOfWeek.Saturday**	Numbers 1 (Saturday) through 7 (Friday).

All functions return a number.

See working with dates and times for more information.

Syntax

Day(*DateTime*)
Month(*DateTime*)
Year(*DateTime*)
Hour(*DateTime*)
Minute(*DateTime*)
Second(*DateTime*)

- *DateTime* - Required. Date/Time value to operate on.

Weekday(*DateTime* [, *WeekdayFirst*])

- *DateTime* - Required. Date/Time value to operate on.
- *WeekdayFirst* - Optional. Excel code specifying which day starts the week. If not supplied, 1 (Sunday first) is used.

Examples

For the following example, the current time is **3:59:37 PM** on **Thursday, April 9, 2015**.

Expand table

Formula	Description	Result
Year(Now())	Returns the year component of the current time and date.	2015
Month(Now())	Returns the month component of the current time and date.	4

Formula	Description	Result
Day(Now())	Returns the day component of the current time and date.	9
Hour(Now())	Returns the hour component of the current time and date.	15
Minute(Now())	Returns the minute component of the current time and date.	59
Second(Now())	Returns the second component of the current time and date.	37
Weekday(Now())	Returns the weekday component of the current time and date, using the default start of the week as Sunday.	5
Weekday(Now(), 14)	Returns the weekday component of the current time and date, using an Excel code to specify the start of the week as Thursday.	1
Weekday(Now(), StartOfWeek.Wednesday)	Returns the weekday component of the current time and date, using a **StartOfWeek** enumeration to specify the start of the week as Wednesday.	2

Create a canvas app from within a solution

Article • 12/16/2022

Create an app from within a solution if, for example, you want to deploy the app to a different environment. Solutions can contain not only apps but also customized tables, choices, and other components. You can quickly customize an environment in a variety of ways by creating apps and other components from within a solution, exporting the solution, and then importing it into another environment.

For more information about solutions, see Solutions overview.

Prerequisite

To follow the steps in this topic, you must switch to an environment that contains a Microsoft Dataverse database.

> **Note**
>
> To use or run a flow in a canvas app that is included in a **solution**, you must be assigned a Dataverse security role with the Read privilege on the **Process (Workflow)** table. For more information about security roles and privileges in Dataverse, see **Security roles and privileges**.

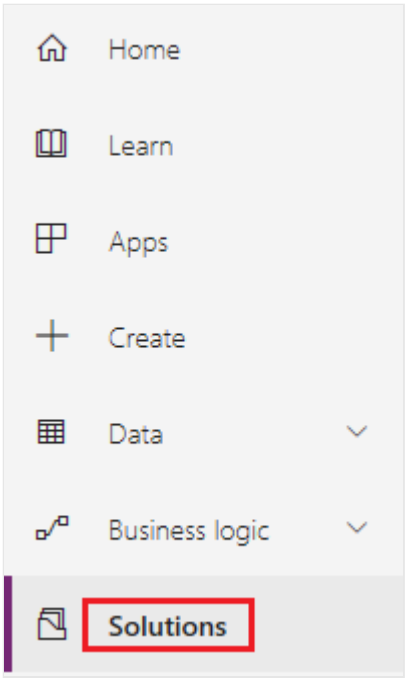
Create a solution

You can skip this procedure if you already have a solution in which you want to create an app or to which you want to link an app.

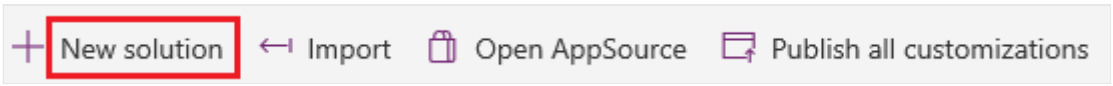
1. Sign in to Power Apps, and then (if necessary) switch to the appropriate environment:

   - If you want to create an app from within a solution, switch to any environment that contains a Dataverse database.
   - If you want to link an existing app to a solution, switch to the environment that contains that app.

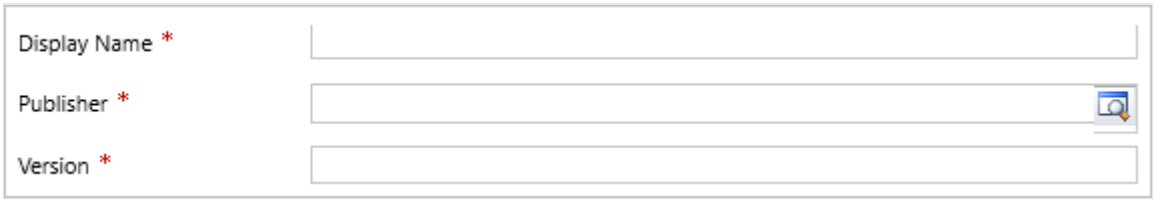
2. In the left navigation bar, select **Solutions**.



3. In the banner under the title bar, select **New solution**.

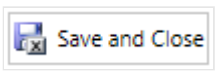


4. In the window that appears, specify a display name, a publisher, and a version for your solution.



A name (with no spaces) will be generated automatically based on the display name that you specify, but you can customize the generated name if you want. You can specify the default publisher for your environment and **1.0** for the version if you don't have specific needs in those areas.

5. Near the upper-left corner, select **Save and Close**.



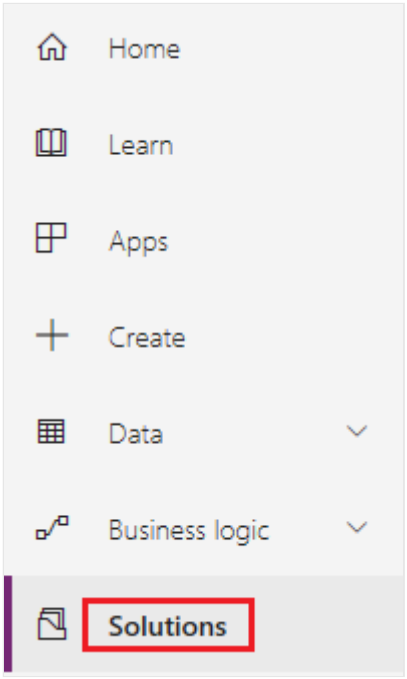
Create a canvas app in a solution

You can create a blank canvas app from within a solution. You can't automatically generate a three-screen app or customize a template or sample app from within a solution.

1. Sign in to Power Apps.

2. If necessary, switch to the environment that contains the solution in which you want to create a canvas app.

3. In the left navigation bar, select **Solutions**.



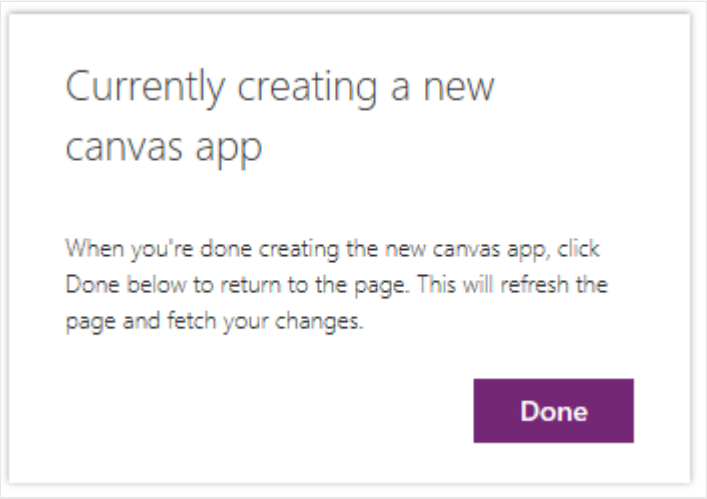
4. In the list of solutions, select the solution in which you want to create a canvas app.

5. In the banner under the title bar, select **New** > **App** > **Canvas app**, and then select the form factor (phone or tablet) of the app that you want to create.

   Power Apps Studio opens with a blank canvas in another browser tab.

6. Create your app (or make at least one change), and then save your changes.

7. On the browser tab where you selected your solution, select **Done** to refresh the list of components in your solution.

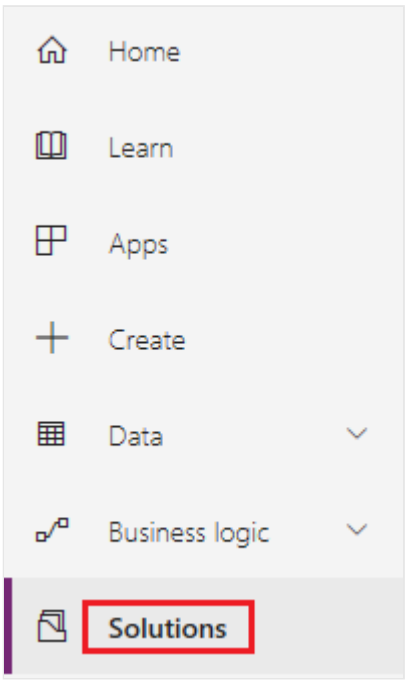


Your new app appears in the list of components for that solution. If you save any changes to your app, they will be reflected in the version that's in the solution.

Add an existing canvas app to a solution

If you want to add an app to a solution, both must be in the same environment, and the app must have been created from within a solution.

1. Sign in to Power Apps.
2. If necessary, switch to the environment that contains the solution to which you want to link an app.
3. In the left navigation bar, select **Solutions**.

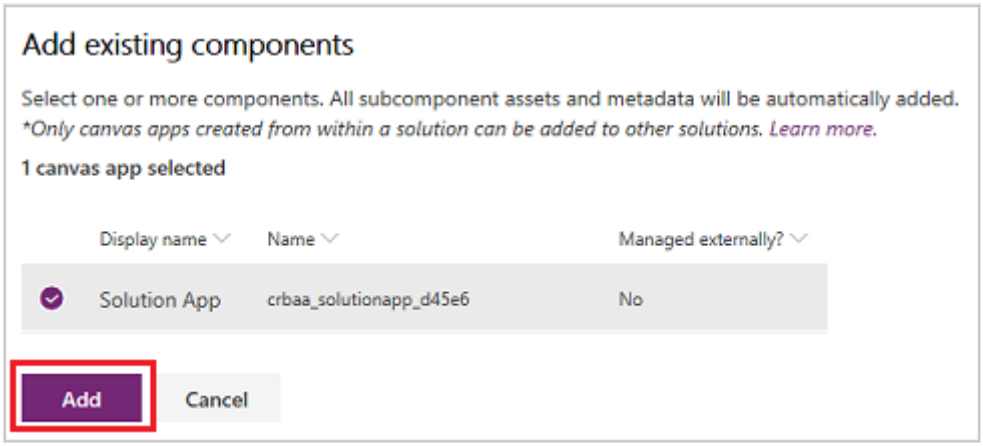


4. In the list of solutions, select the solution to which you want to link an app.

5. In the banner under the title bar, select **Add existing** > **App** > **Canvas app**.

   A list of canvas apps that were created within a solution in this environment appears.

6. In the list of apps, select the app that you want to link to the solution, and then select **Add**.



Known limitations

For information about known limitations, see Solutions overview.

Next steps

- Create or link more apps and other components, such as tables, flows, and dashboards, to your solution.
- Export your solution so that you can deploy it to another environment, on AppSource, and so forth.

Add canvas apps to solution by default (preview)

Add canvas apps and cloud flows to a solution by default

You can create a canvas app in a solution in Power Apps or create a cloud flow in a solution in Power Automate. Creating a canvas app or a cloud flow in a solution previously required manual steps. Now you can create them in a solution by default.

Because canvas apps and cloud flows in a solution are defined in Microsoft Dataverse, you can use Dataverse capabilities to manage them, including connection references, environment variables, the Dataverse API, role-based security, and solution-based application lifecycle management (ALM).

> **Important**
>
> - The canvas apps setting is a preview feature.
> - Preview features aren't meant for production use and might have restricted functionality. These features are subject to supplemental terms of use, and are available before an official release so that customers can get early access and provide feedback.

Prerequisites

- Solutions are stored in Dataverse, so the environment must have a Dataverse database to use this feature. If yours doesn't, add a Dataverse database.
- To create canvas apps in solutions, you must have **write** privileges to the CanvasApp table. To create cloud flows in solutions, you should have the Environment Maker role. Learn more in Security roles and privileges.
- A canvas app or cloud flow in a solution must be shared with you before you can view or edit it.

> **Important**
>
> Before you enable the creation of canvas apps and cloud flows in solutions by default, review the Considerations section in this article.

Supported creation methods and entry points

Several methods and entry points are available for creating canvas apps and cloud flows.

Canvas apps creation methods and entry points

The following table summarizes the methods that allow you to create canvas apps in a solution by default.

Expand table

Method	Available for canvas apps in a solution by default?
Create a canvas app from Dataverse	Yes
Create a canvas app from other data sources, such as SharePoint, Excel, Azure Blob Storage, and others	Yes
Create a blank canvas app **NOTE**: Power Apps > **Apps** > **New app** > **Canvas** also creates a blank canvas app.	Yes
Create a canvas app from a template	No
Create a canvas app by customizing SharePoint forms	No

Cloud flows creation methods and entry points

The following table summarizes the methods that allow you to create cloud flows in a solution by default.

Expand table

Method	Available for cloud flows in a solution by default?
Create a cloud flow from blank in a portal	Yes
Create a cloud flow from a template in a portal	Yes
Create a cloud flow from Power Automate Management connector	Yes
Create a cloud flow from PowerShell	Yes
Create a cloud flow from Power Apps	Yes
Create a cloud flow from Teams	Yes
Create a cloud flow from OneDrive	Yes

Method	Available for cloud flows in a solution by default?
Create a cloud flow from Dynamics 365	Yes
Create a cloud flow from the Excel add-in	Yes
Create a cloud flow from the Power Automate mobile app	Yes
Create a cloud flow from SharePoint	Yes
Create a cloud flow from Project Roadmap	Yes

> **Important**
>
> Unsupported entry points will fail to create any cloud flow until that support is added to create a solution cloud flow with that entry point. You must first create a cloud flow in a solution using a supported method.

Manage feature settings for Cloud flows and Canvas apps in Dataverse solutions

You can control whether makers can create new canvas apps and cloud flows directly in Dataverse solutions.

Existing environments

1. Sign in to the Power Platform admin center and select an environment.
2. Go to **Settings** > **Product** > **Features**.
3. Under **Create new canvas apps and cloud flows in Dataverse solutions**, turn on **Canvas apps (Preview)** or **Cloud flows** as desired.

New environments

- All new environments provisioned with a Dataverse database have the **Cloud flows** setting enabled by default.
- The **Canvas apps (Preview)** setting is also enabled by default, though it remains in preview.
- If you prefer not to use these features, you must manually disable them in the environment settings.

Learn more about managing feature settings in Manage feature settings.

View canvas apps and cloud flows in solutions

To view canvas app and cloud flow objects in a solution, use the solution view. You must have access to the object added inside a solution to view it in a solution view.

Export and import using solutions

Once the feature is enabled, use solutions export and import instead of exporting and importing legacy packages of canvas apps and flows. Legacy packages can be imported in environments with the environment setting turned off.

Move flows into a solution with PowerShell

Use the Add-AdminFlowsToSolution cmdlet to move non-solution Power Automate flows into a solution for better lifecycle management and deployment. This command lets you migrate multiple flows by specifying environment and solution IDs, and targeting flows by name or ID. For more information, see Microsoft.PowerApps.Administration.PowerShell Module.

Considerations

Take the following considerations into account before you decide to create canvas apps and cloud flows in a solution by default.

- Your Dataverse environment capacity consumption and related cost might increase.
- Known solution limitations related to canvas apps still apply to canvas apps created in solutions by default.
- This feature automatically creates environment variables when you add data sources for your apps.
- By default, this feature saves all canvas apps to the default solution, **Common Data Services Default Solution**, published by **Microsoft Dataverse Default Publisher**. However, we recommend that you save your canvas apps to a different solution. Learn more about adding existing canvas apps to solutions.
- When you turn the feature on or off for canvas apps and cloud flows in the Power Platform admin center, the Dataverse properties `enablecanvasappsinsolutionsbydefault` and `enableFlowsInSolutionByDefault` in the organization table are updated. You can view the value of these properties using the following sample ODATA snippet: `[org URI]/api/data/v9.0/organizations`. Learn more in Organization table reference.
- If you're planning to change the prefix for the default publisher or solution for your environment, you can learn more in Solution publisher prefix, Create solution publisher

prefix and Change solution publisher prefix.
- Non-solution canvas apps and non-solution cloud flows can be added into a solution to add them into Dataverse, but there's no way to revert back.

Improvements

The following scenarios were improved to support cloud flows and canvas apps defined in Dataverse:

- The **Monitor** > **Cloud flow activity** page now supports solution cloud flows.
- The List My Flows API doesn't return any solution cloud flows.
- Audit log events for cloud flow permissions that provide visibility into sharing now include solution cloud flows.
- The List Flows as Admin API now returns solution cloud flows that weren't previously turned on (published). This API now returns all non-solution and solution cloud flows.
- Flows with delegated authentication to Roadmap can be added into a solution and migrated to Dataverse.
- Flows with delegated authentication to SharePoint can be added into a solution and migrated to Dataverse.

Is this feature generally available or preview?

As of October 29, 2024, the cloud flows setting is generally available. The canvas apps setting remains in preview.

The cloud flows setting continues to be off by default and optional.

Does putting flows into Dataverse use Dataverse capacity?

Moderately. Flow definitions use a small amount of Dataverse storage. A large flow definition could reach 10 KB. With this worst case scenario: 10,000 flows x 10 KB = 100 MB or 0.1 GB. The small increase in Dataverse storage used provides significant benefits, since solution cloud flows are needed to leverage capabilities including application lifecycle management (ALM), governance with Dataverse, automation center, drafts and versioning, and expanded security capabilities.

Install Northwind Traders database and apps

Article • 03/11/2023

By following the steps in this series of topics, you can discover concepts about relational data as implemented in a sample database in Microsoft Dataverse. You can also explore sample business apps, both canvas and model-driven, for managing that data and earn practical experience by creating such an app. This first topic explains how to install the Northwind Traders database in your own environment and gain access to the sample apps, which you can open for editing to reveal how they were built.

Northwind Traders is a fictitious organization that manages orders, products, customers, suppliers, and many other aspects of a small business. This sample appeared with the first versions of Microsoft Access and is still available as an Access template.

Prerequisites

- A Power Apps license that supports Dataverse. You can use a free trial license for 30 days.
- An environment with a Dataverse database. You can create such an environment if you have appropriate permissions.

Download the solution

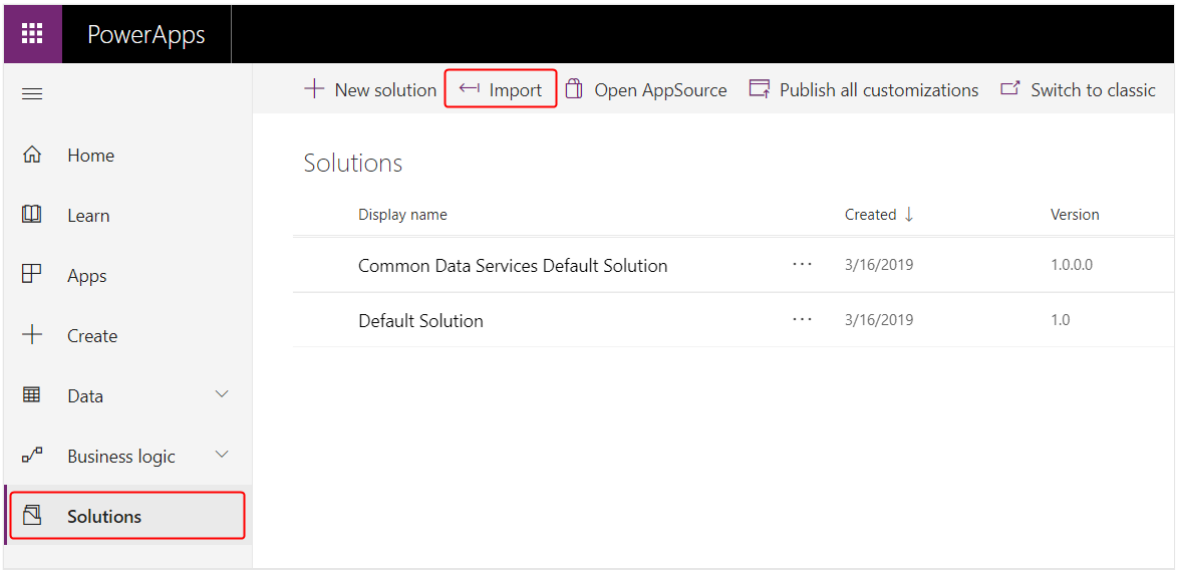
Download the Northwind Traders Solution File

This solution file (.zip) contains the definitions of tables, choices, and business processes; the canvas and model-driven apps; and any other pieces that are used together.

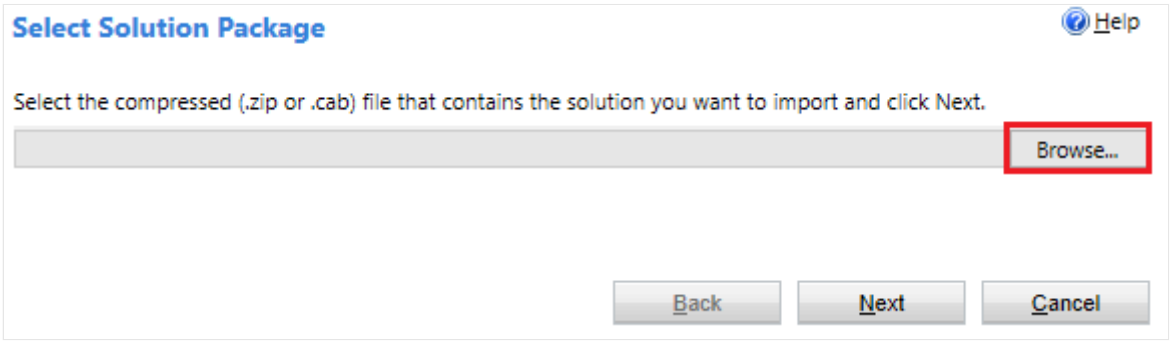
Install the solution

1. Sign in to Power Apps, and then ensure that you're working in an environment that contains a Dataverse database.

2. In the left navigation pane, select **Solutions**. If the item isn't in the left navigation pane, select ...More and then select the item you want. Then select **Import** in the toolbar near the top of the screen:



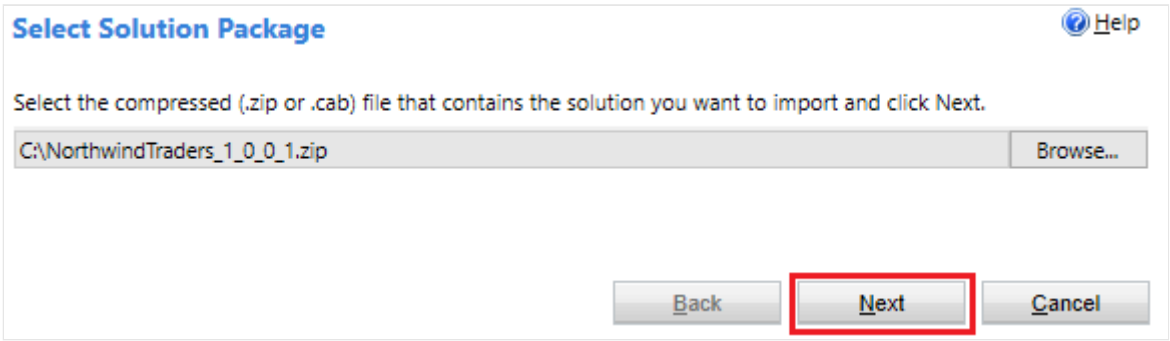
3. In the **Select Solution Package** page, select **Browse**.



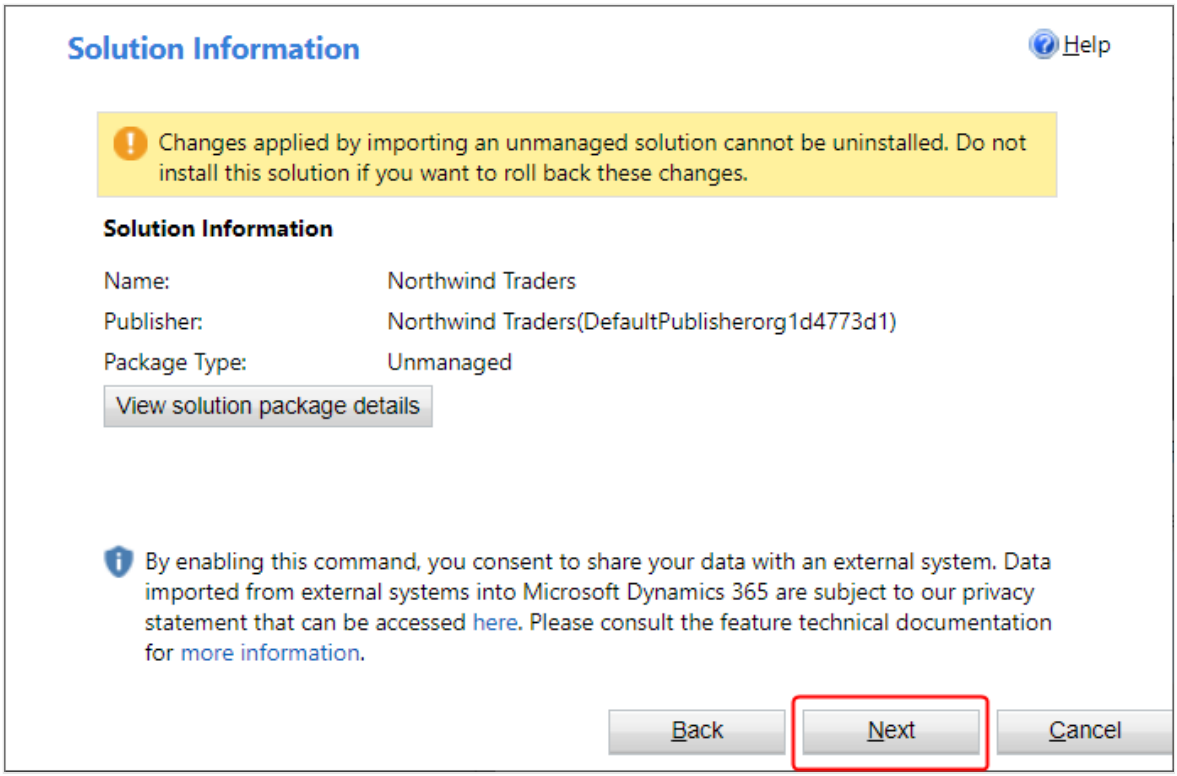
4. Find the file that you downloaded, and then select **Open**.

   Unless you selected a different location, the file will be in your Downloads folder.

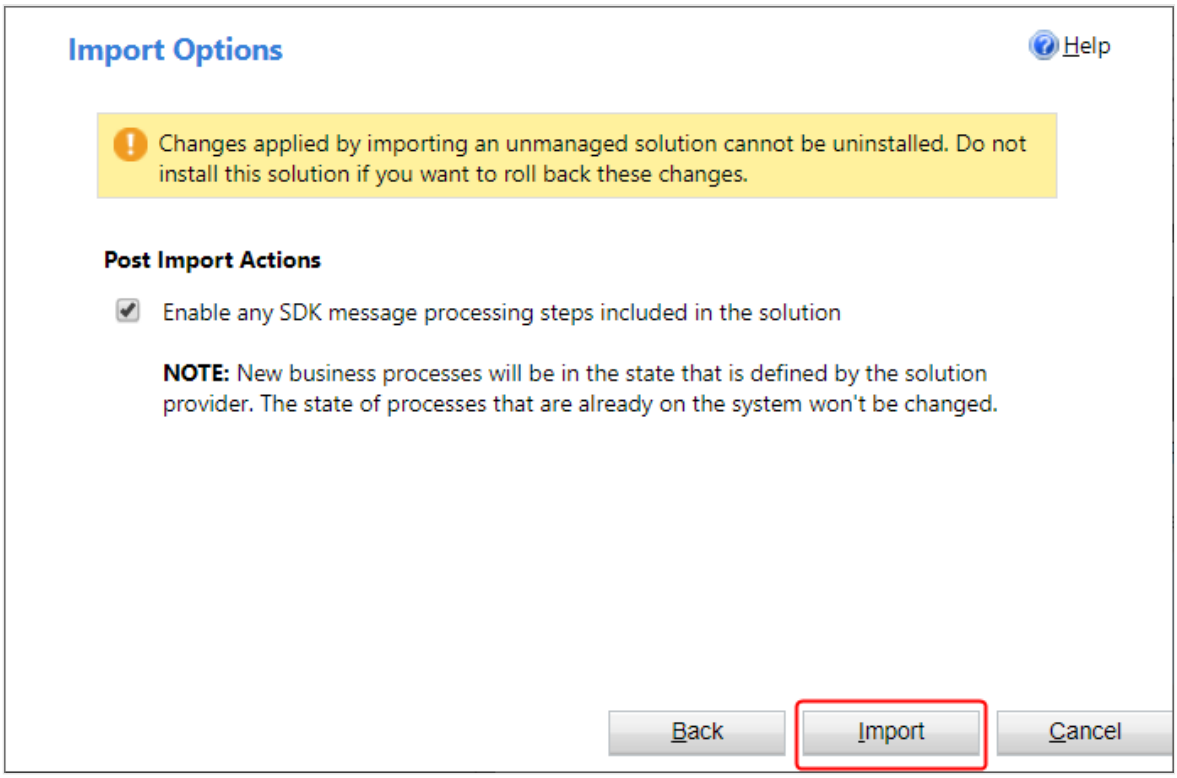
5. If you have the correct file (the version number might vary), select **Next**:



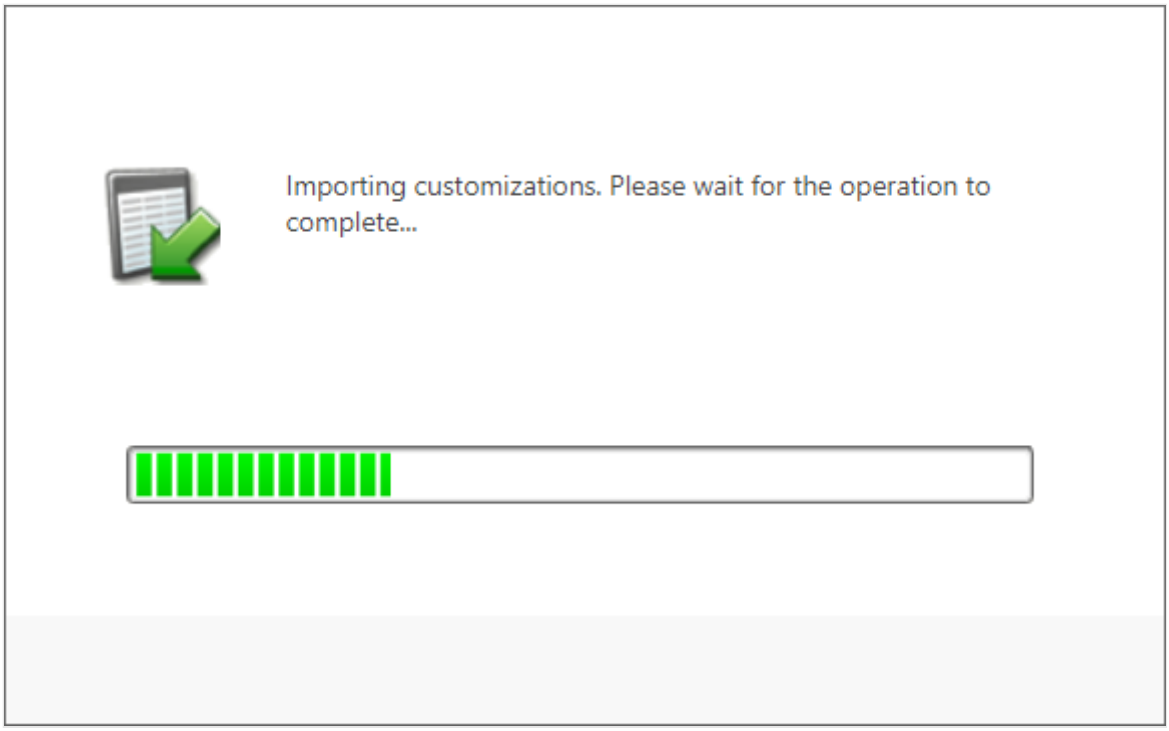
6. In the **Solution Information** page, select **Next** if the name of the solution and the publisher are correct.



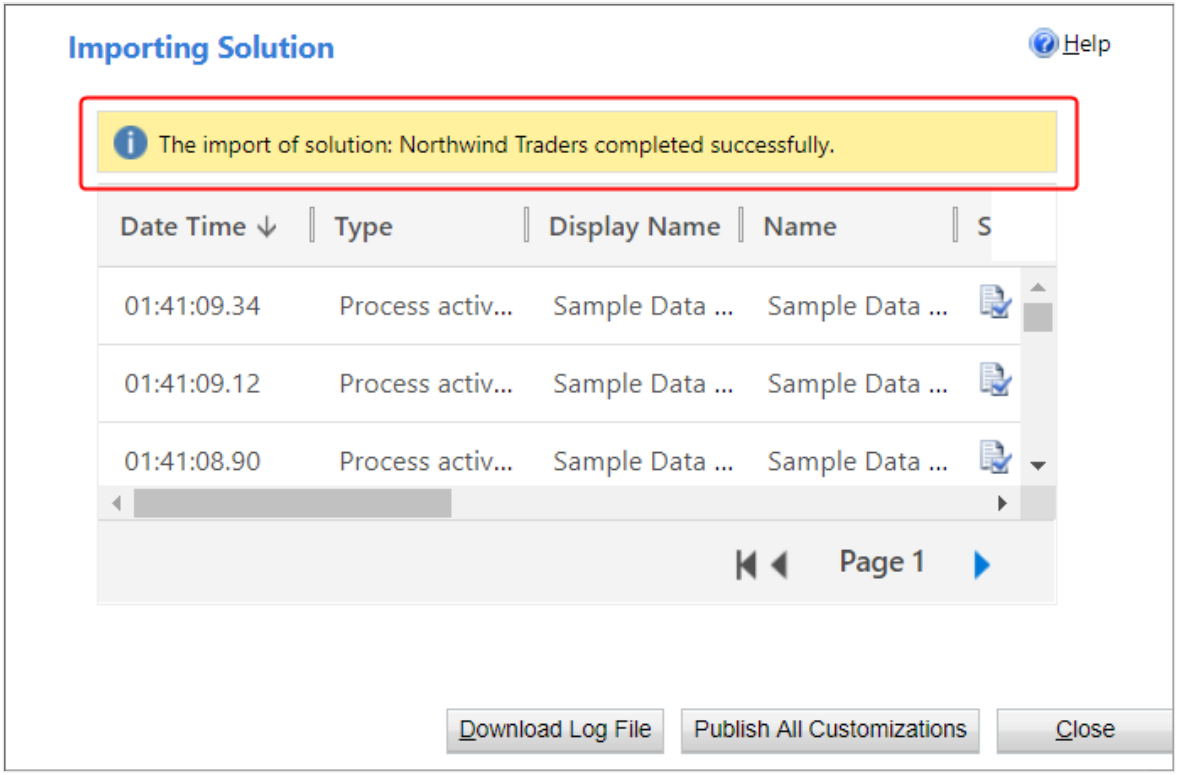
7. In the **Import Options** page, select **Import** to confirm SDK message handling, which the sample requires:



Another page appears and shows progress as the solution is installed over the next few minutes:



When the installation finishes, the original page shows the result:

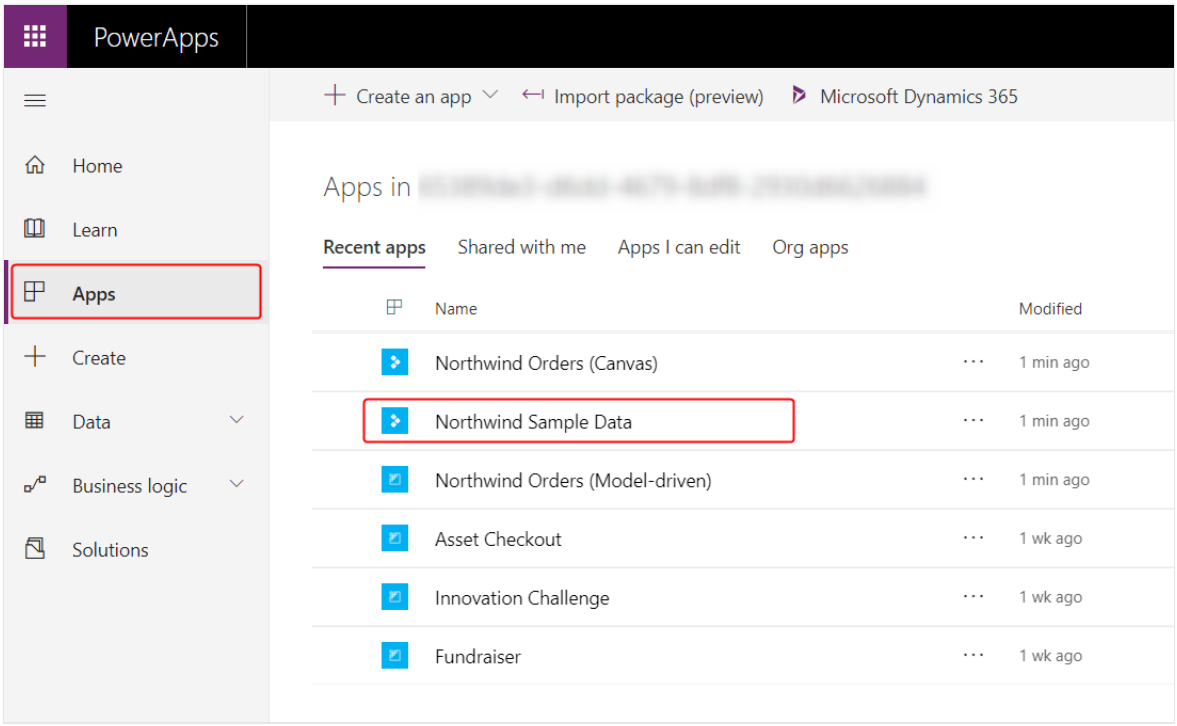


8. Select **Close**.

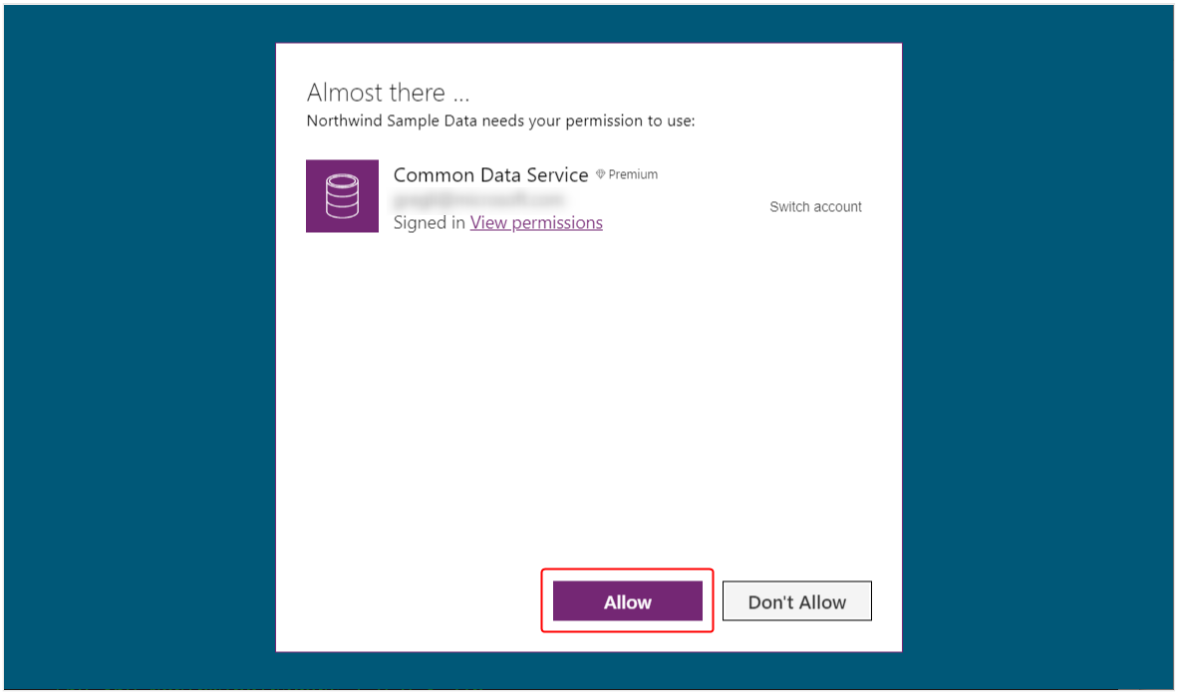
Load the sample data

1. Select **Apps**, and then select **Northwind Sample Data**.

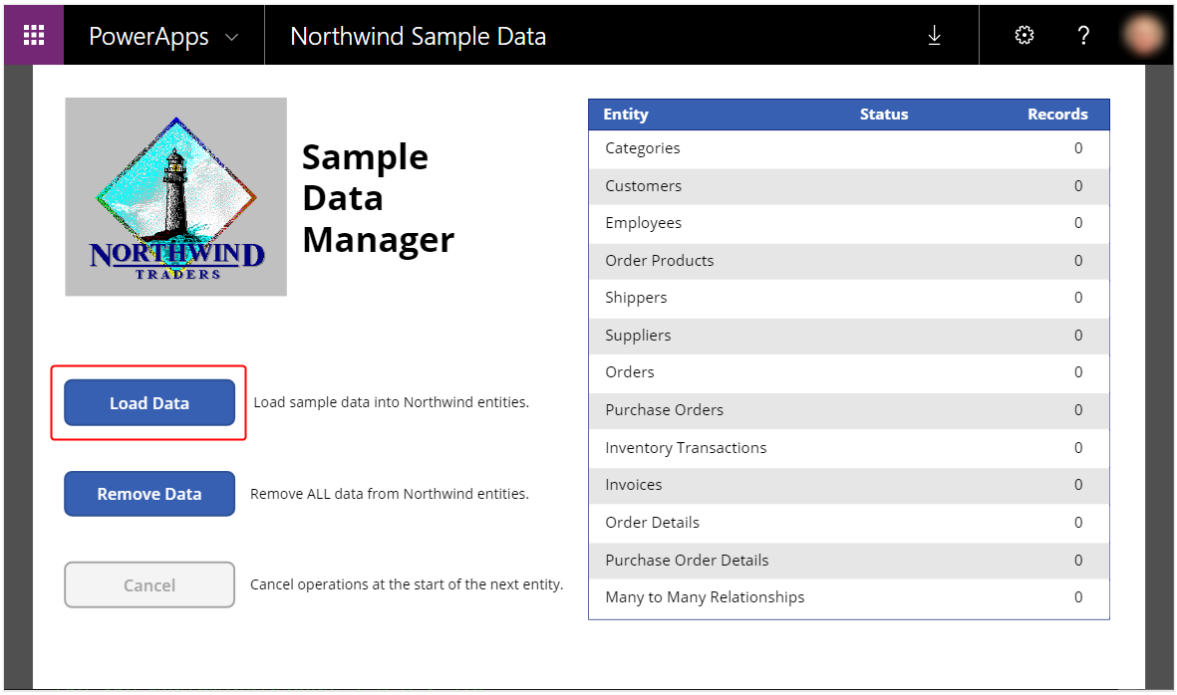
   Wait a few minutes if the Northwind apps don't appear immediately after you install the solution:



2. When the app asks for permission to interact with Dataverse, select **Allow**:



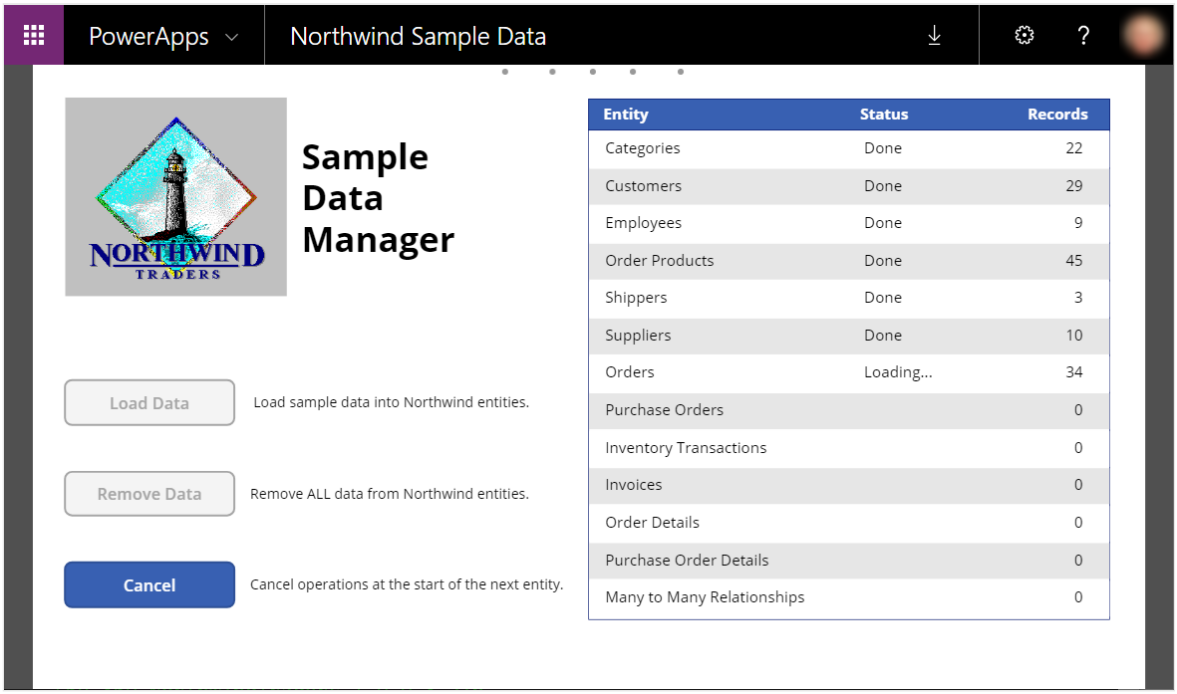
3. After the app loads and shows that the sample tables contain no records, select **Load Data** to populate the tables:



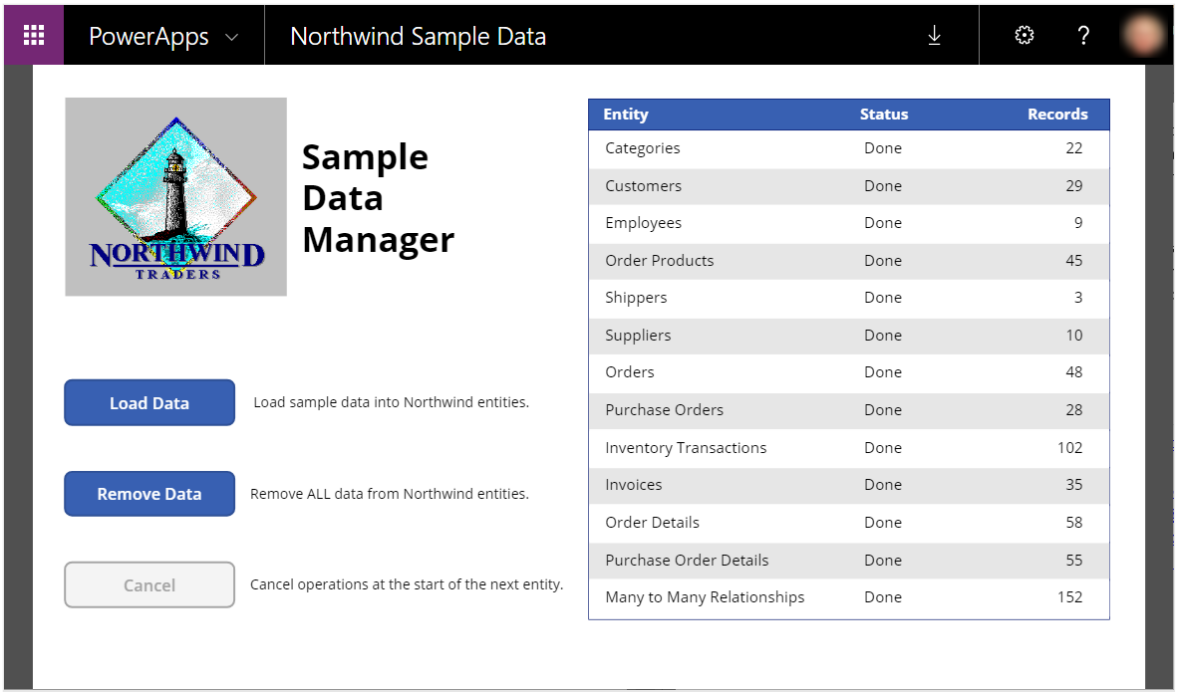
As the app loads the data, dots march across the top of the app, and the number of records increases.

Tables are loaded in a specific order so that relationships can be established between records. For example, the **Order Details** table has a many-to-one relationship with the **Orders** and **Order Products** tables, which are loaded first.

You can cancel the process at any time by selecting **Cancel**, and you can remove the data at any time by selecting **Remove Data**:



When the data finishes loading, the last row (**Many to Many Relationships**) shows **Done**, and the **Load Data** and **Remove Data** buttons are enabled again:



Sample apps

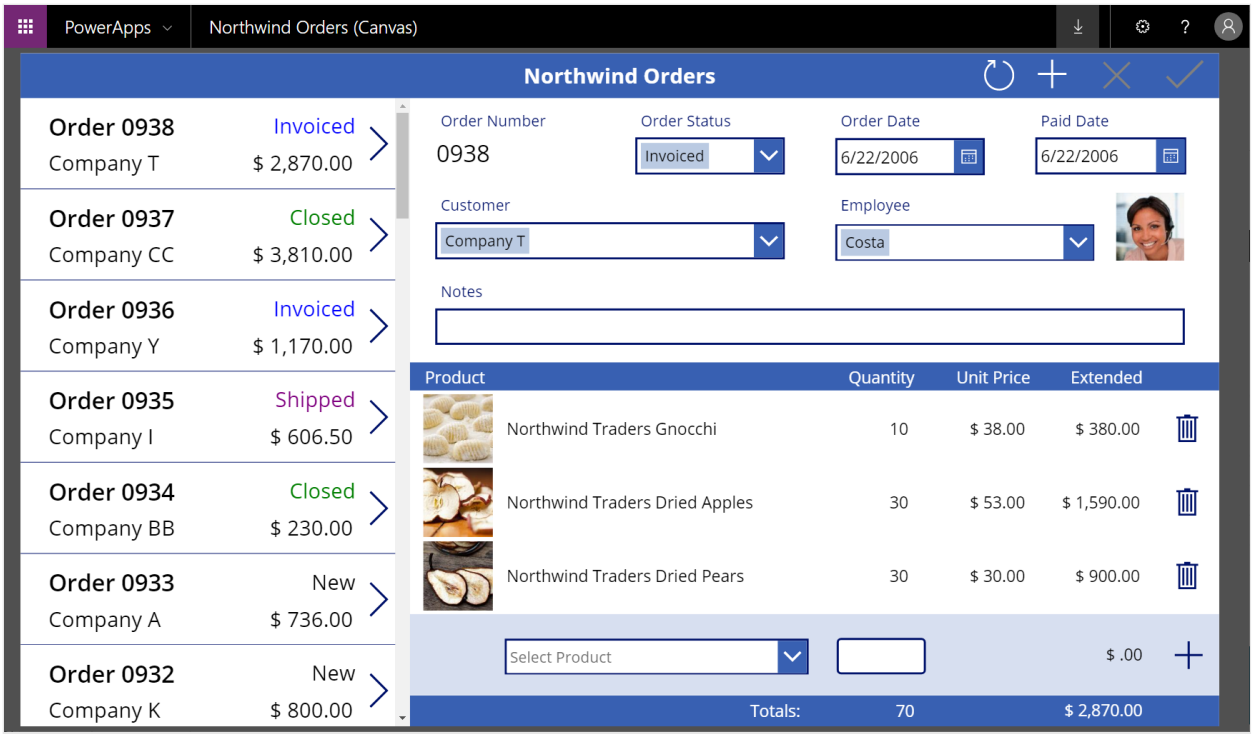
The Northwind solution includes these apps for interacting with this data:

- Northwind Orders (Canvas)
- Northwind Orders (Model-driven)

You open these apps the same way that you opened the app in the previous procedure.

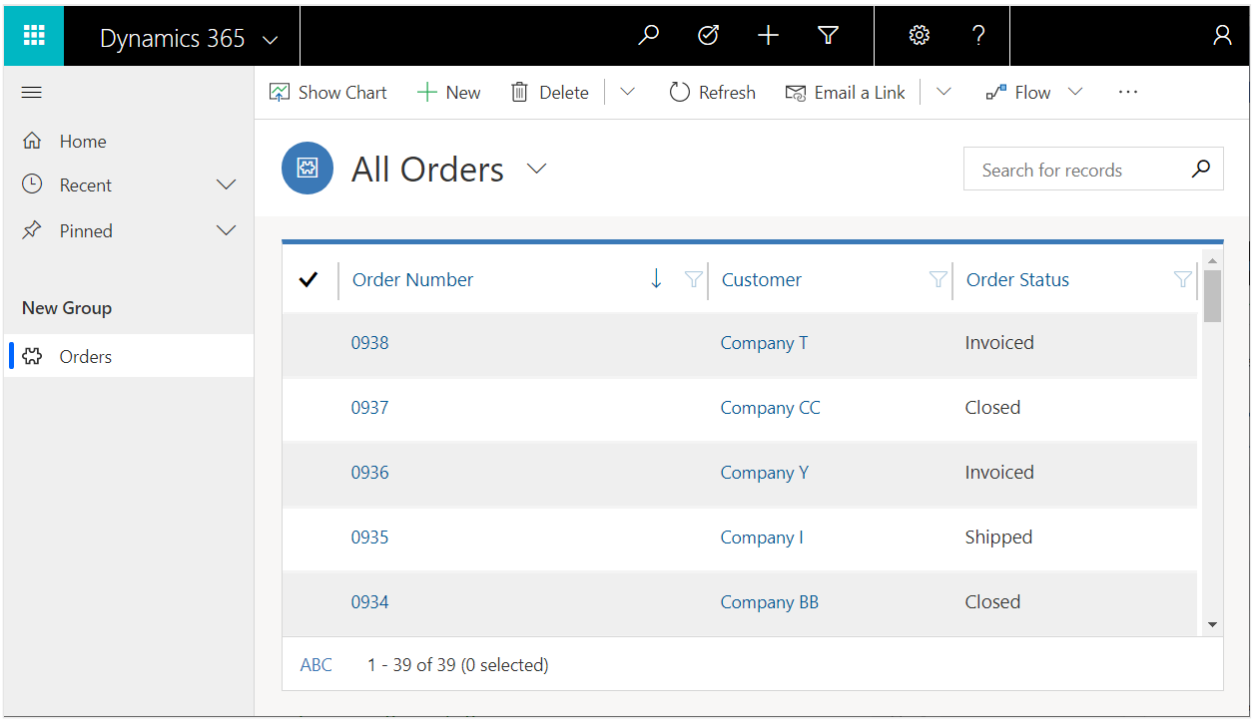
Canvas

This single-screen app offers a simple master-detail view of the **Orders** table, where you can view and edit a summary of the order and each line item for an order. A list of orders appears near the left edge, and you can select an arrow in that list to show a summary and the details of that order. More information: Overview of the canvas app for Northwind Traders.

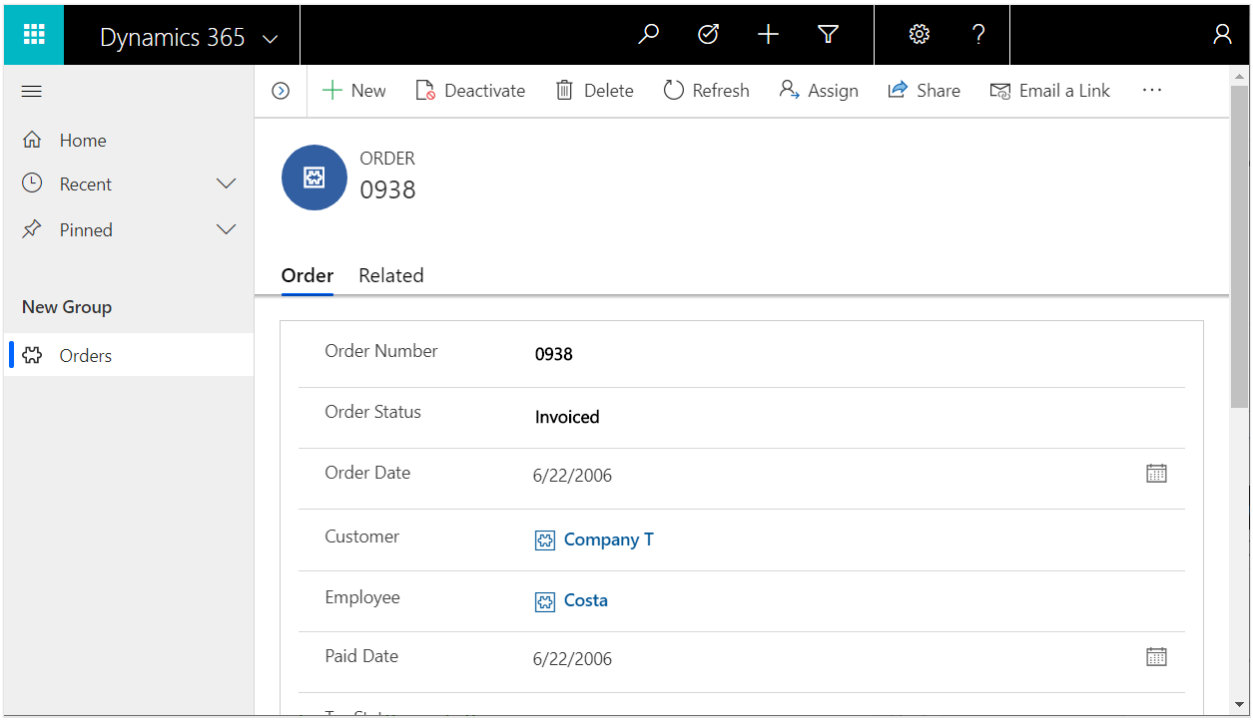


Model-driven

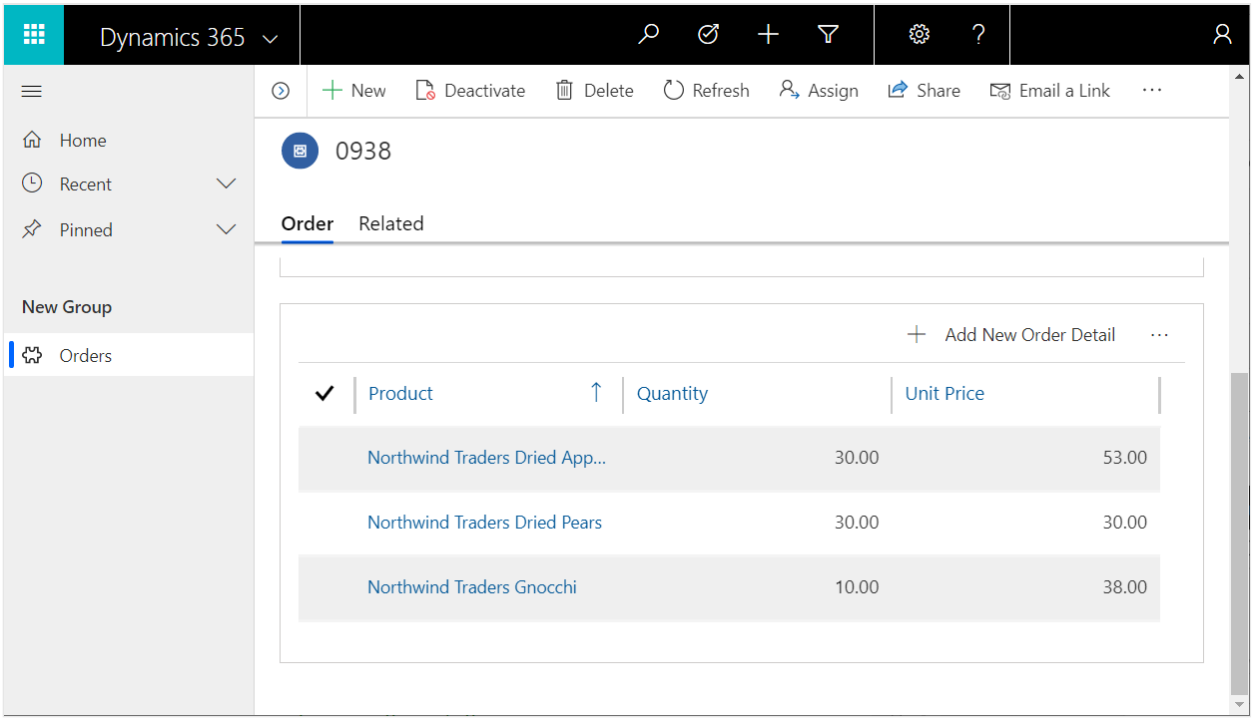
This app operates on the same data (in the **Orders** table) as the canvas app. In the list of orders, show more information about an order by selecting its number:



A summary of the order appears on a separate form:



If you scroll down the form, it shows the same line items as the canvas app does:



Do it yourself

You can follow step-by-step instructions to create the canvas app shown earlier in this topic. The instructions are divided into three parts:

1. Create an order gallery.
2. Create a summary form.
3. Create a detail gallery.

If you want to skip ahead, the solution contains a starting-point app for each part. In the list of apps, look for **Northwind Orders (Canvas) - Begin Part 1** and so on.

This overview of the app explains the user interface, data sources, and how relationships are used.

Start by reading the overview

Overview of the canvas app for Northwind Traders

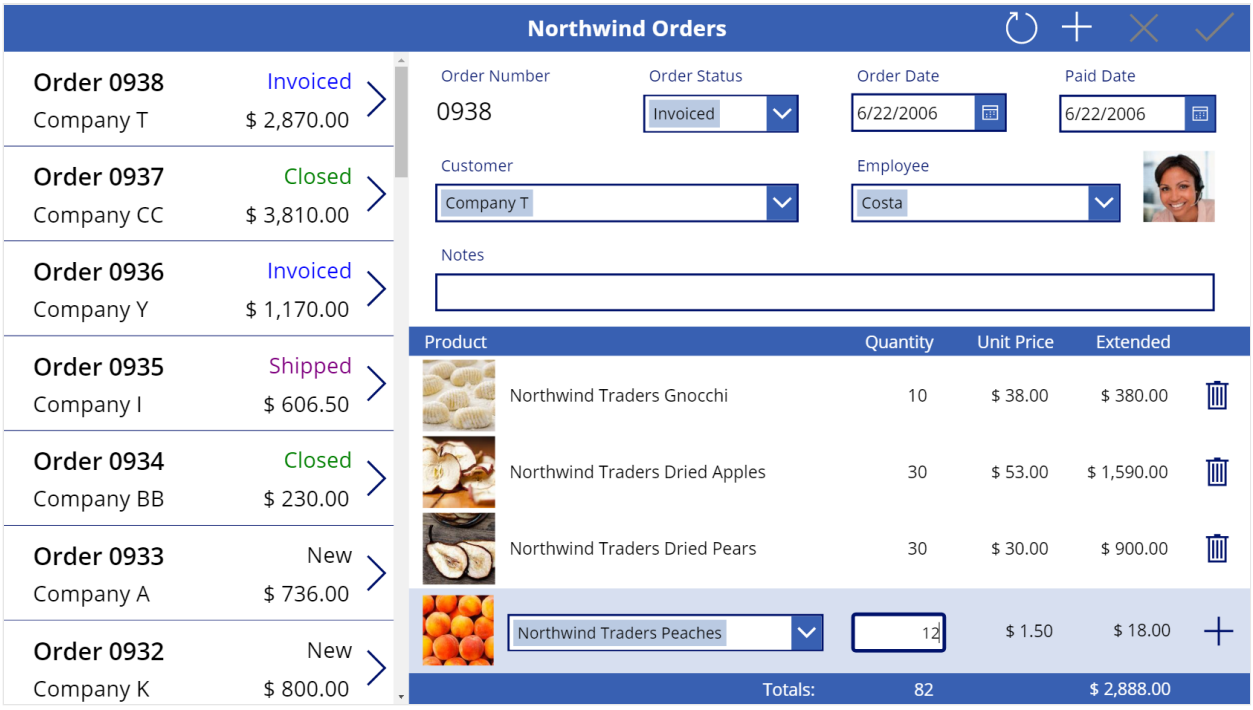
Article • 12/16/2022

Learn about the canvas app for managing relational data in the Northwind Traders database that you installed in your environment. Then follow step-by-step instructions in subsequent topics to build this app from scratch, thereby gaining hands-on experience working with relational data.

In this topic, discover:

- How an app user shows and manages relational data in the app.
- Which types of data drive the app.
- How relationships between those types of data were created.

In a single screen, the app user can show, update, create, and delete orders.



Explore the user interface

Order gallery

On the left edge of the app, a gallery shows a list of orders, including the order number, the status, the name of the customer, and the total cost of the order. The user can scroll through the list to find an order and then show more information about it by selecting the order's arrow. More information: Create the order gallery.

Summary form

In the upper-right corner, a form summarizes the order that the user selected in the order gallery. The summary includes much of the same information as that gallery does, but the summary also shows the dates when the order was created and paid, as well as the name and the picture of the employee who managed the order. The user can change the data in the form, save those changes, cancel them, or delete the order by selecting an icon near the right edge of the title bar. More information: Create the summary form.

Detail gallery

In the lower-right corner, another gallery shows information about which products the selected order contains and in what quantities. Each item in this gallery is known as an order detail. The app user can add and delete any item in that gallery by using controls in and under it. More information: Create the detail gallery.

Explore the data sources

To create this app, you'll show data from five tables and an choice. In fact, most areas of this app show data from multiple tables. For example, the order gallery contains this information:

- The order number is a field in the **Orders** table.
- The status is another field in the **Orders** table, an option from the **Orders Status** choice.

- The customer name is a field in the **Customers** table.
- The total cost is calculated based on data in the **Order Details** table.

The summary contains some of the same information as the list of orders, but it also contains the name and the picture of the employee who managed the order. That information is pulled from fields in the **Employees** table. The detail gallery shows records in the **Order Details** table, and each product in those details is a record in the **Order Products** table.

Explore the relationships

You can show data from different sources (for example, tables) in the same gallery or form because those tables have relationships that were created for you in the database.

Many-to-one relationships

For example, information about the customer and the employee for each order resides in the **Customers** and **Employees** tables. Therefore, the **Orders** table has many-to-one relationships with those tables because there are many orders, each of which can be placed by only one customer and managed by only one employee.

Each order also has one or more line items that represent the products that the order contains and their quantities. Each line item is a record in the **Order Details** table, which pulls information about each product from the **Order Products** table. Each detail identifies only one product, but each product can appear in multiple details. Therefore, the **Order Details** table has a many-to-one relationship with the **Order Products** table.

One-to-many relationships

Each order can contain multiple line items, but each line item relates to only one order. Therefore, the **Orders** table has a one-to-many relationship with the **Order Details** table.

Dot notation for relationships

To show data based on a relationship between tables, you can use the dot property selector to walk across a relationship from one table to another. For example, each record in the **Orders** table pulls information from the **Customers** table so that the order gallery can show the customer names. In that gallery, you configure this behavior by setting the **Text** property of a label to this expression:

`ThisItem.Customer.Company`

ThisItem specifies a record in the **Orders** table and pulls information from the **Customers** table about the customer who placed the order. In this case, the expression specifies that the customer's company name appears. However, the entire record for that customer is pulled, so you could just as easily show, for example, an email address for that customer instead.

As another example of walking from one table to another, you can specify that a gallery should show records in one table based on a record that the user selected in another gallery and that's in another table. To show the order details, you'll set the detail gallery's **Items** property to this expression:

```
Gallery1.Selected.'Order Details'
```

In this case, **Gallery1.Selected** specifies a record in the **Orders** table, just as **ThisItem** did in the previous example. However, this expression doesn't pull just one record as the previous expression did. Instead, it pulls an entire table of records to show the name and per-unit cost of each product (as reflected in the **Order Products** table) and the quantity (as reflected in the **Order Details** table).

Do it yourself

You can follow step-by-step instructions to create the Northwind Orders canvas app. The instructions are divided into three parts:

1. Create an order gallery.
2. Create a summary form.
3. Create a detail gallery.

If you want to skip ahead, the solution contains a starting-point app for each part. In the list of apps, look for **Northwind Orders (Canvas) - Begin Part 1** and so on.

Continue by creating the order gallery

Create an order gallery in a canvas app

Article • 12/16/2022

Follow step-by-step instructions to create an order gallery in a canvas app for managing fictitious data in the Northwind Traders database. This topic is part of a series that explains how to build a business app on relational data in Microsoft Dataverse. For best results, explore these topics in this sequence:

1. Create an order gallery (**this topic**).
2. Create a summary form.
3. Create a detail gallery.

Prerequisites

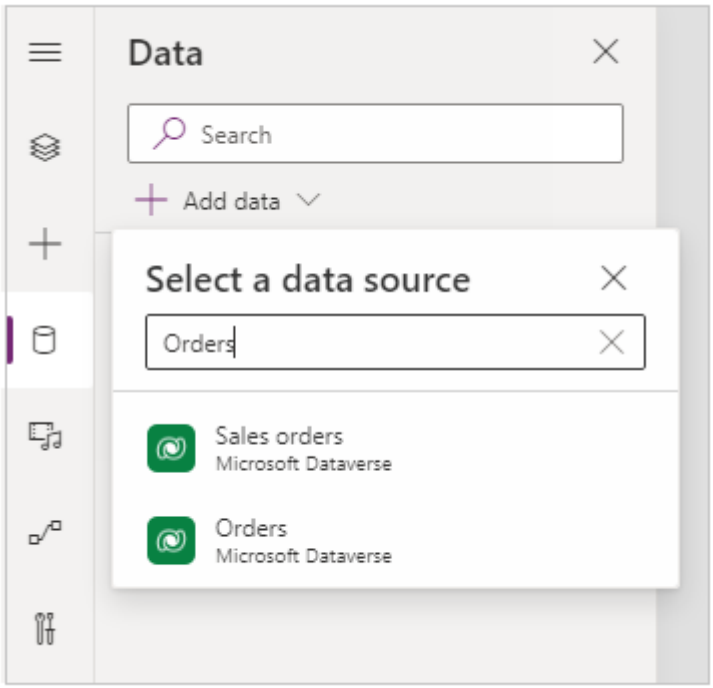
- Install the Northwind Traders database and apps.
- Read through the overview of the canvas app for Northwind Traders.

Create a blank app

Create a blank canvas app, and give it a name such as "My Northwind Orders (Canvas app)".

Add the data

1. On the left-pane, select **Data** > **Add data** > search for, and select **Orders** table.



The **Orders** table contains many fields of various types:

Display name	Name	Data type	Type	Required	Searcha...
Customer	nwind_customerid	Lookup	Custom		✓
Employee	nwind_employeeid	Lookup	Custom		✓
Notes	nwind_notes	Multilin...	Custom		✓
Order Date	nwind_orderdate	Date Only	Custom		✓
Order Number	nwind_ordernumber	Autonu...	Custom		✓
Order Status	nwind_orderstatusid	Option ...	Custom		✓
Paid Date	nwind_paiddate	Date Only	Custom		✓
Payment Type	nwind_paymenttype	Text	Custom		✓
Sample Data Order Status	nwind_sampledataorder...	Text	Custom		✓
Sample Data Original ID	nwind_sampledataorigi...	Text	Custom		✓
Ship Address	nwind_shipaddress	Multilin...	Custom		✓
Ship City	nwind_shipcity	Text	Custom		✓

Each field has a **Display name** and a **Name**, which is sometimes called the logical name. Both names refer to the same thing. In general, you'll use the display name when you build an app, but some cases require the more cryptic **Name**, as noted in a procedure.

2. As we will be working with screens and controls next, in Power Apps Studio switch back to the **Tree View** on the left hand side by pressing the three stacked squares icon. You can return to the **Data Sources** at any time by pressing the cylinder icon.

Create the order gallery

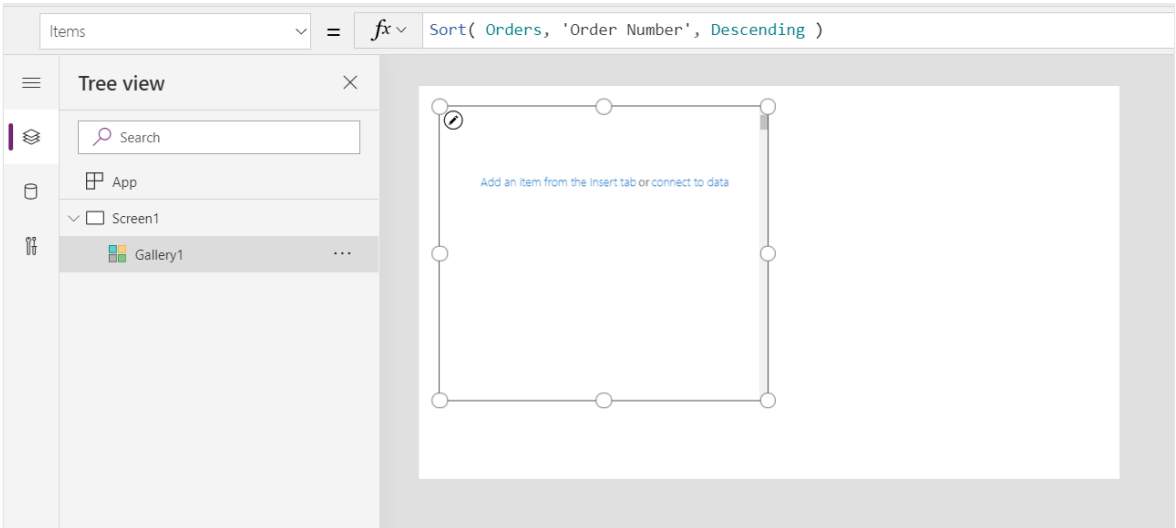
1. On the **Insert** tab, select **Gallery** > **Blank vertical** to add a Gallery control, which will show the orders.

   The control will be placed on the canvas and a fly out dialog will appear asking which data source to connect to.

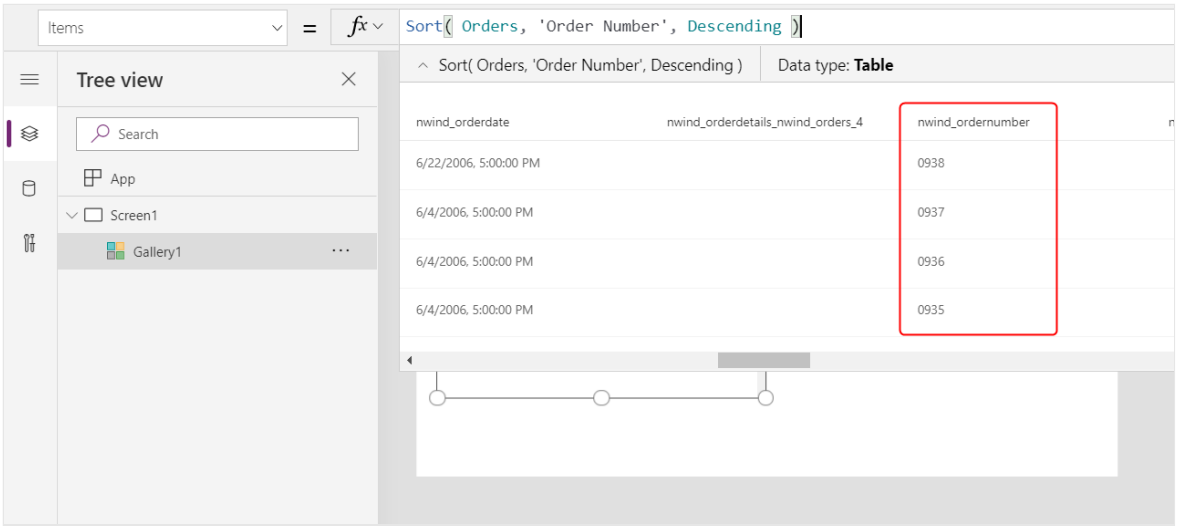
2. We could connect it directly to **Orders** here, but instead we'd like to control the sort order of the gallery. Ignore the fly out dialog and in the formula bar set the gallery's **Items** property to this formula:

```
Power Apps
Sort( Orders, 'Order Number', Descending )
```

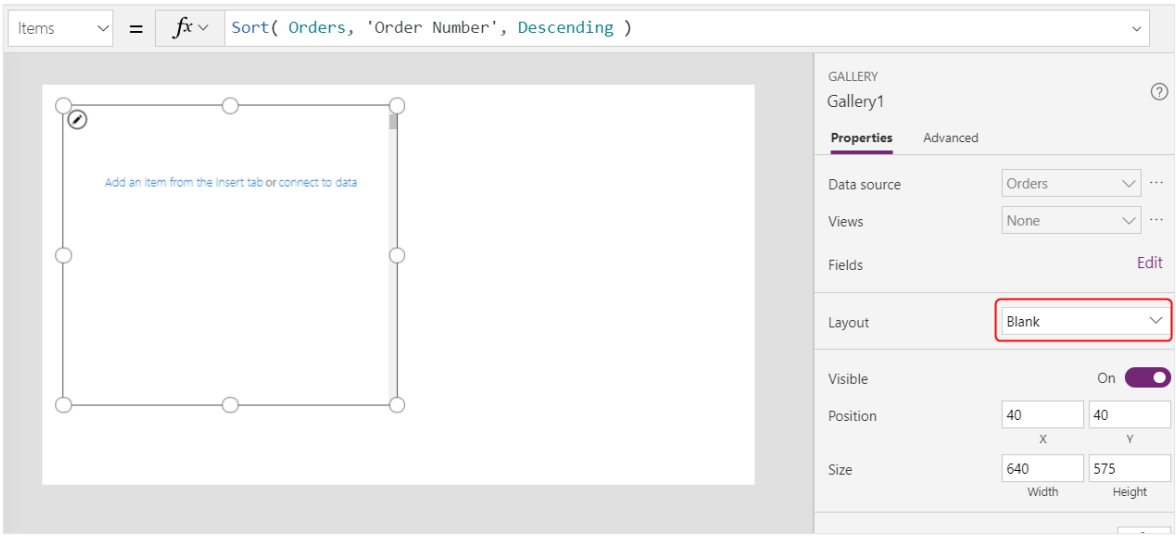
   The Sort function orders the list so that the newest order (which has the highest order number) appears first.



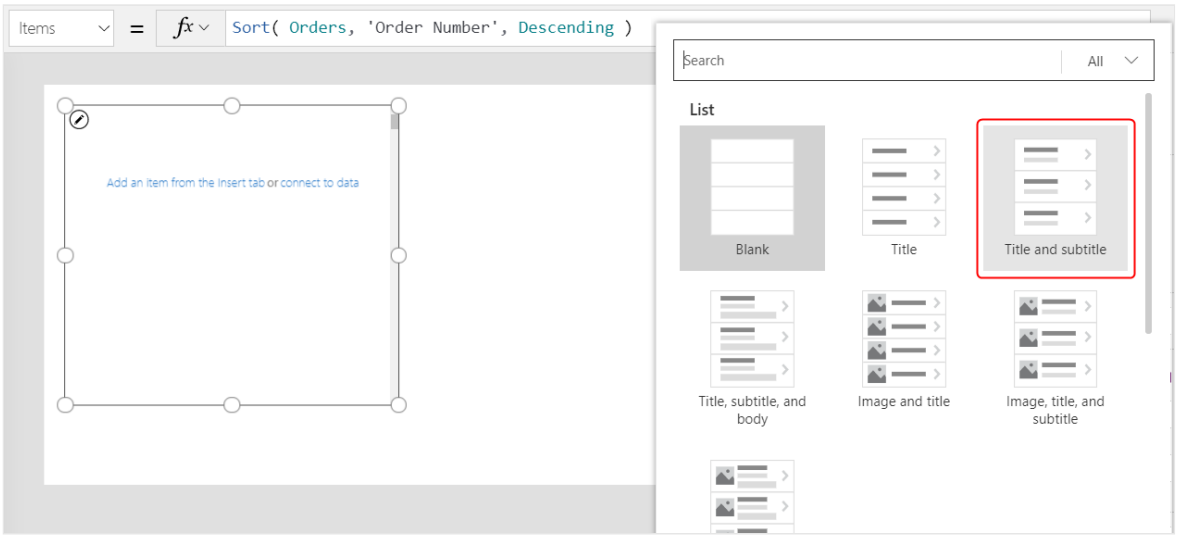
3. After a few moments the Result View will appear below the formula bar. Pull down on the arrow at the left to see the result of our formula. Scroll to the right to see the **Order Number** column and ensure it is sorted the way want (highest to lowest).



4. In the **Properties** tab near the right edge, open the **Layout** list:

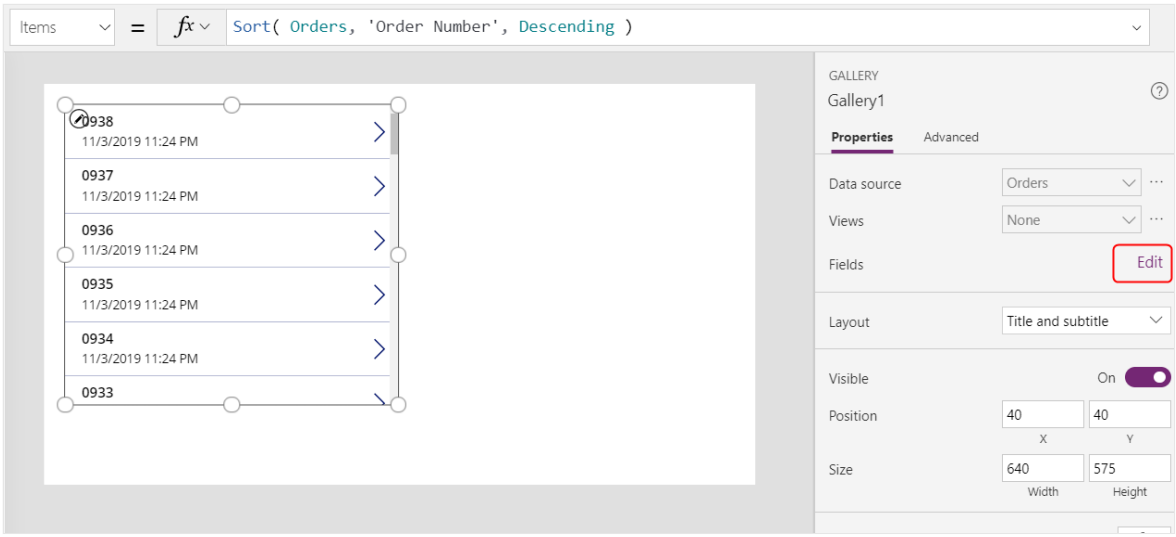


5. In the list of options, select **Title and subtitle**:



Two **Label** controls are added in the gallery's template. By default, these controls show two columns of the **Orders** table, which you'll change next. The gallery's template is replicated vertically for each record in the table.

6. Select **Edit** (next to **Fields**) in the **Properties** tab near the right edge.

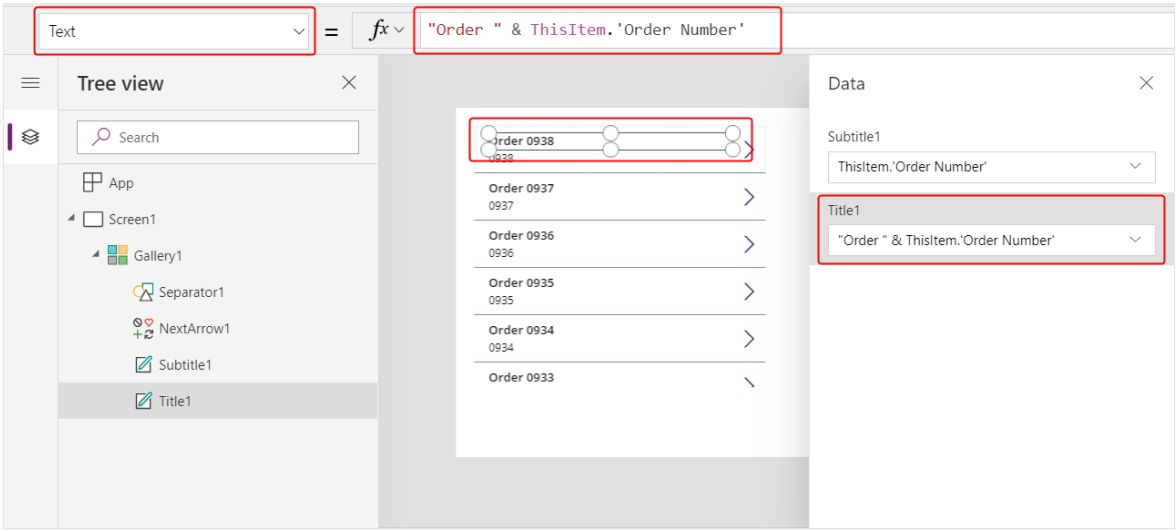


7. In the **Data** pane, select **Title1** (or select the upper label in the gallery's template).

8. In the formula bar, set the label's **Text** property to this expression:

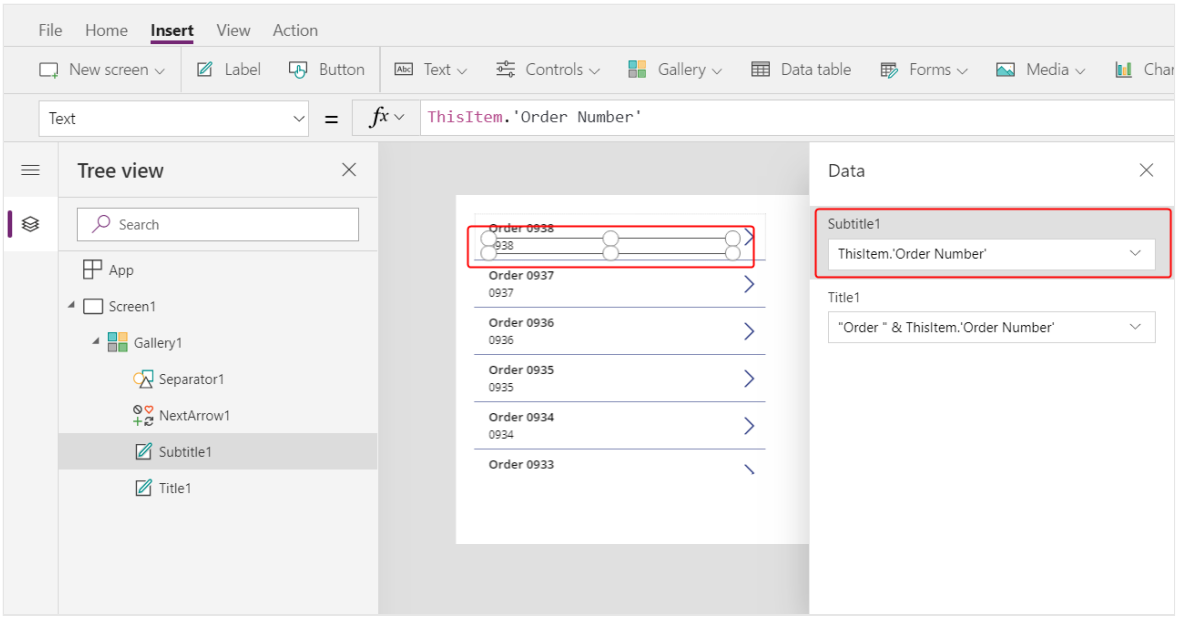
```
Power Apps

"Order " & ThisItem.'Order Number'
```



The order number appears at the top of each gallery item. In the gallery template, **ThisItem** grants access to all fields in the **Order** table.

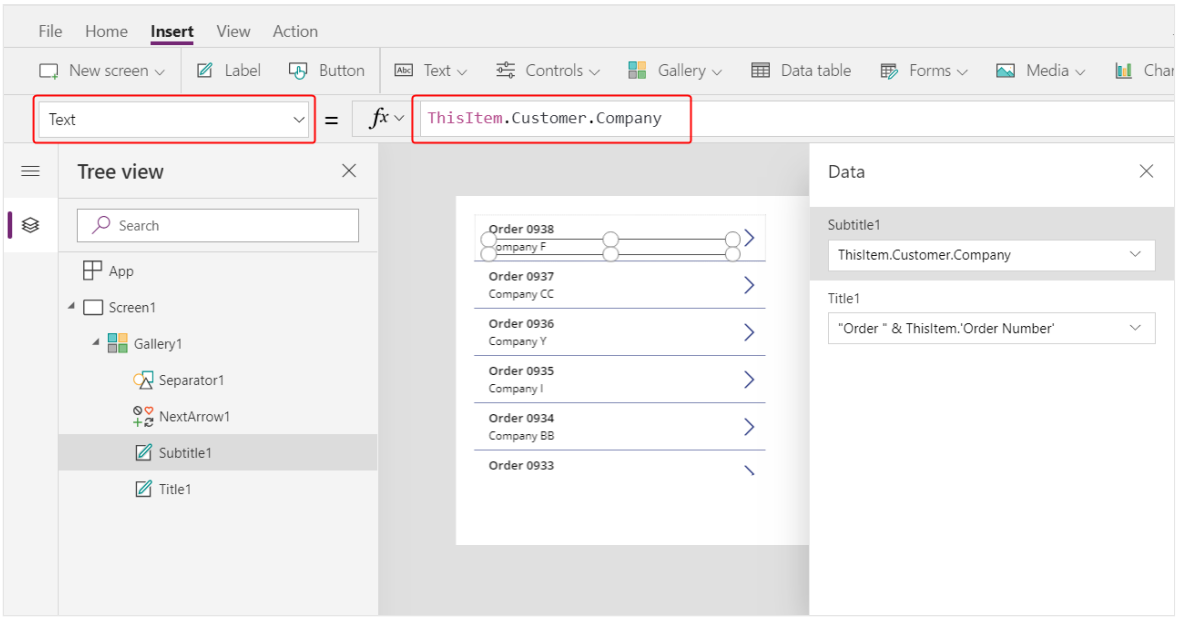
9. In the **Data** pane, select **Subtitle1** (or select the lower label in the gallery's template):



10. In the formula bar, set the label's **Text** property to this expression:

```
Power Apps

ThisItem.Customer.Company
```



After you enter this formula, it may show a red squiggly error for a moment. The error should clear if you select anything outside the formula bar and then return the cursor to the formula bar. If the error persists or you don't see a value, select the **View** tab, select **Data sources**, and then refresh the **Orders** table by selecting the ellipsis (...) to the right of the data-source name.

When you specify **ThisItem.Customer**, you're leveraging a many-to-one relationship between the **Orders** and **Customers** tables and retrieving the customer record that's associated with each order. From the customer record, you're extracting data in the **Company** column for display.

You can show all the relationships from the **Orders** table to other tables, including the **Customer** table:

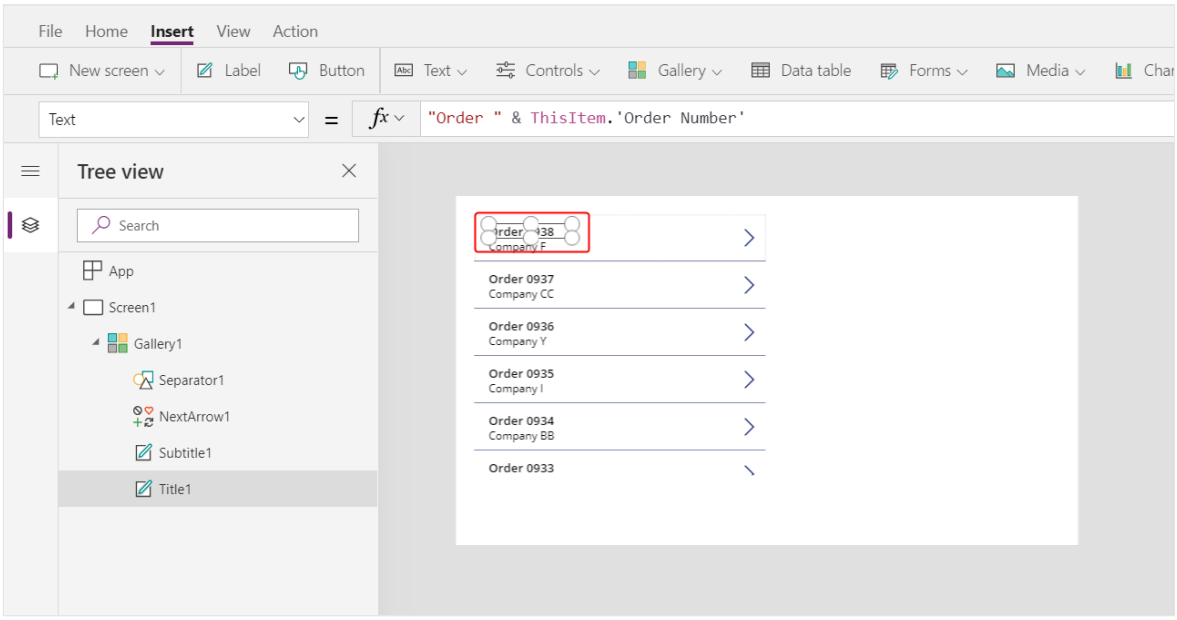
Display name	Relationship name	Related ...	Relationshi...	Type
Customer	nwind_orders_nwind_c...	Customer	Many-to-one	Custom
Customer Order	nwind_inventorytransa...	Inventory T...	One-to-many	Custom
Employee	nwind_orders_nwind_e...	Employee	Many-to-one	Custom
Order	nwind_orderdetails_nw...	Order Detail	One-to-many	Custom
Order	nwind_invoices_nwind_...	Invoice	One-to-many	Custom
Shipper	nwind_orders_nwind_s...	Shipper	Many-to-one	Custom

11. Close the **Data** pane by selecting the close icon (x) in its upper-right corner.

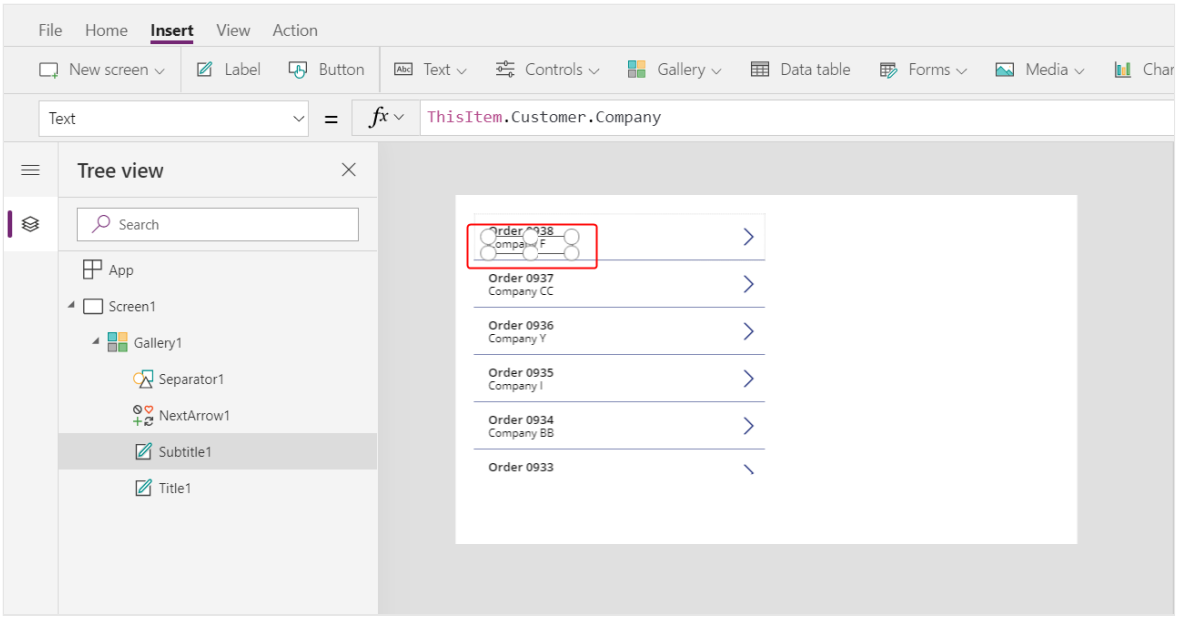
Show each order's status

In this procedure, you'll add space in the gallery for a label and configure it to show each order's status in a different color based on the data.

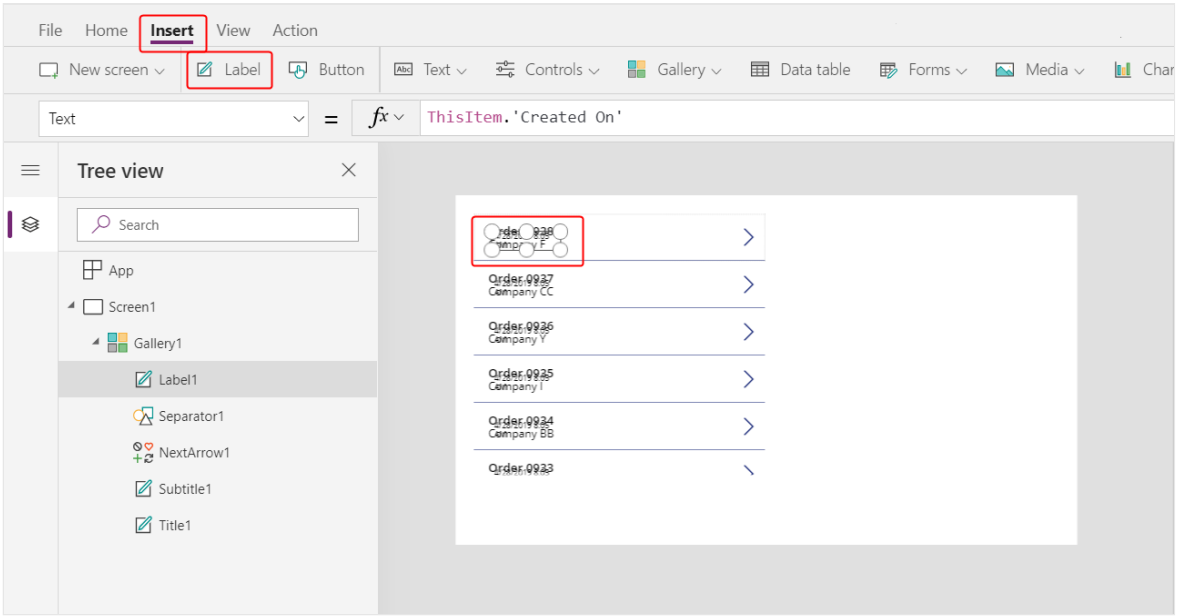
1. In the gallery's template, reduce the width of the first label, **Title1**:



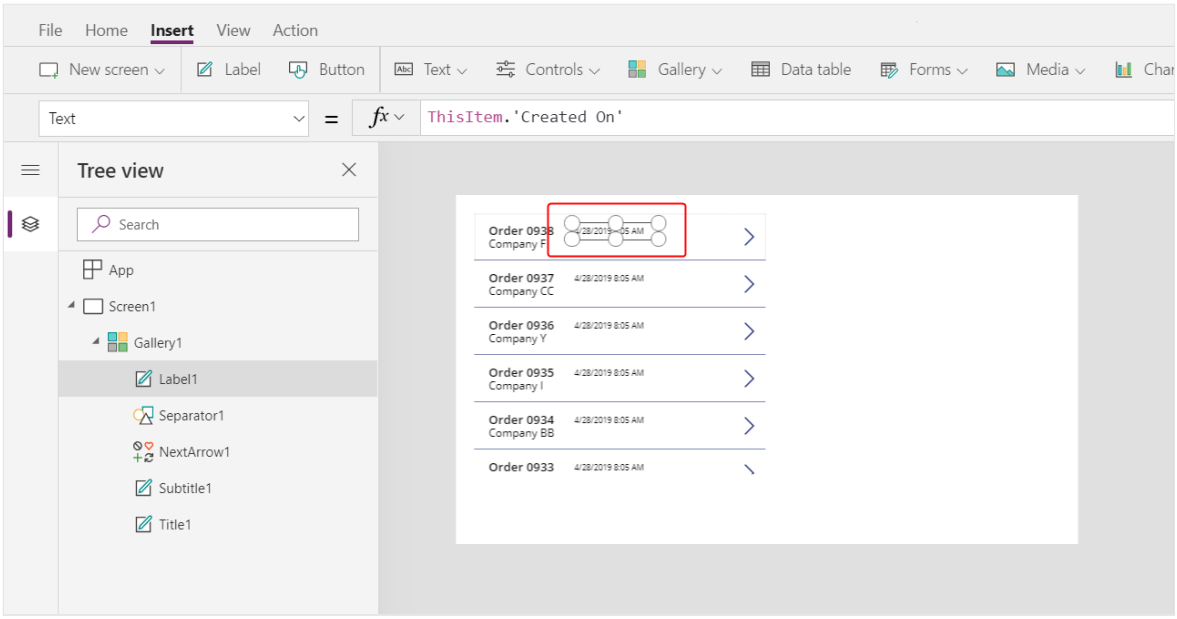
2. Repeat the previous step with the second label, **Subtitle1**:



3. With the gallery template (or a control in the template) selected, select **Label** on the **Insert** tab:



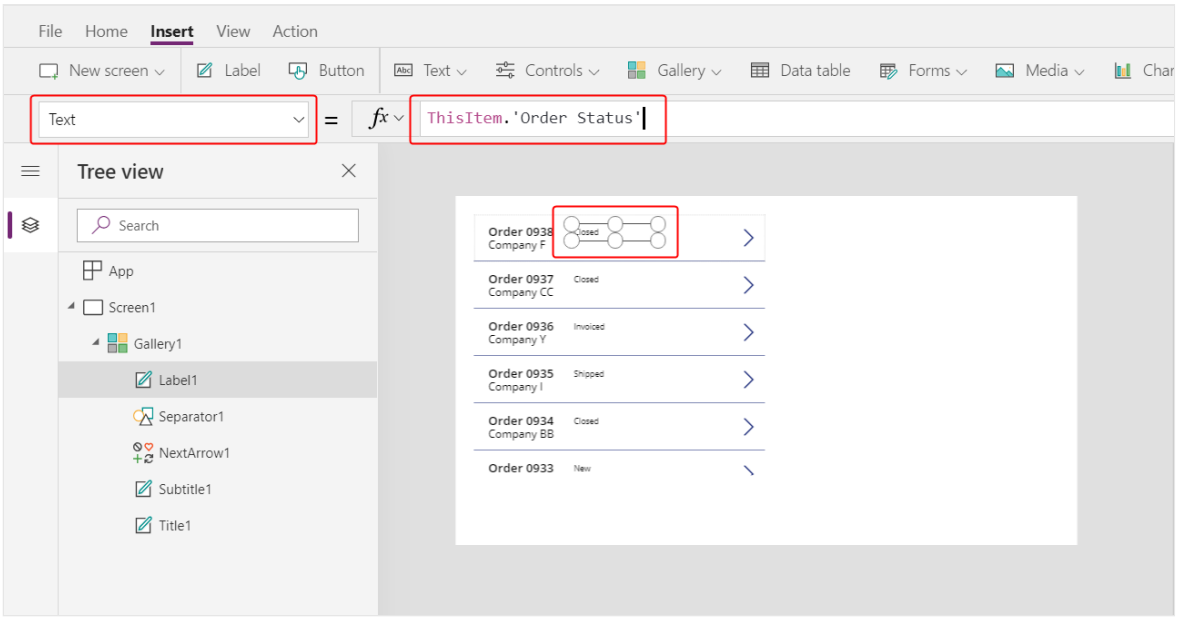
4. Move the new label to the right of the **Title1** label:



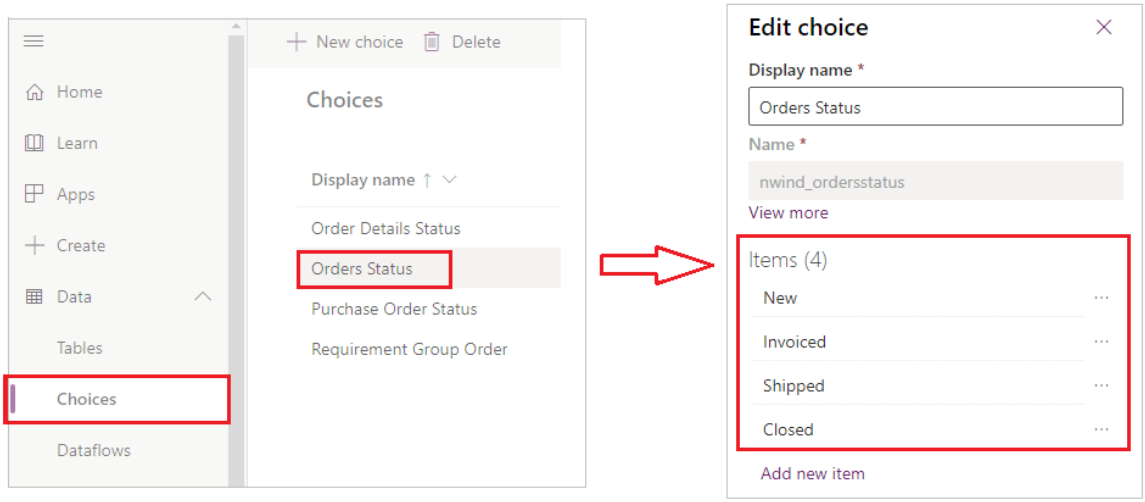
5. Set the **Text** property of the new label to this expression:

```
Power Apps

ThisItem.'Order Status'
```



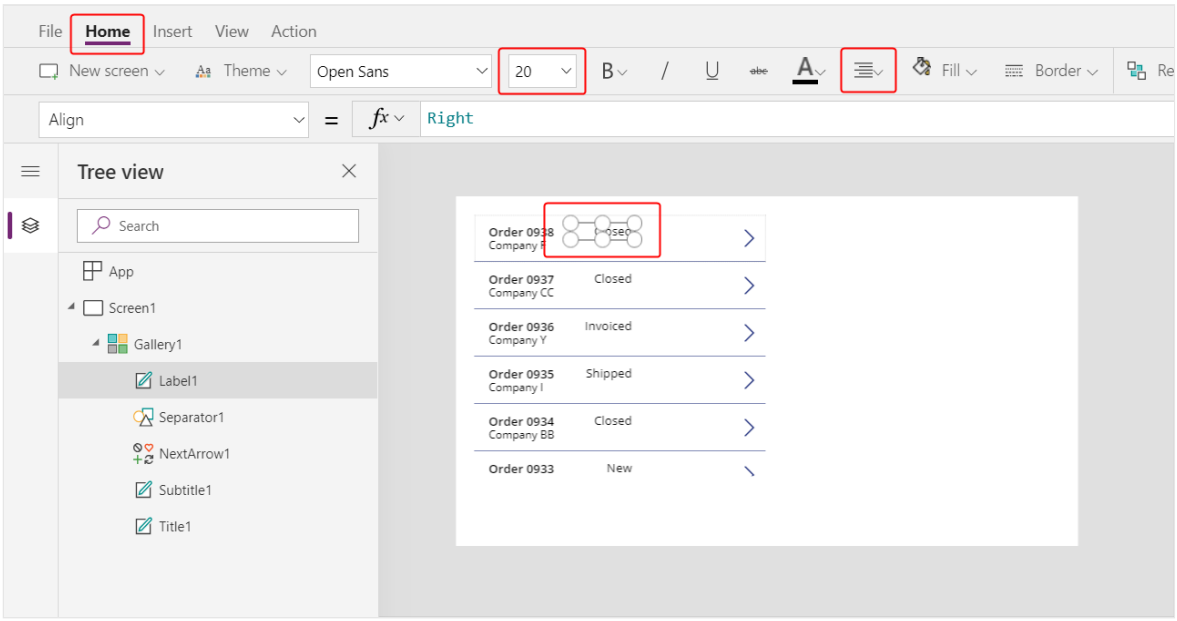
In the **Orders** table, the **Order Status** field holds a value from the **Orders Status** choice. A choice is similar to an enumeration in other programming tools. Each set of options is defined in the database, so users can specify only those options that are in the set. The **Orders Status** choice is also global, not local, so you can use it in other tables:



Each option in a set has a name that appears if you show it in a label. These names can be localized, and the app recognizes the same option whether an English user selects **Apple**, a French user selects **Pomme**, or a Spanish user selects **Manzana**. For this reason, you can't create a formula that relies on a hard-coded string for an option, as this topic demonstrates later.

In formulas, you must surround **Order Status** with single quotation marks because it contains a space. However, that name functions the same way as any other name in Power Apps, such as **Customer** or **Company**, does.

6. On the **Home** tab, increase the font size of the status label to 20 points, and right align the text:

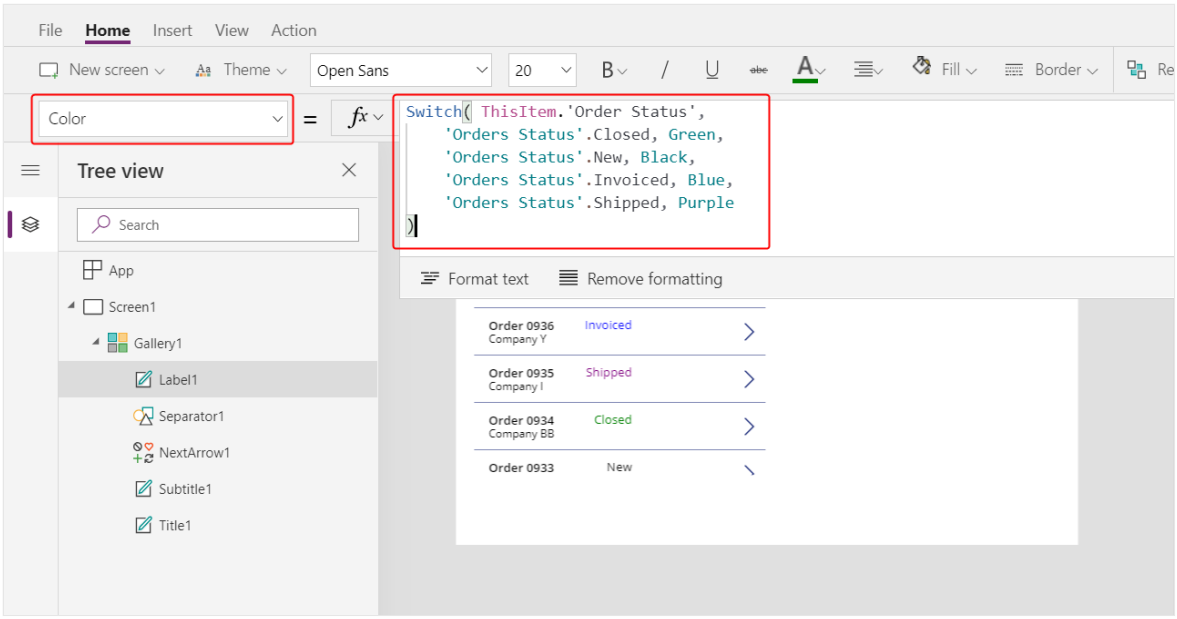


7. In the formula bar, set the **Color** property of the status label to this formula:

Power Apps

```
Switch( ThisItem.'Order Status',
    'Orders Status'.Closed, Green,
```

```
    'Orders Status'.New, Black,
    'Orders Status'.Invoiced, Blue,
    'Orders Status'.Shipped, Purple
)
```

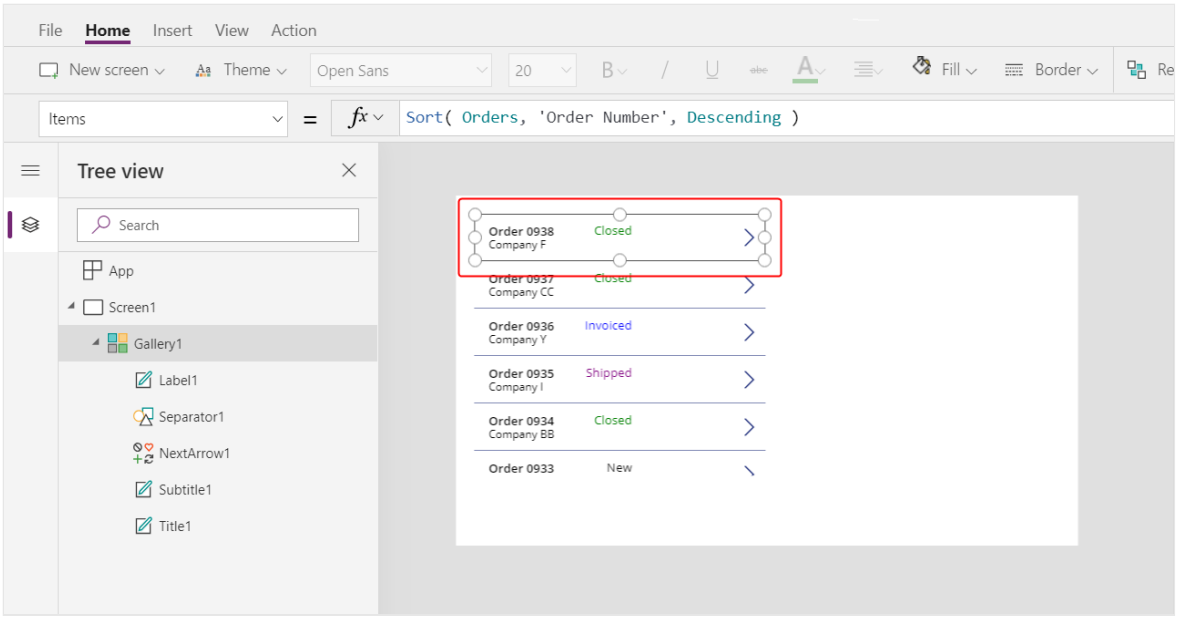


Power Apps prevents you from creating a formula that relies on a hard-coded string for each option in a set because such formulas could produce inappropriate results if the option names are localized. Instead, the **Switch** function determines the color based on whatever string appears in the label based on the user's settings.

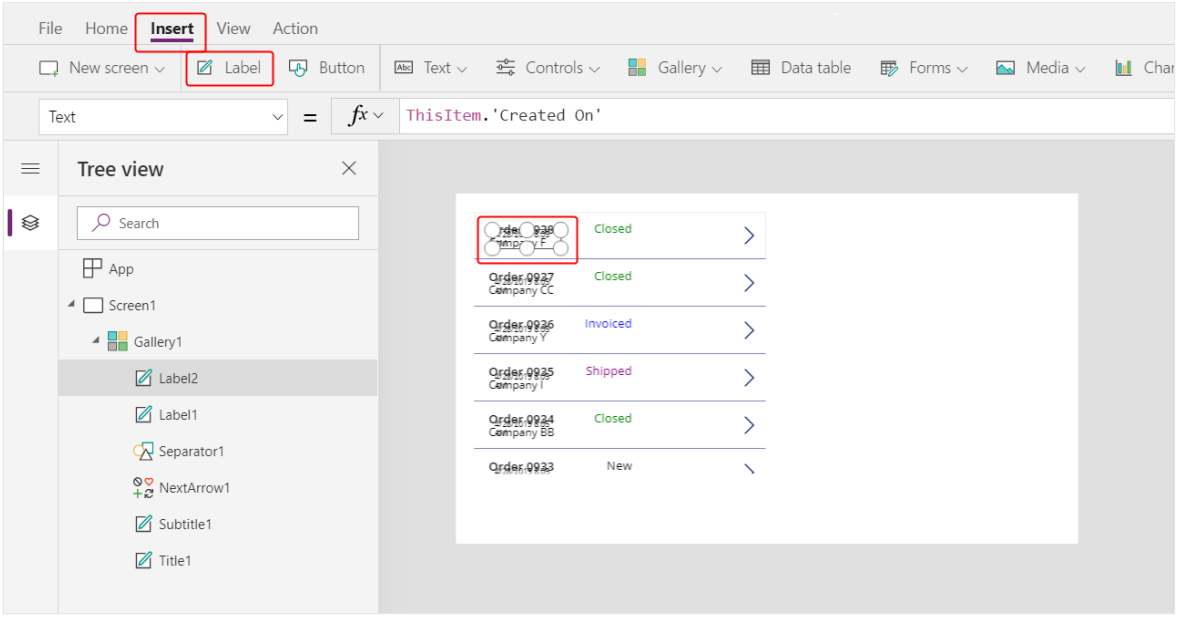
With this formula in place, different status values appear in different colors, as the previous graphic shows.

Display each order's total

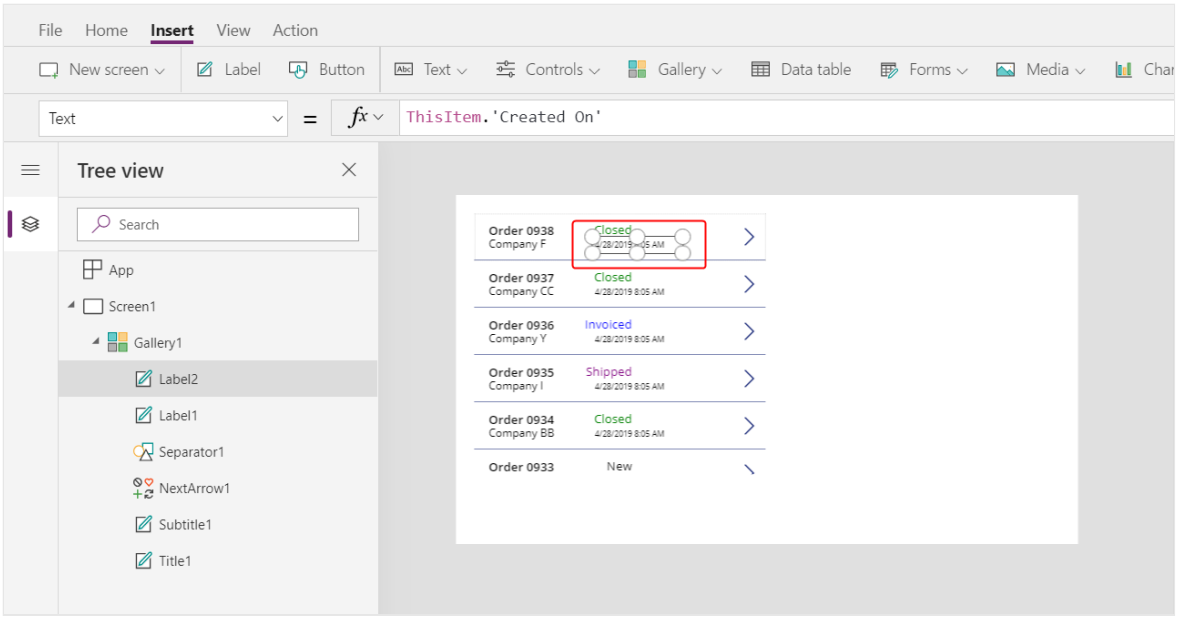
1. Select the first item in the gallery, which is the gallery's template:



2. On the **Insert** tab, select **Label** to add another label:



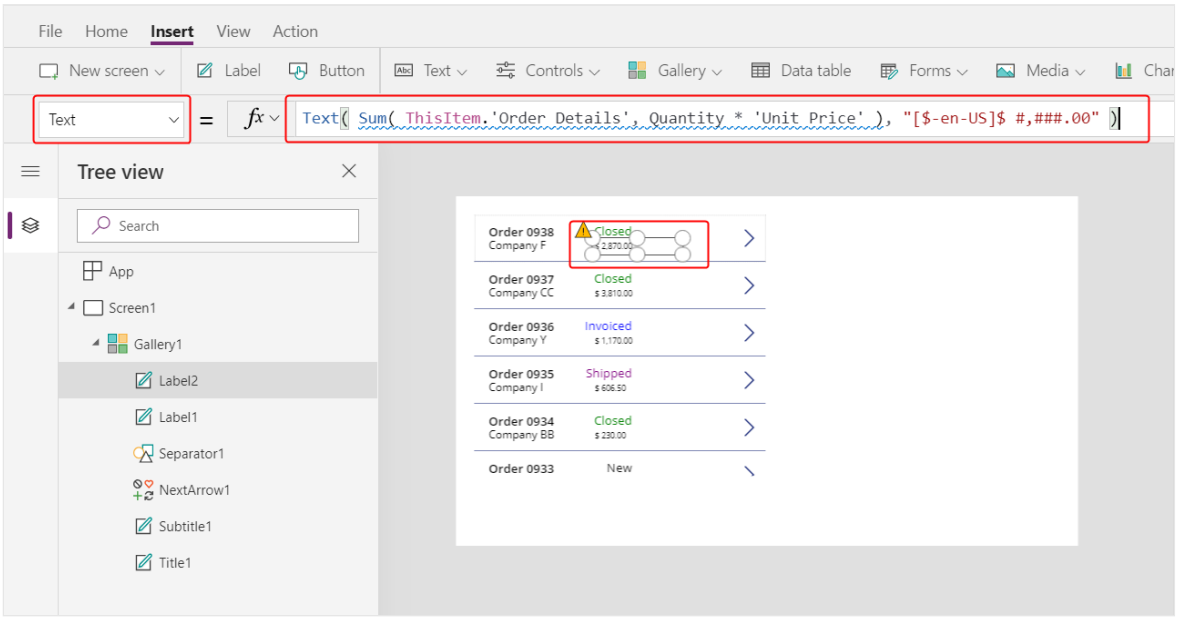
3. Move the new label so that it appears under the status label:



4. In the formula bar, set the new label's **Text** property to this formula:

```
Power Apps

Text( Sum( ThisItem.'Order Details', Quantity * 'Unit Price' ), "[$-en-US]$ #,###.00" )
```



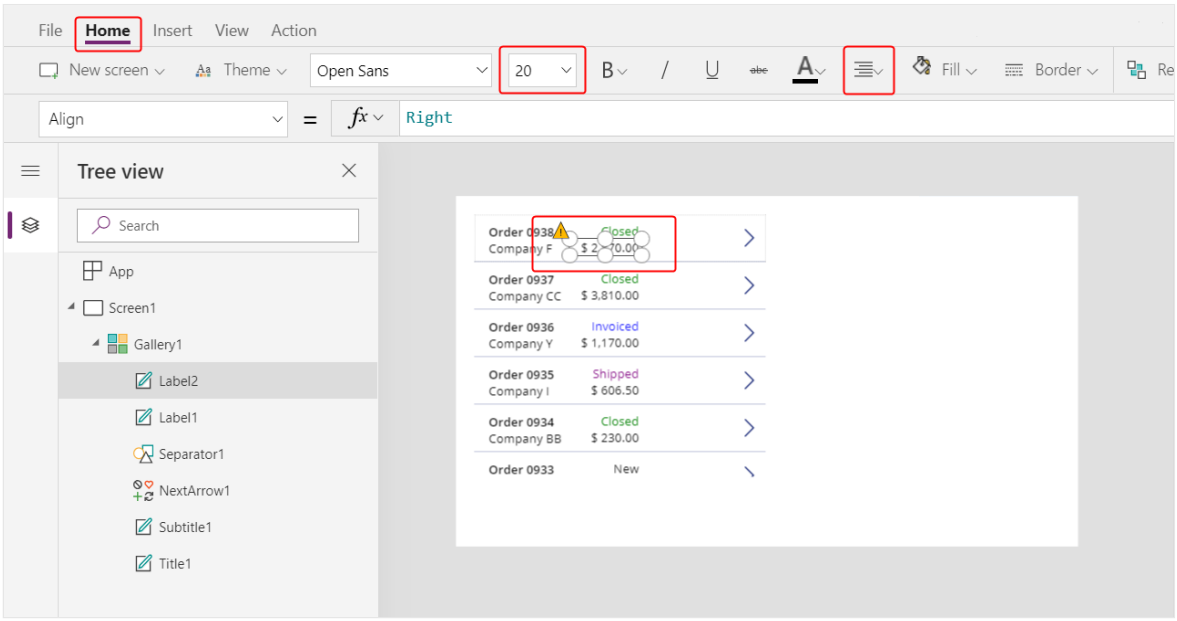
In this formula, the Sum function adds up the records in the **Order Details** table that are associated with each record in the **Order** table through a one-to-many relationship. These line items make up each order, and you'll use the same one-to-many relationship to show and edit the line items in the lower-right area of the screen.

This formula shows a blue underline and a delegation warning because Dataverse doesn't support delegation of complex aggregate functions (for example, the sum of a multiplication). You can ignore this information because no order in this

example will contain more than 500 line items. If necessary for a different app, you can increase that limit in **App settings**.

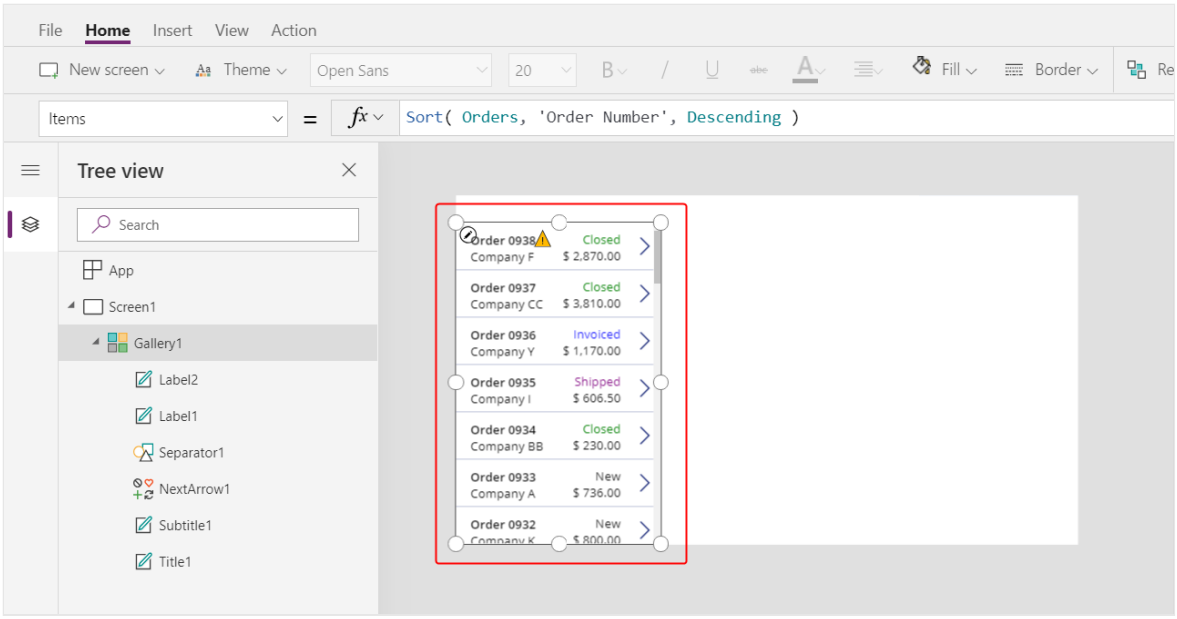
The **Text** function in this formula adds a currency symbol and formats the result with thousands and decimal separators. As written, the formula includes the language tag for U.S. English (**[$-en-US]**) and a dollar symbol (**$**). If you remove the language tag, it will be replaced with one based on your language settings, and the label will show the appropriate formats for that tag. If you leave the dollar symbol, the label will show the appropriate currency symbol based on the user's settings. However, you can force a different symbol to appear by replacing the dollar symbol with the one that you prefer.

5. On the **Home** tab, change the font size of the newest label to 20 points, and right align its text:



6. Move the gallery to the left edge of the screen, and decrease the gallery's width to close up some space.

7. Increase the gallery's height so that it's almost as tall as the screen, but leave a little room at the top for a title bar, which you'll add at the start of the next topic:



Summary

To recap, you started to build a single-screen canvas app by adding the order gallery, which includes these elements:

- An expression to show the order number: `"Orders " & ThisItem.OrderNumber`
- A field in a many-to-one relationship: `ThisItem.Customer.Company`
- A label that shows the name of an option in a set: `ThisItem.'Order Status'`
- A label that changes format based on which option in a set the label shows: `Switch( ThisItem.'Order Status', 'Orders Status'.Closed, Green, ...`
- A complex aggregate function over a one-to-many relationship: `Sum( ThisItem.'Order Details', Quantity * 'Unit Price' )`

Next topic

In the next topic, you'll add an **Edit form** control to display and edit an summary of whatever order the user selects in the gallery that you just created.

Create the summary form

Create a summary form in a canvas app

Article • 12/16/2022

Follow step-by-step instructions to create a summary form in a canvas app for managing fictitious data in the Northwind Traders database. This topic is part of a series that explains how to build a business app on relational data in Microsoft Dataverse. For best results, explore these topics in this sequence:

1. Create an order gallery.
2. Create a summary form (**this topic**).
3. Create a detail gallery.

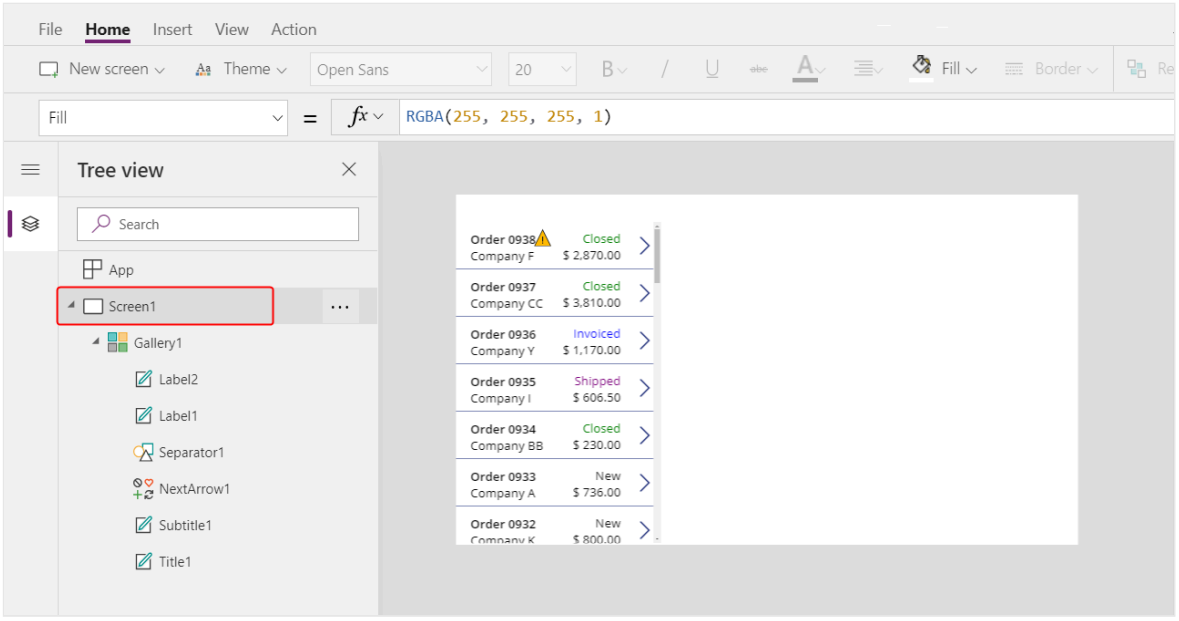
Prerequisites

1. Install the Northwind Traders database and apps.
2. Review the overview of the canvas app for Northwind Traders.
3. Create the order gallery yourself, or open the **Northwind Orders (Canvas) - Begin Part 2** app, which already contains that gallery.

Add a title bar

Across the top of the app, create a title bar, which will hold action buttons by the end of this topic.

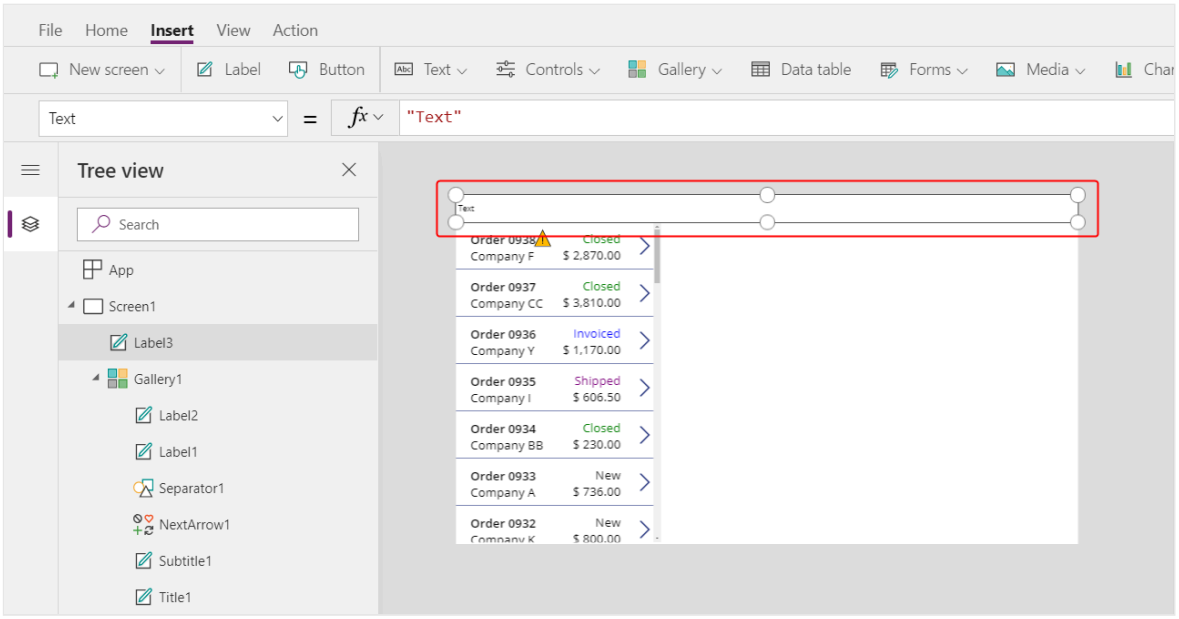
1. In the **Tree view** pane, select **Screen1** to ensure that you don't accidentally add a control to the order gallery:



2. On the **Insert** tab, select **Label** to insert a Label control:

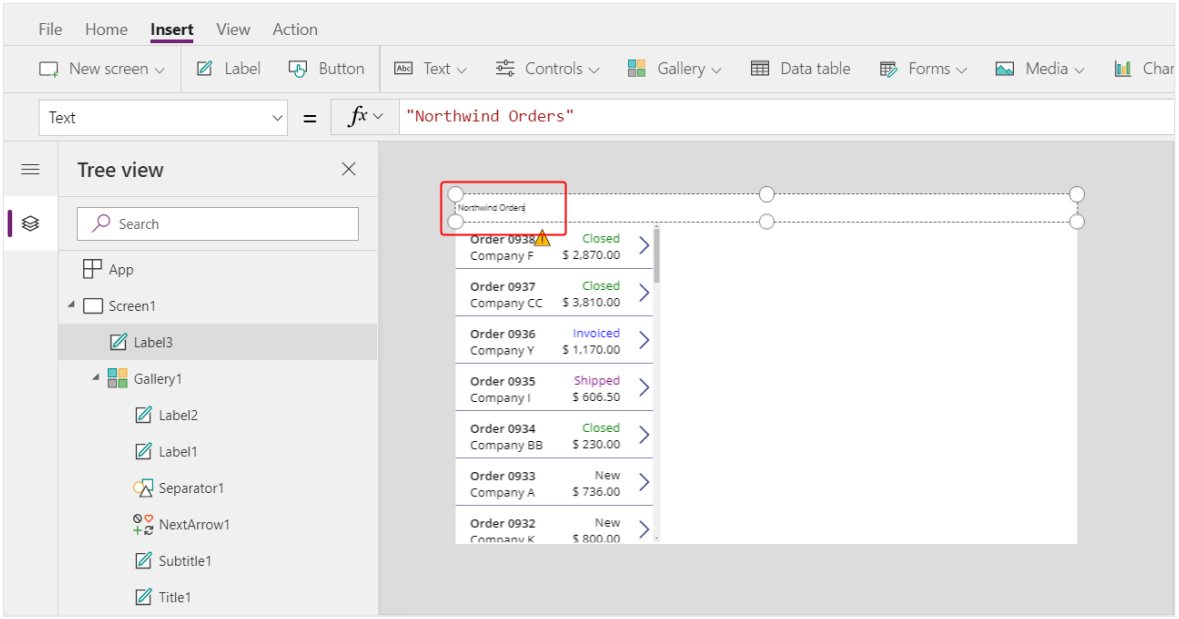
   The new label should appear only once, above the gallery. If it appears in each item of the gallery, delete the first instance of the label, ensure that the screen is selected (as the previous step describes), and then insert the label again.

3. Move and resize the new label to span the top of the screen:



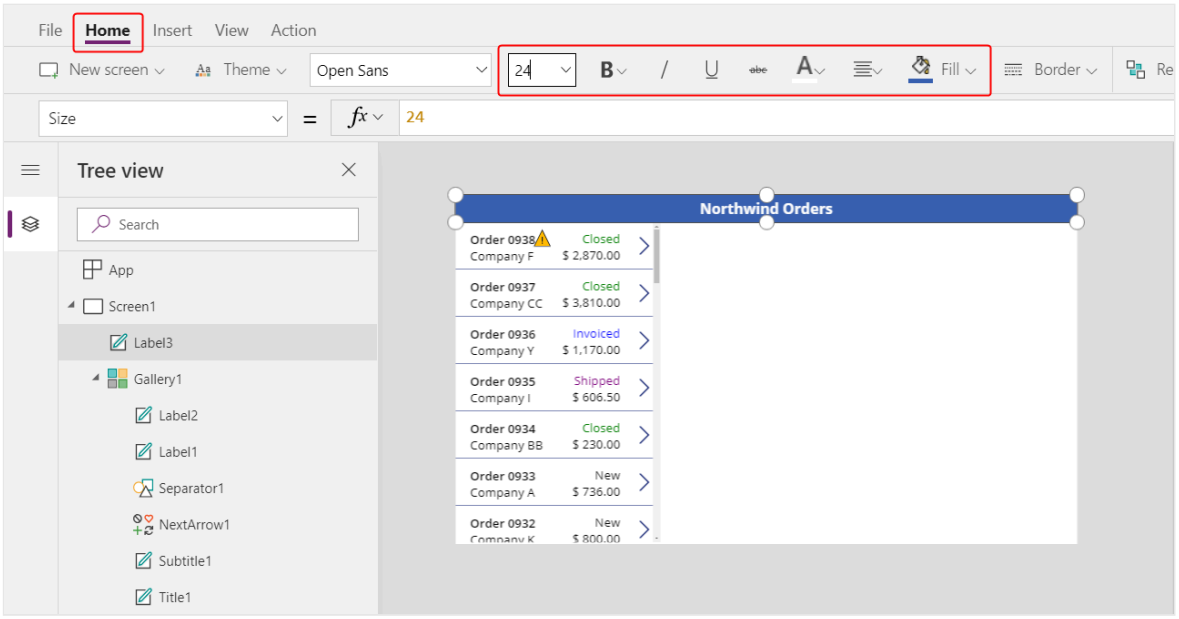
4. Double-click the text of the label, and then type **Northwind Orders**.

   As an alternative, modify the **Text** property in the formula bar to achieve the same result:



5. On the **Home** tab, format the label:

   - Increase the font size to 24 points.
   - Make the text bold.
   - Make the text white.
   - Center the text.
   - Add a dark-blue fill to the background.

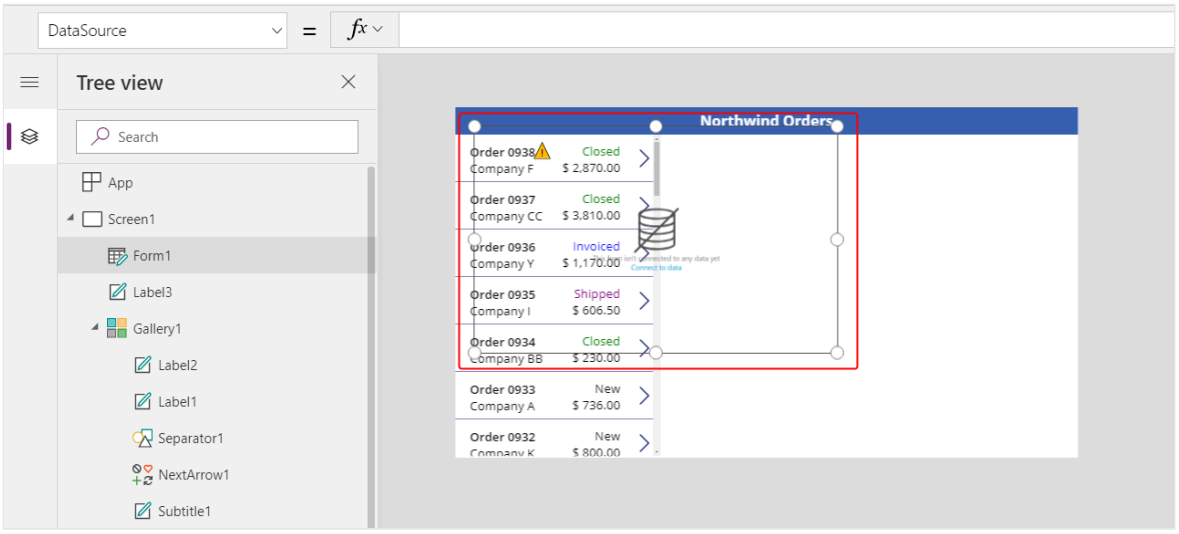


Add an Edit form control

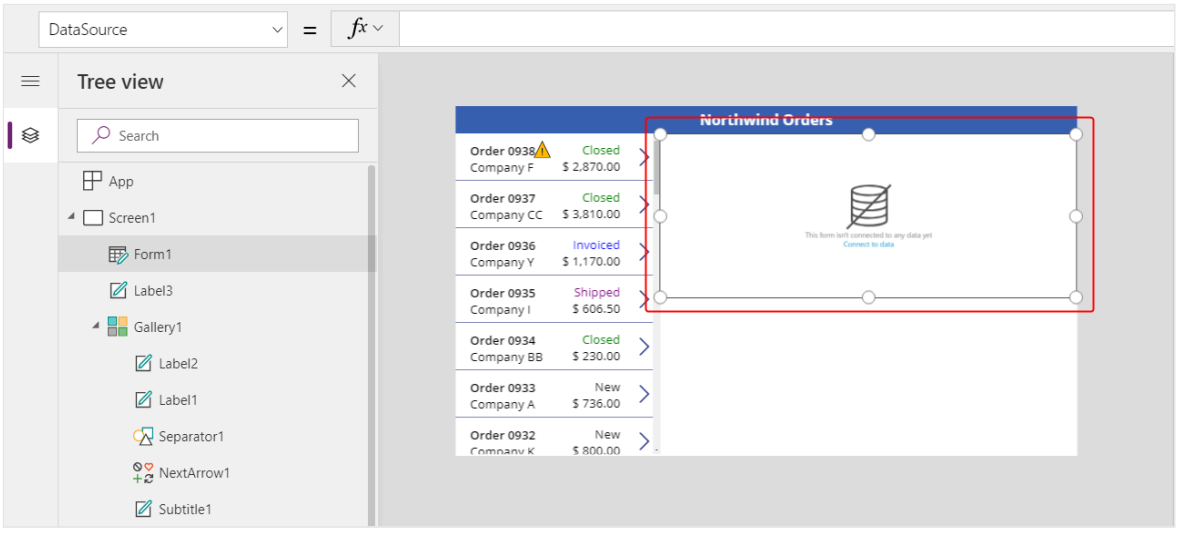
In this section, you'll add controls to show a summary of any order that the user selects in the gallery.

1. On the **Insert** tab, insert an **Edit form** control:

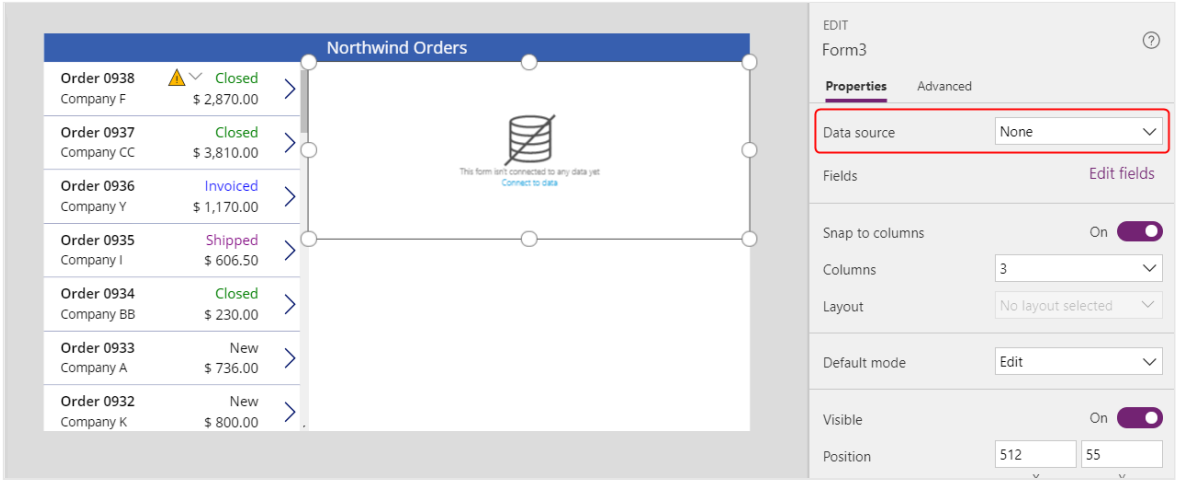
   By default, the form appears in the upper-left corner, where other controls might make it difficult to find:



2. Move and resize the form to cover the upper-right corner of the screen under the title bar:



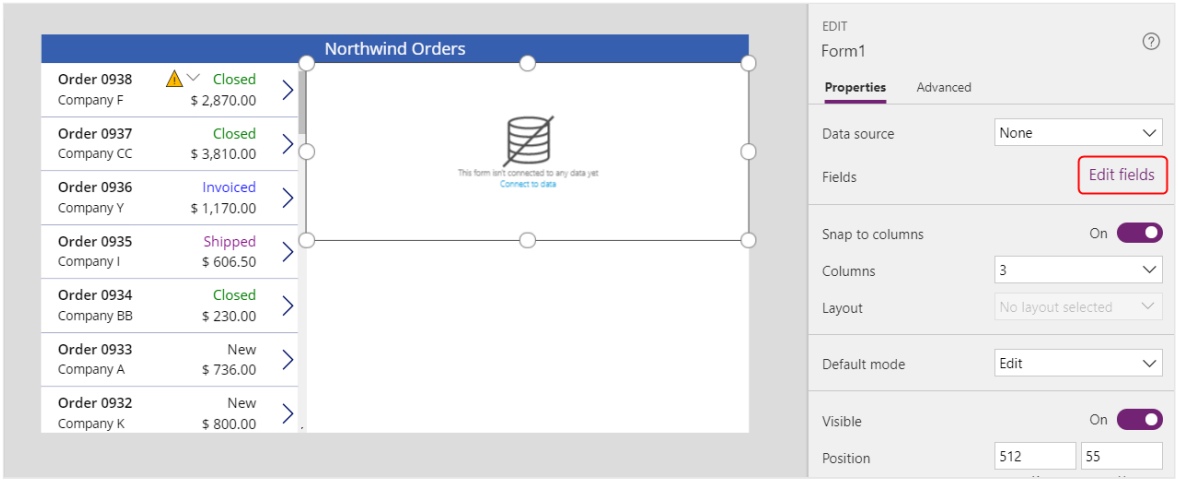
3. In the **Properties** pane, select the **Data source** drop down.



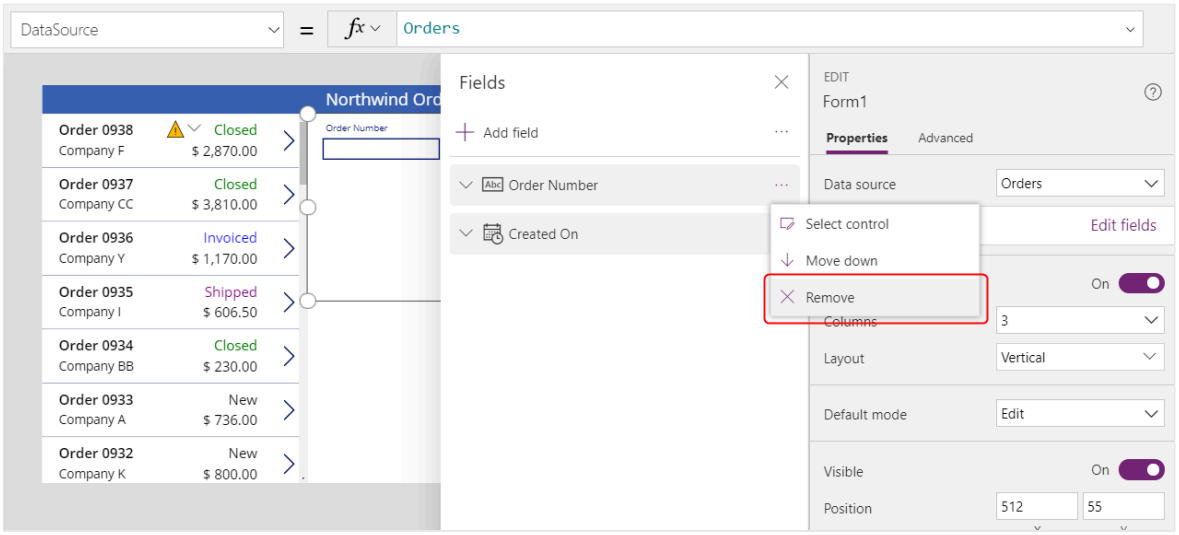
4. Select the **Orders** data source.

Add and arrange fields

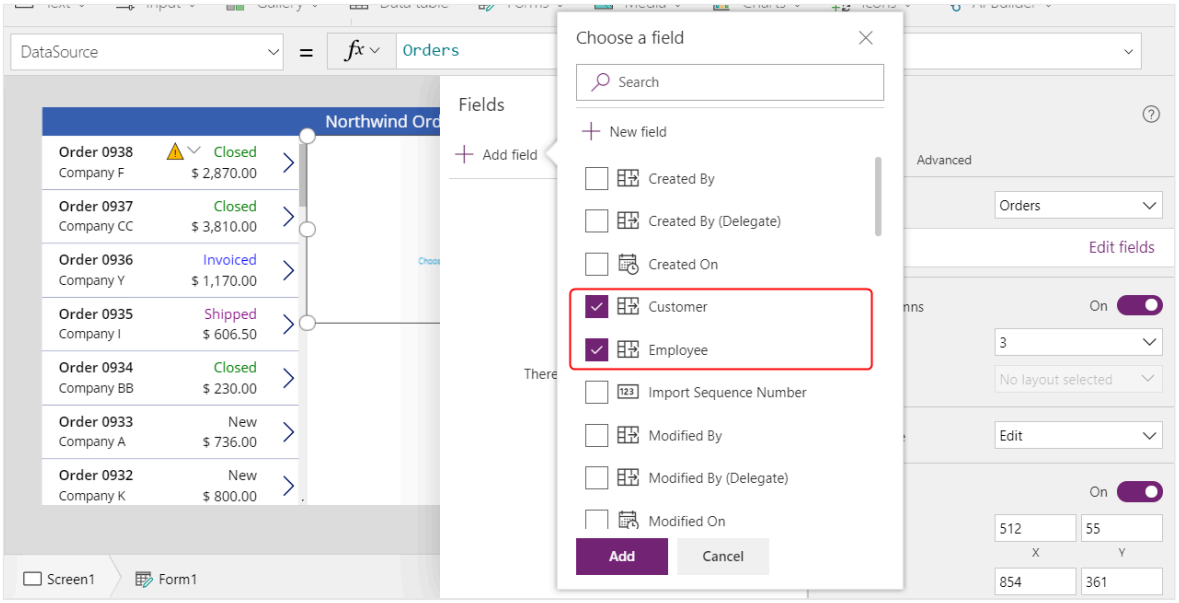
1. In the **Properties** tab near the right edge, select **Edit fields** to open the **Fields** pane.



2. If the **Fields** pane is not empty, remove the fields that have already been inserted.

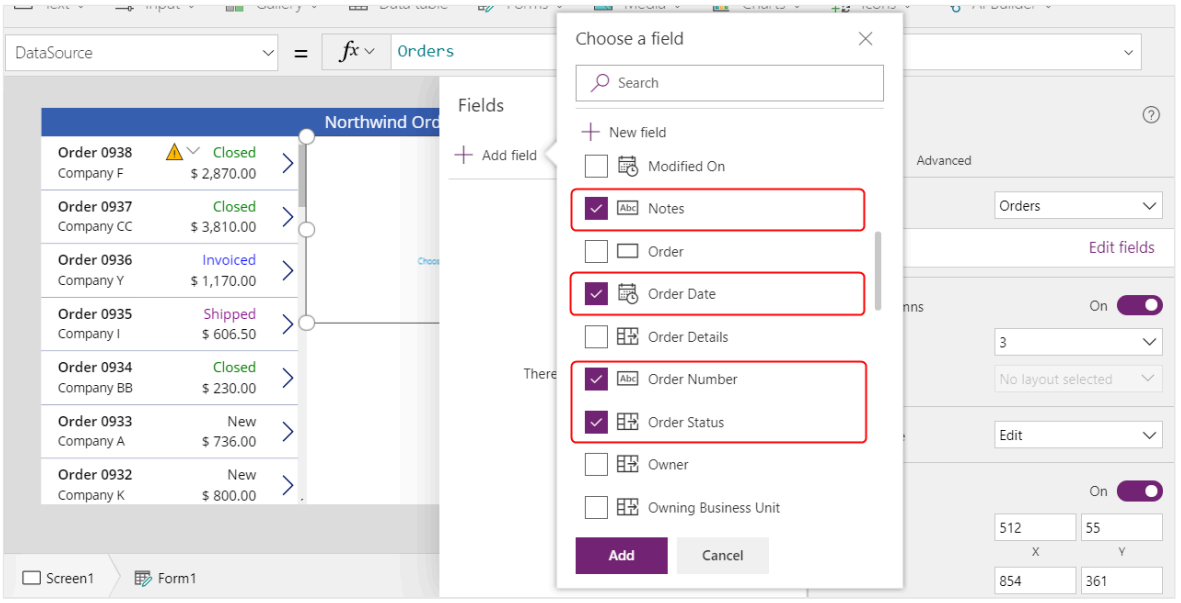


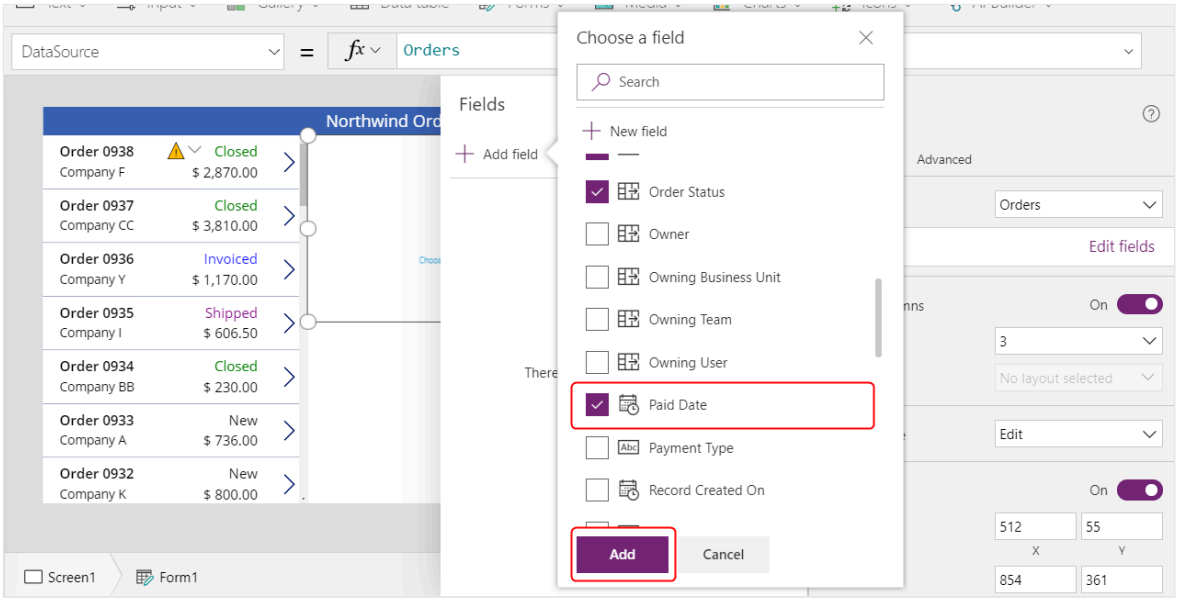
3. After the fields list is empty, select **Add field**, and then select the check boxes for the **Customer** and **Employee** fields.



4. Scroll down until these fields appear, and then select their check boxes:

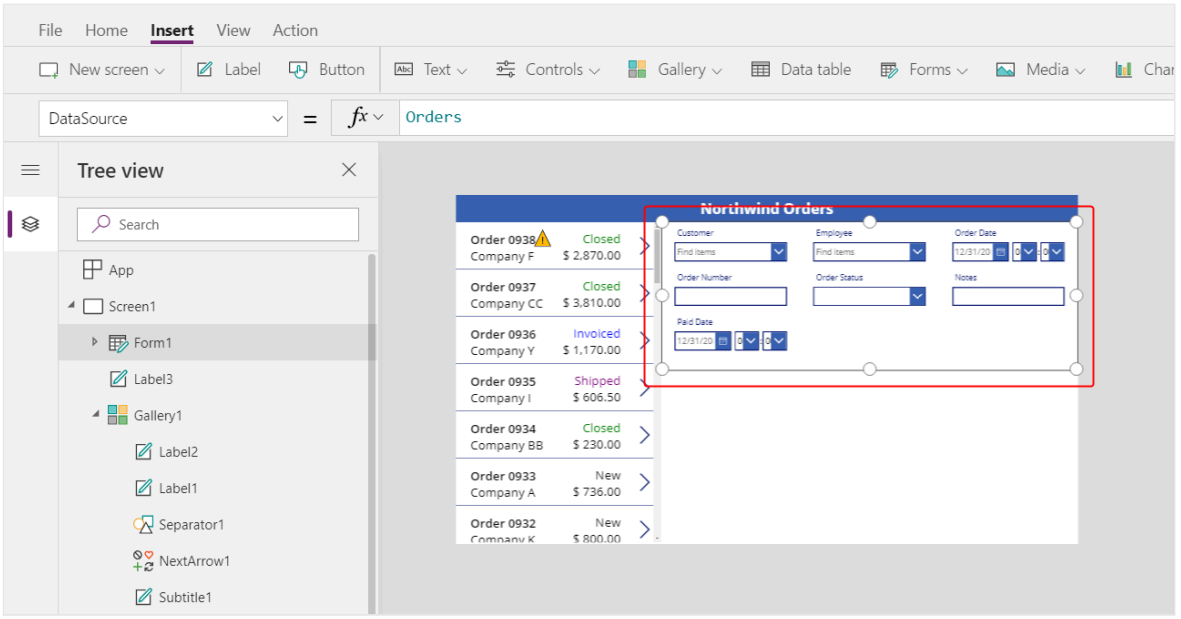
   - **Notes**
   - **Order Date**
   - **Order Number**
   - **Order Status**
   - **Paid Date**





5. At the bottom of the **Fields** pane, select **Add**, and then close the **Fields** pane.

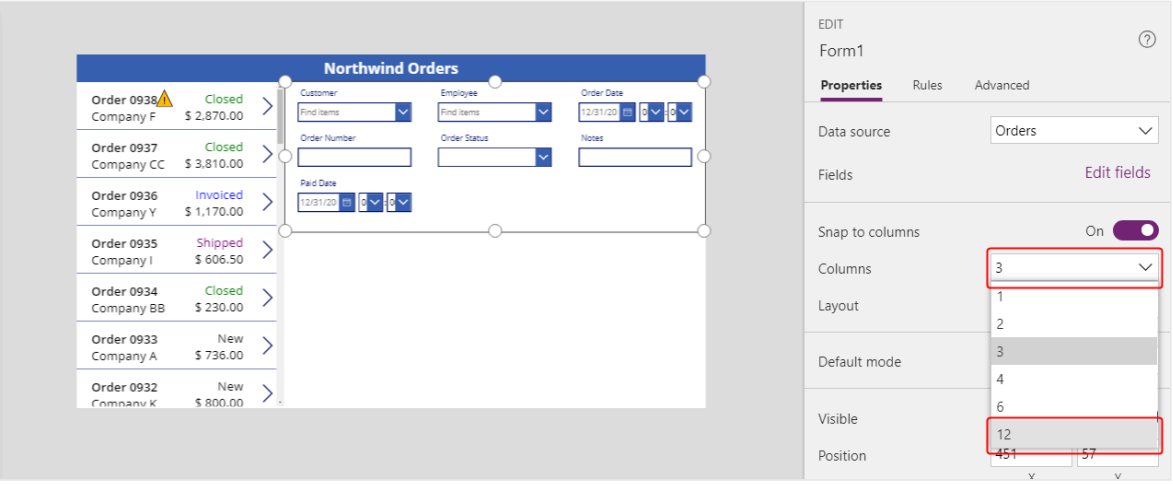
   The form shows seven fields, which may be in a different order:



> **Note**
>
> If any field shows a red error icon, a problem might have occurred when data was pulled from the source. To resolve the error, refresh the data:
>
> a. On the **View** tab, select **Data sources**.
>
> b. In the **Data** pane, select **Data sources**.
>
> c. Next to **Orders**, select the ellipsis (...), select **Refresh**, and then close the **Data** pane.
>
> If the combo box for the customer or employee name still shows an error, check the **Primary text** and **SearchField** of each box by selecting it and then opening the **Data** pane. For the customer box, both fields should be set to **nwind_company**. For the employee box, both fields should be set to **nwind_lastname**.

6. With the form selected, change the number of columns in the form from 3 to 12 in the **Properties** tab near the right edge.

   This step adds flexibility as you arrange the fields:

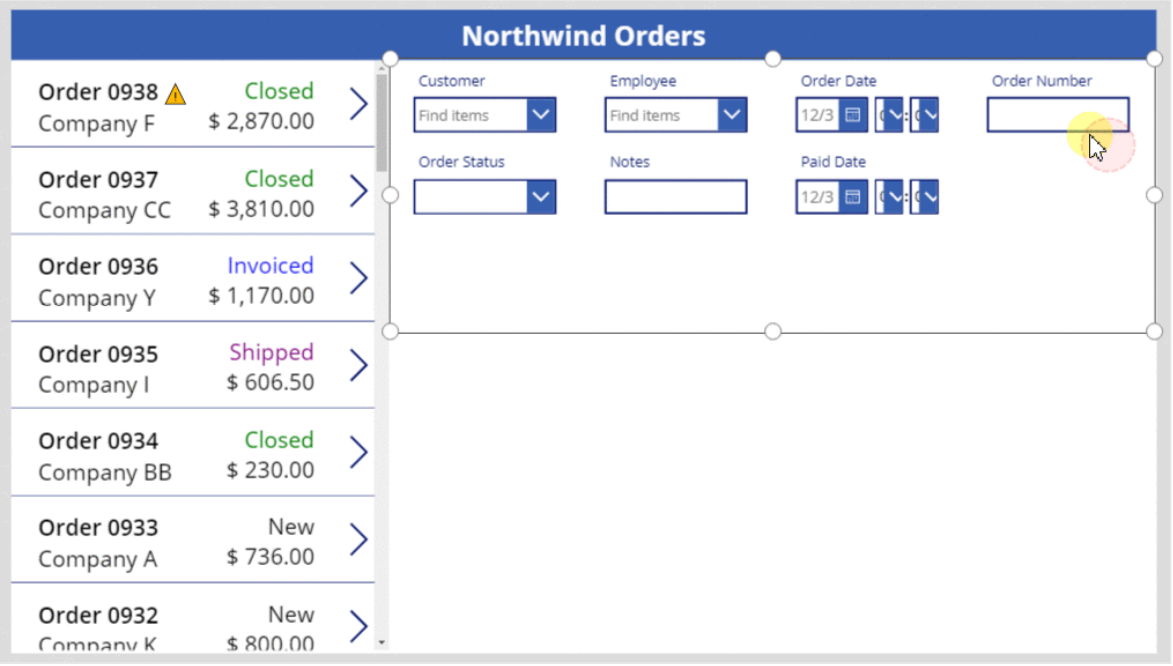


Many UI designs rely on 12-column layouts because they can evenly accommodate rows of 1, 2, 3, 4, 6, and 12 controls. In this topic, you'll create rows that contain 1, 2, or 4 controls.

7. Move and resize the fields by dragging their handles, just as you would any other control, so that each row contains these data cards in the specified order:

   - First row: **Order Number**, **Order Status**, **Order Date**, and **Paid Date**
   - Second row: **Customer** and **Employee**
   - Third row: **Notes**

> **Note**
>
> You might find it easier to widen the **Notes**, **Customer**, and **Employee** data cards before you arrange them.



More information about how to arrange fields in a form: Understand data-form layout for canvas apps.

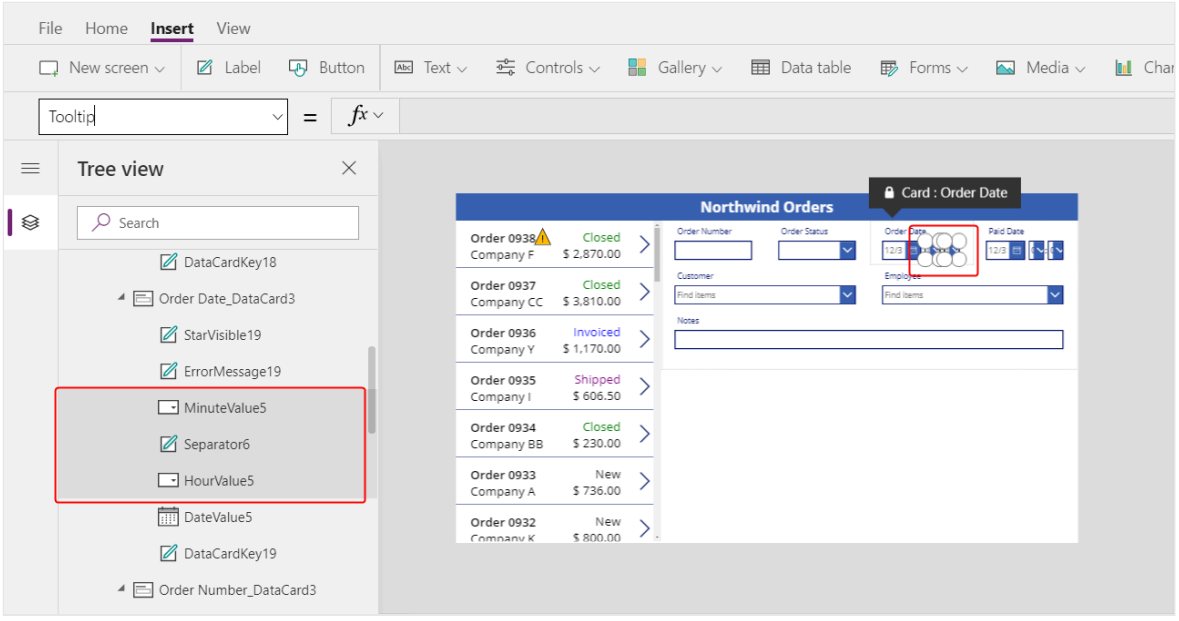
Hide time controls

In this example, you don't need the time portions of the date fields because that level of granularity can distract the user. If you delete them, you might cause problems in formulas that rely on those controls to update date values or determine the position of another control in the data card. Instead, you'll hide the time controls by setting their **Visible** property.

1. In the **Tree view** pane, select the **Order Date** data card.

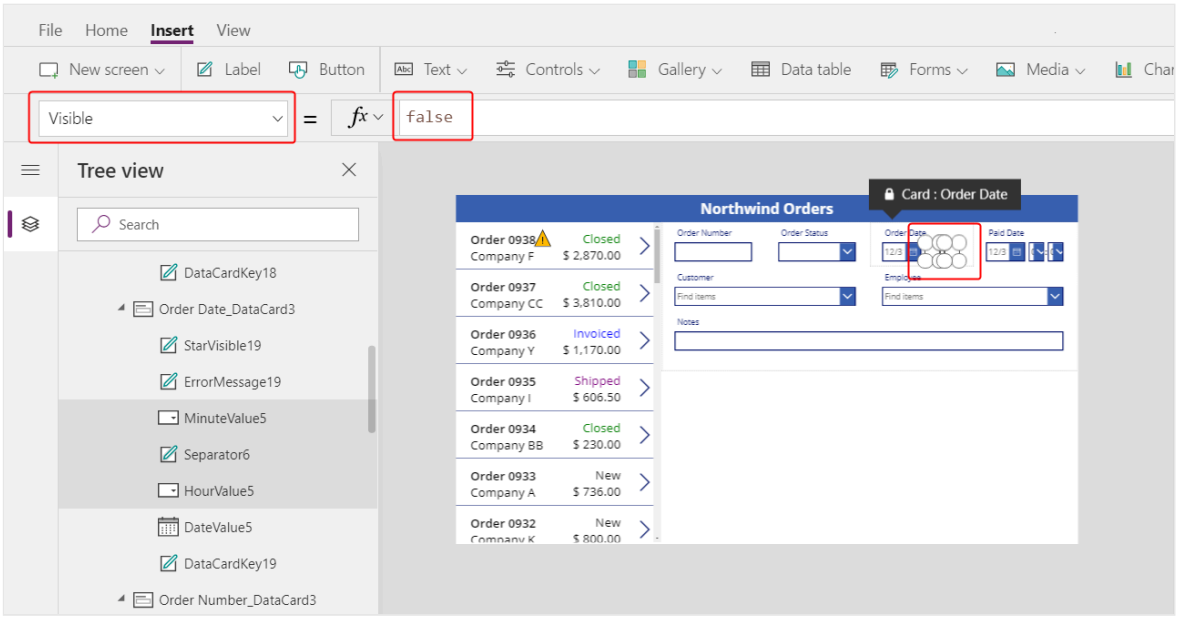
   The card might have a different name, but it contains **Order Date**.

2. While holding down the Shift key, select the hour, minute, and colon-separator controls in the **Order Date** data card.

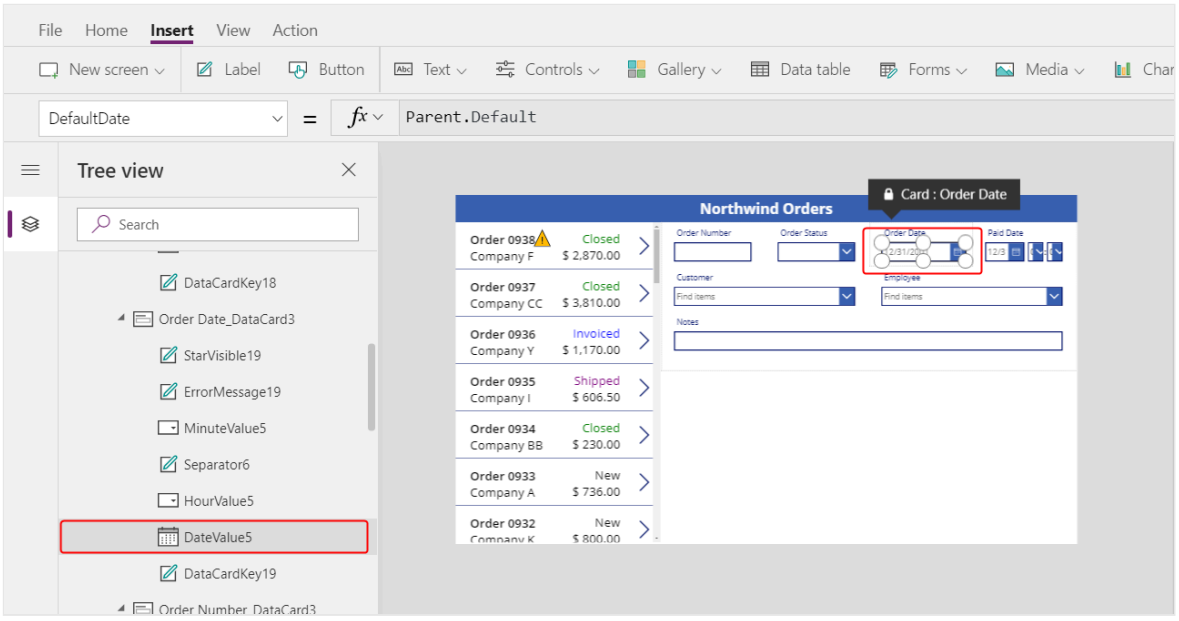


3. Set the controls' **Visible** property to **false**.

   All selected controls disappear from the form:

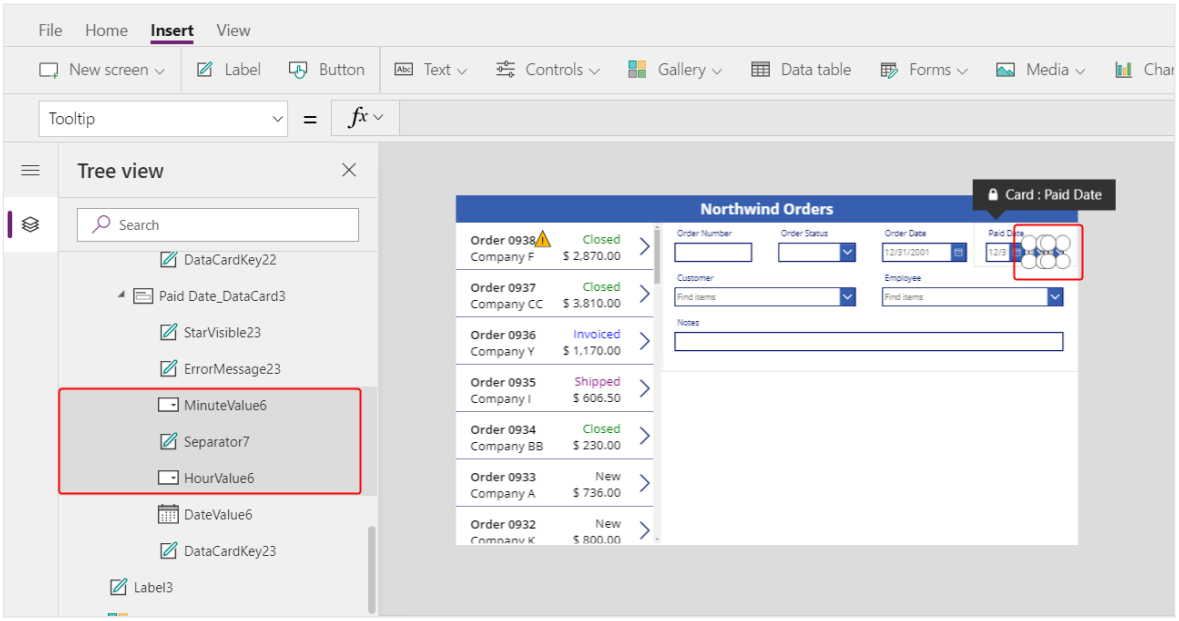


4. Resize the **Date picker** control to show the complete date:

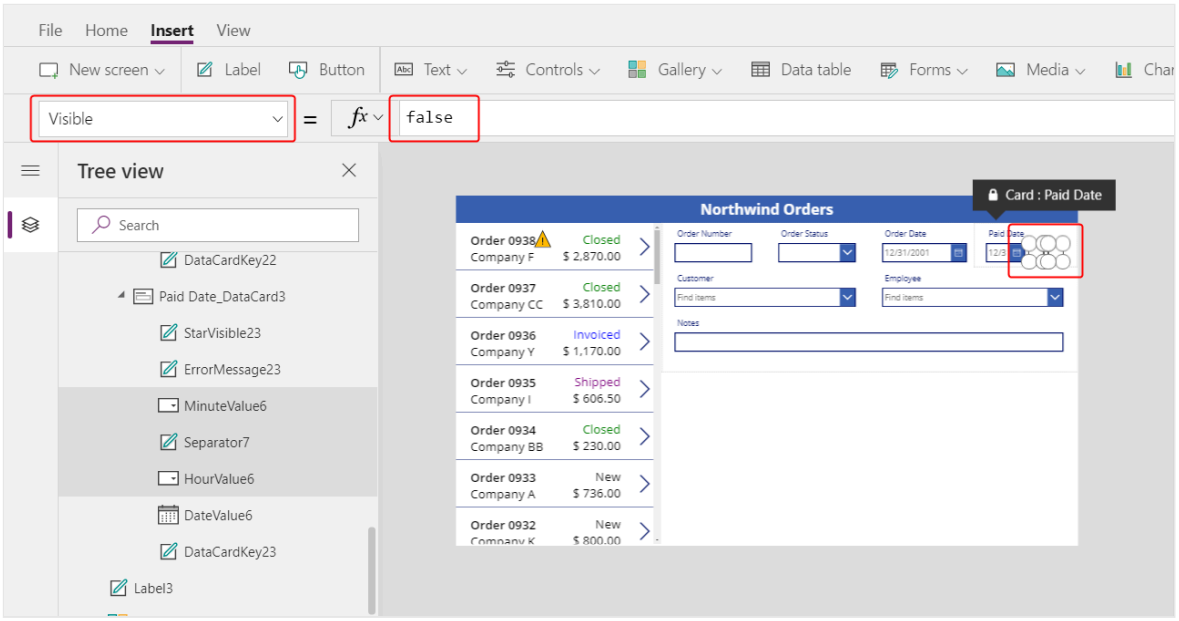


Next, you'll repeat the last few steps for the **Paid Date** field.

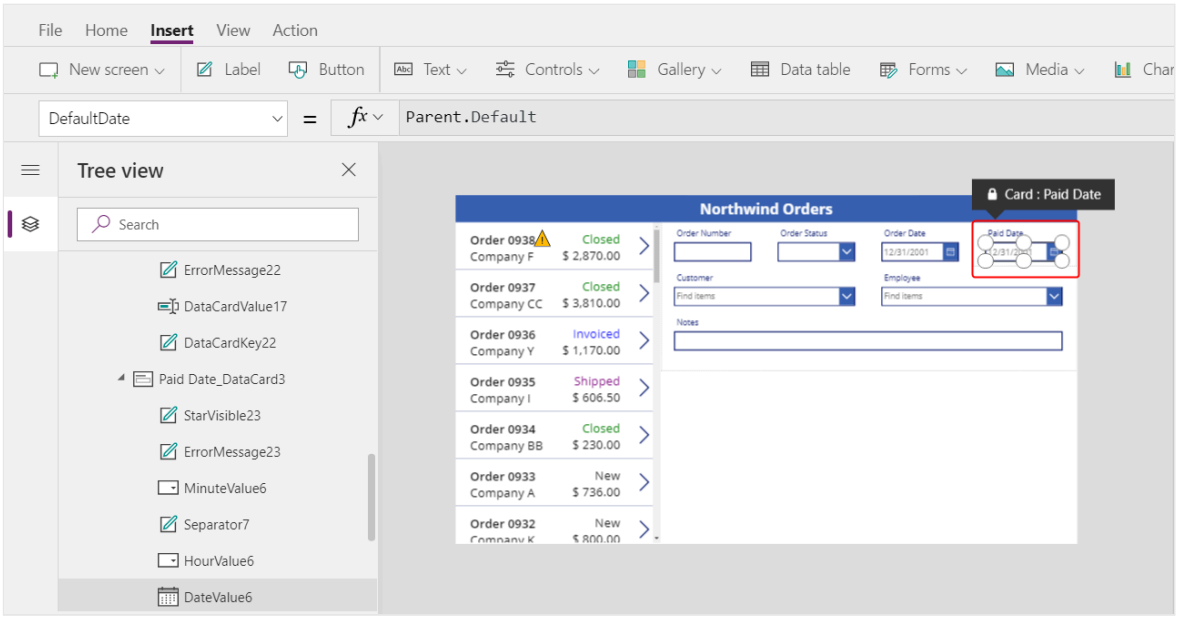
5. In the **Tree view** pane, select the time controls in the **Paid Date** data card:



6. Set the selected controls' **Visible** property to **false**:



7. Resize the date picker in the **Date Paid** card:



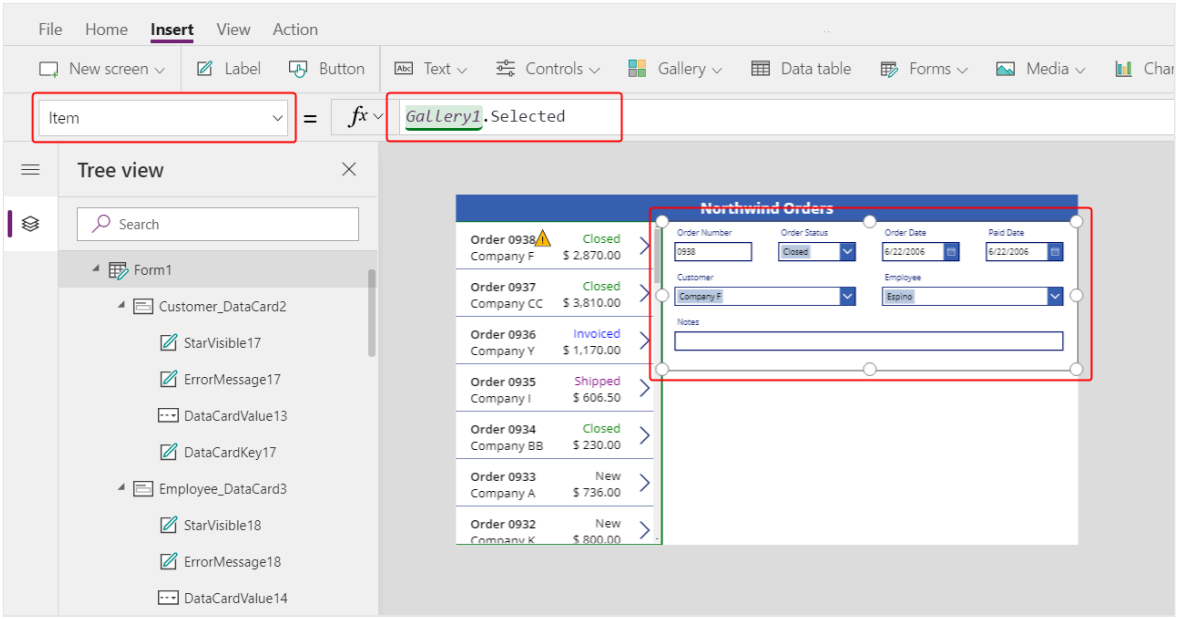
Connect the order gallery

1. In the **Tree view** pane, collapse the form to more easily find the name of the order gallery, and then, if necessary, rename it to **Gallery1**.

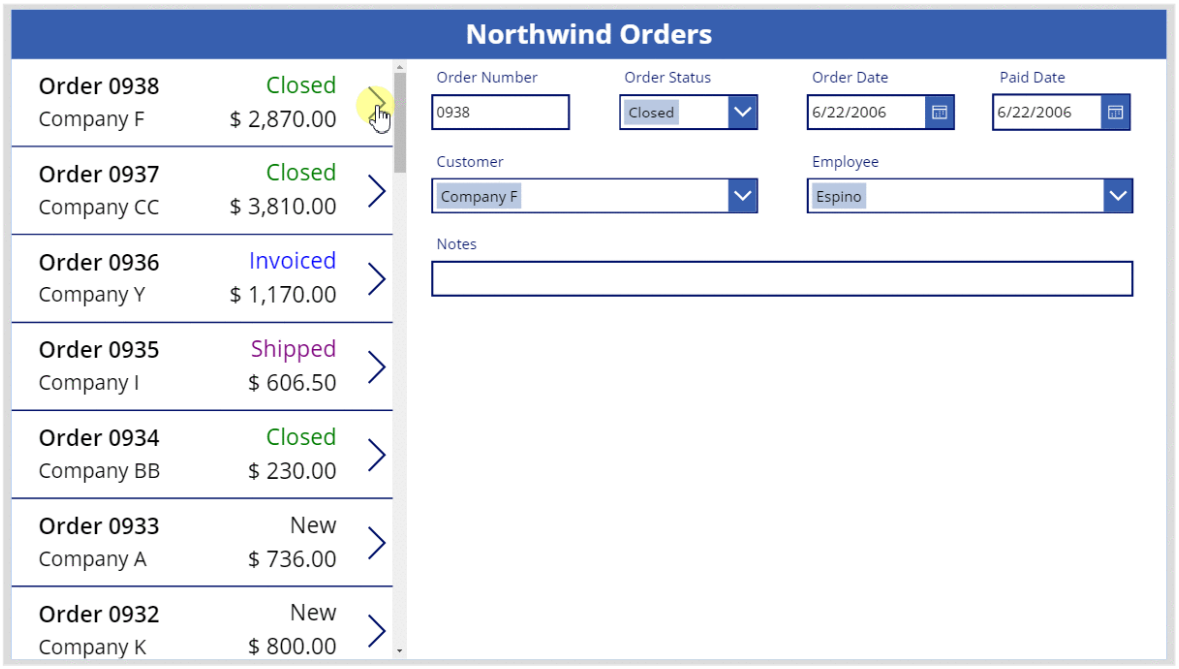
2. Set the summary form's **Item** property to this expression:

```
Power Fx

Gallery1.Selected
```



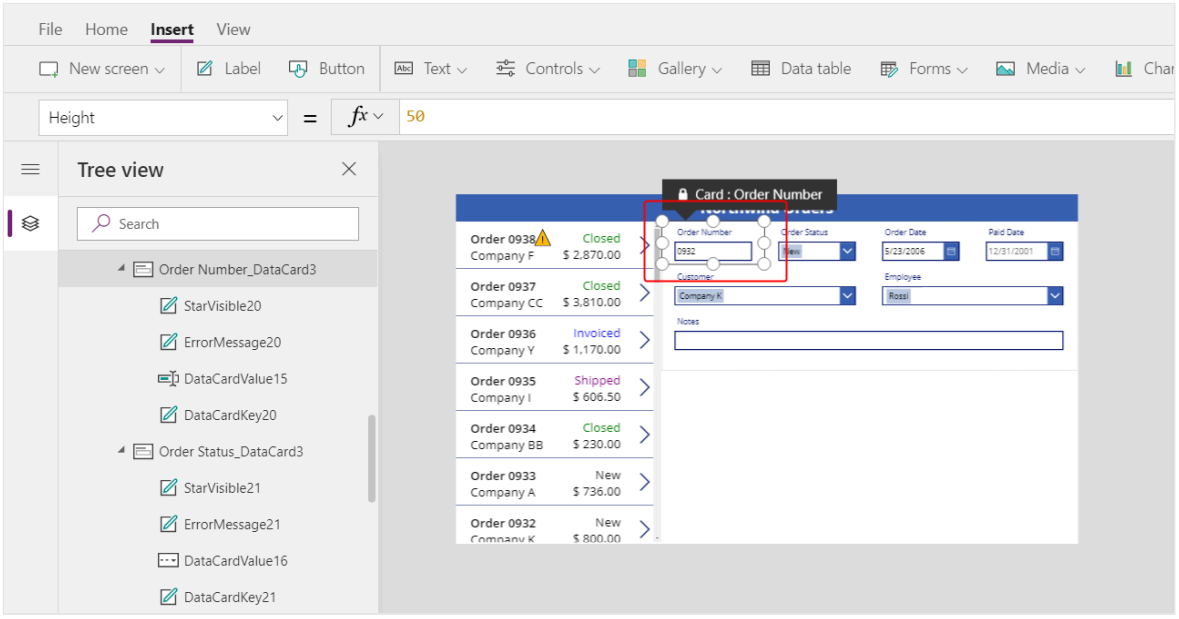
The form shows an summary of whatever order the app user selects in the list.



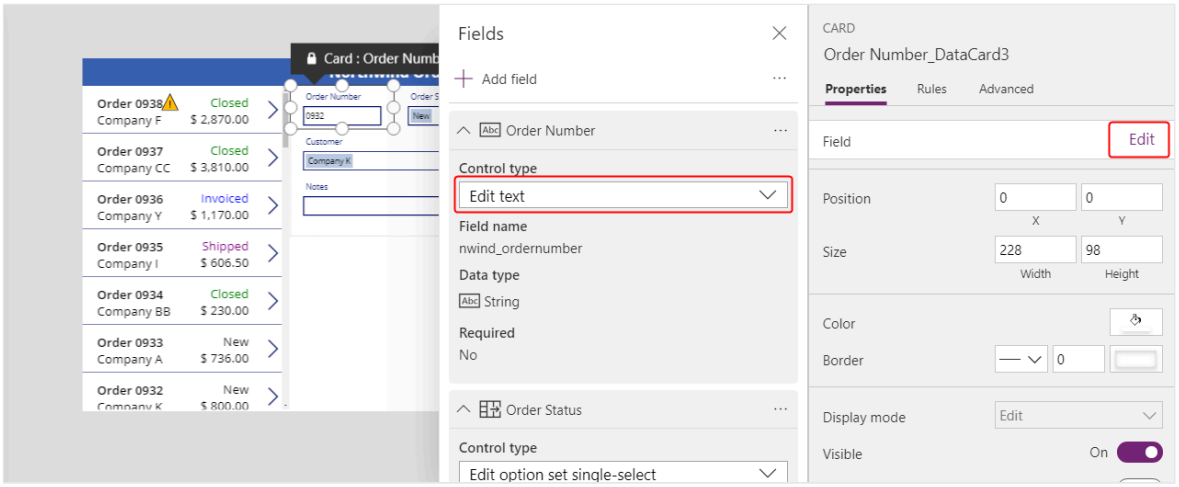
Replace a data card

Order number is an identifier that Dataverse assigns automatically when you create a record. This field has a **Text input** control by default, but you'll replace it with a label so that the user can't edit this field.

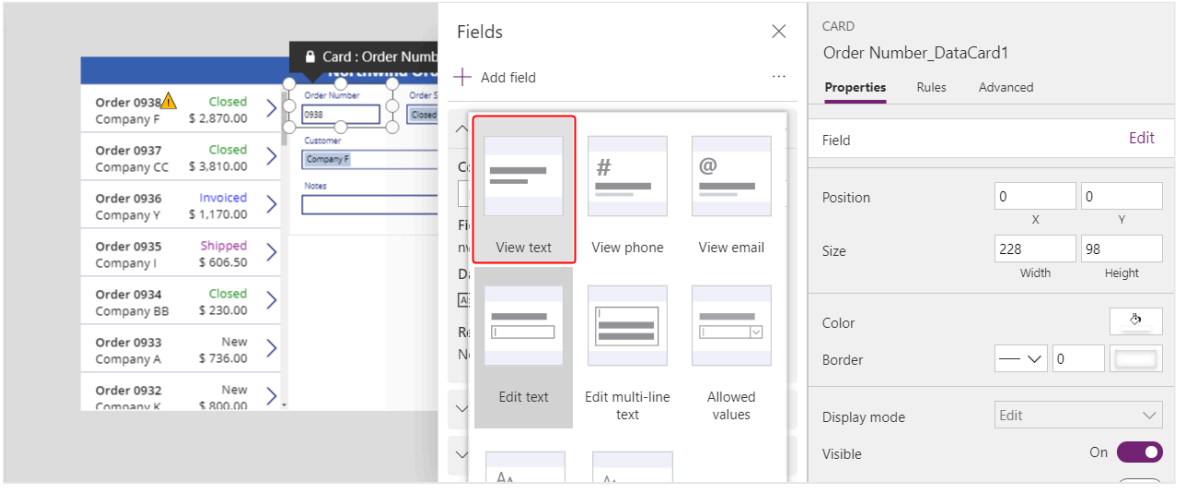
1. Select the form, select **Edit fields** in the **Properties** tab near the right edge, and then select the **Order number** field:



2. Open the **Control type** list:

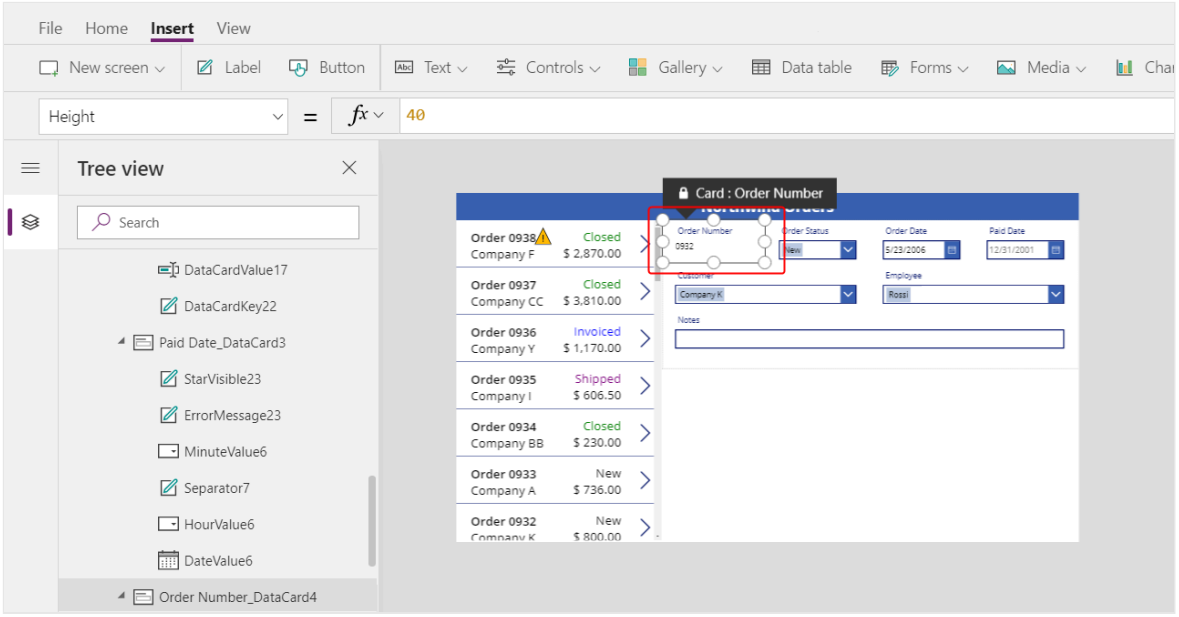


3. Select the **View text** data card:

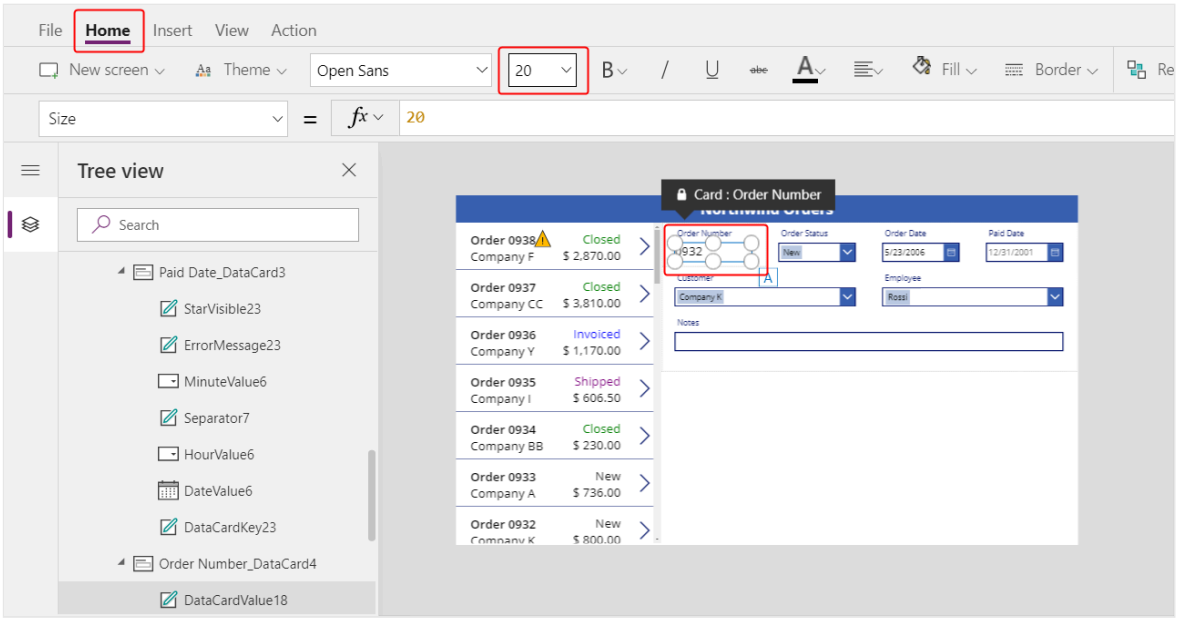


4. Close the **Fields** pane.

   The user can no longer change the order number:



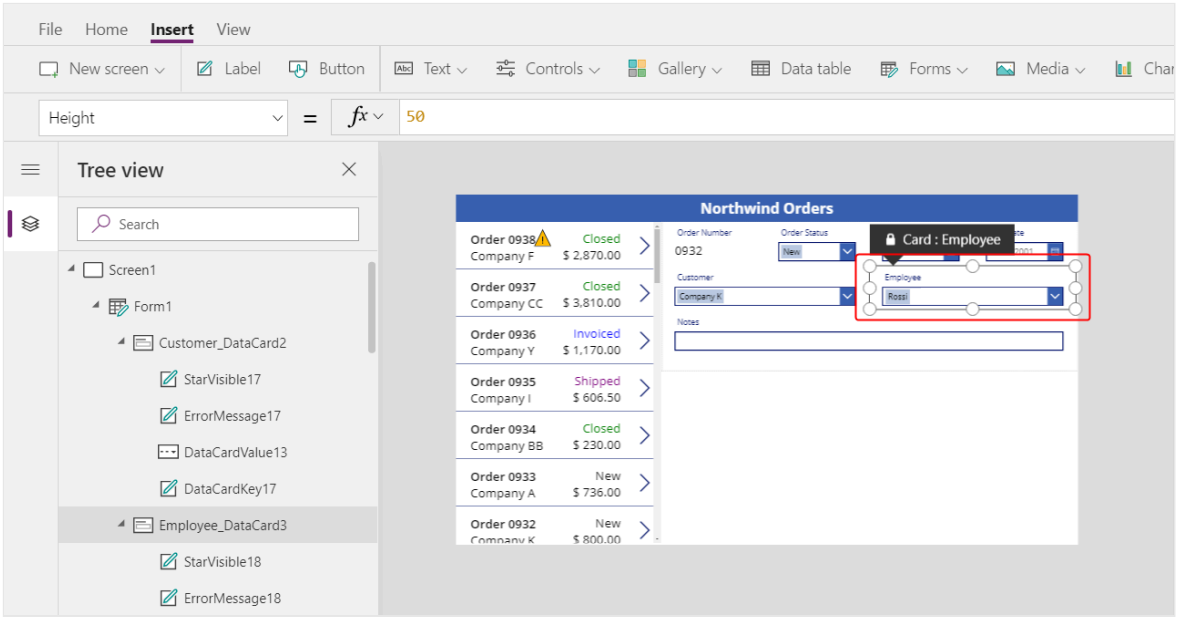
5. On the **Home** tab, change the order number's font size to 20 points so that the field is easier to find:



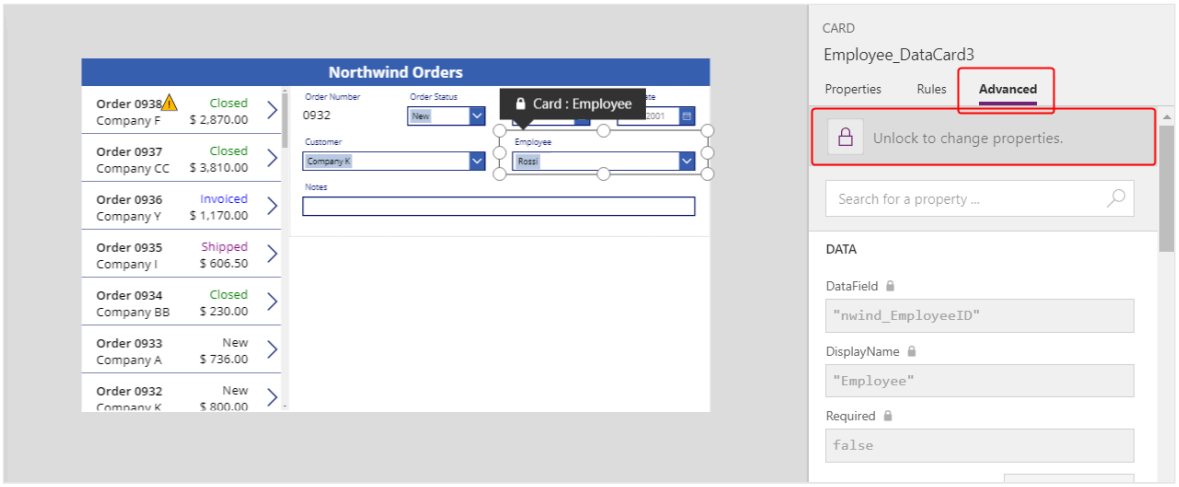
Use a many-to-one relationship

The **Orders** table has a many-to-one relationship with the **Employees** table: each employee can create many orders, but each order can be assigned to only one employee. When the user selects an employee in the Combo box control, its **Selected** property provides that employee's entire record from the **Employees** table. As a result, you can configure an Image control to show the picture of whatever employee the user selects in the combo box.

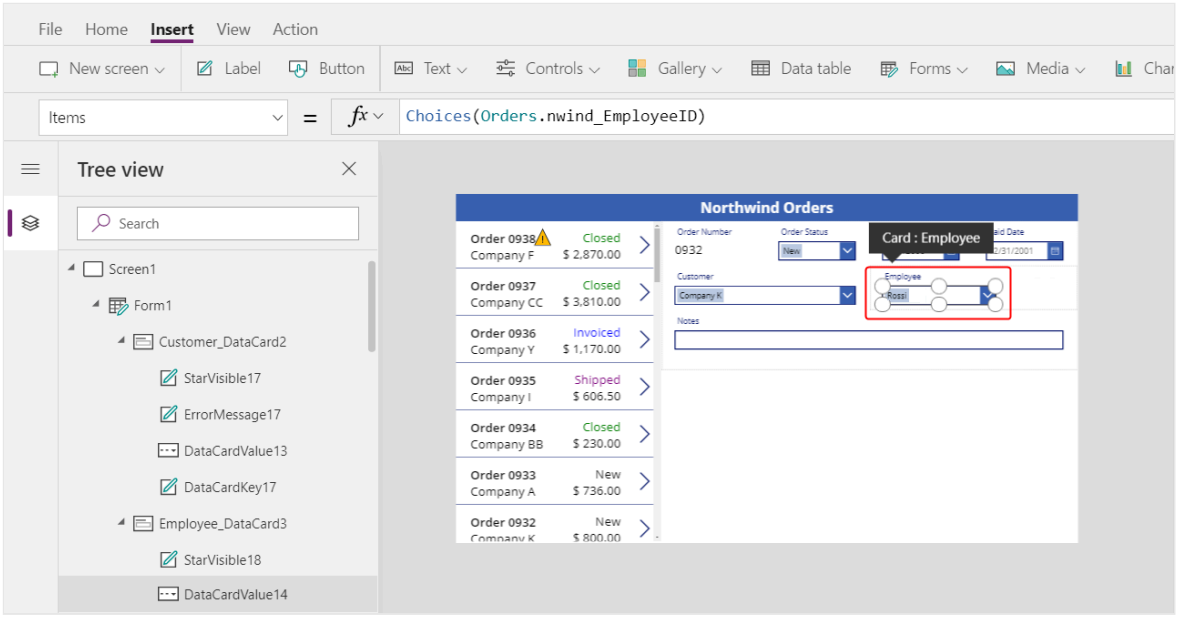
1. Select the **Employee** data card:



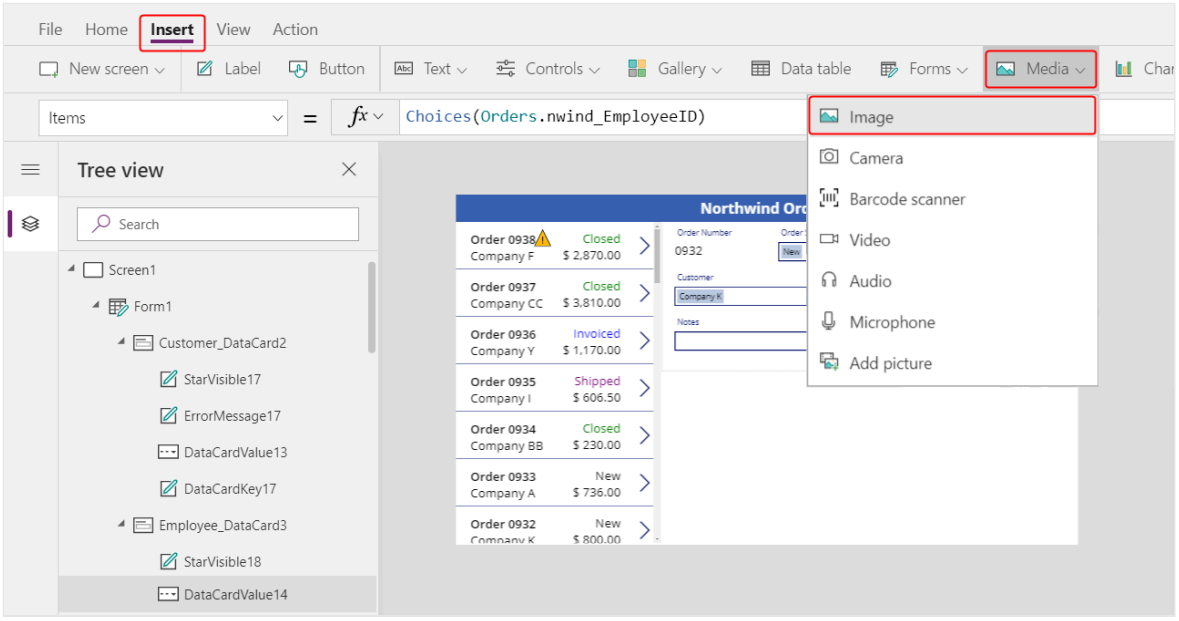
2. In the **Advanced** tab near the right edge, unlock the data card so that you can edit formulas that were previously read-only:



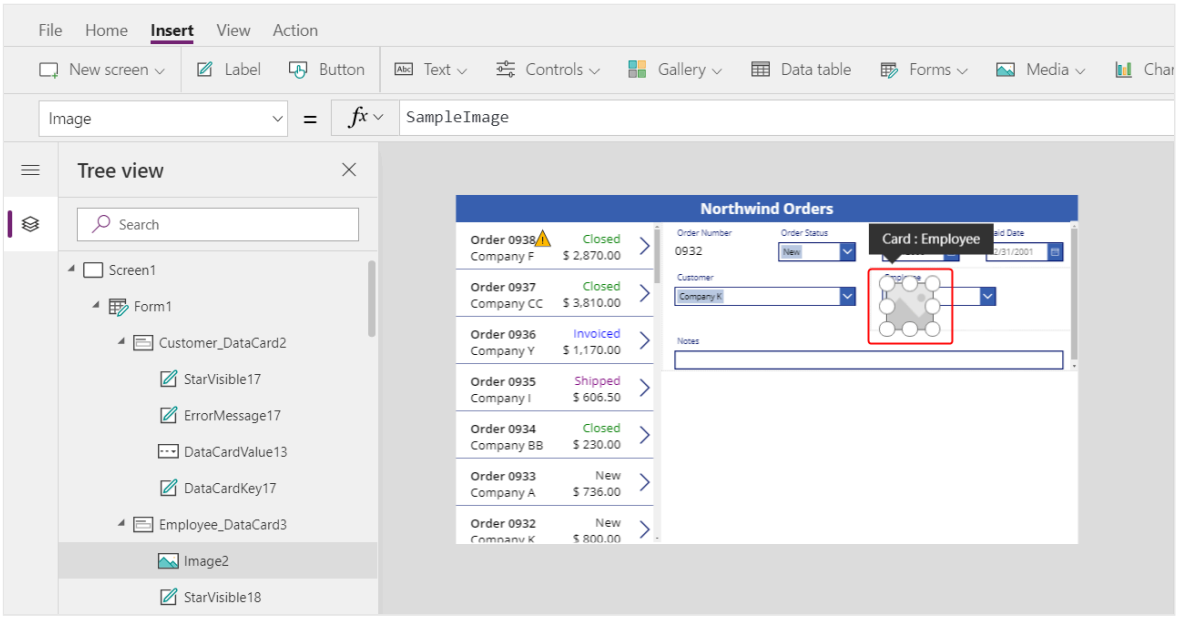
3. In the data card, reduce the width of the combo box to make room for the employee picture:



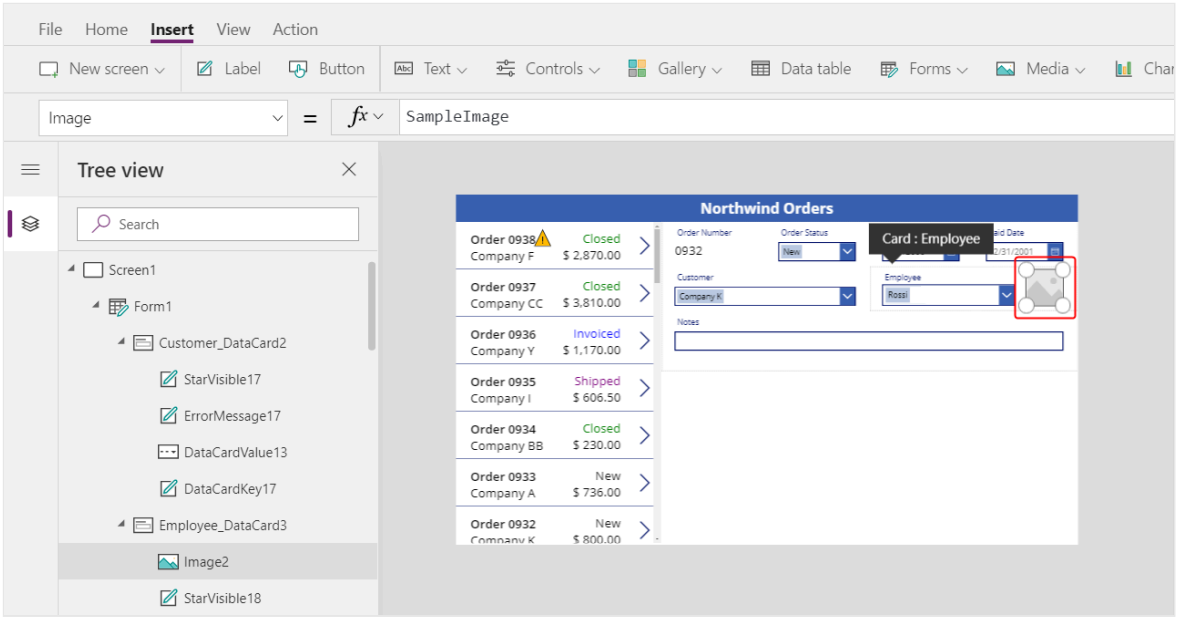
4. On the **Insert** tab, select **Media** > **Image**:



An image appears in the data card, which expands to accommodate it:



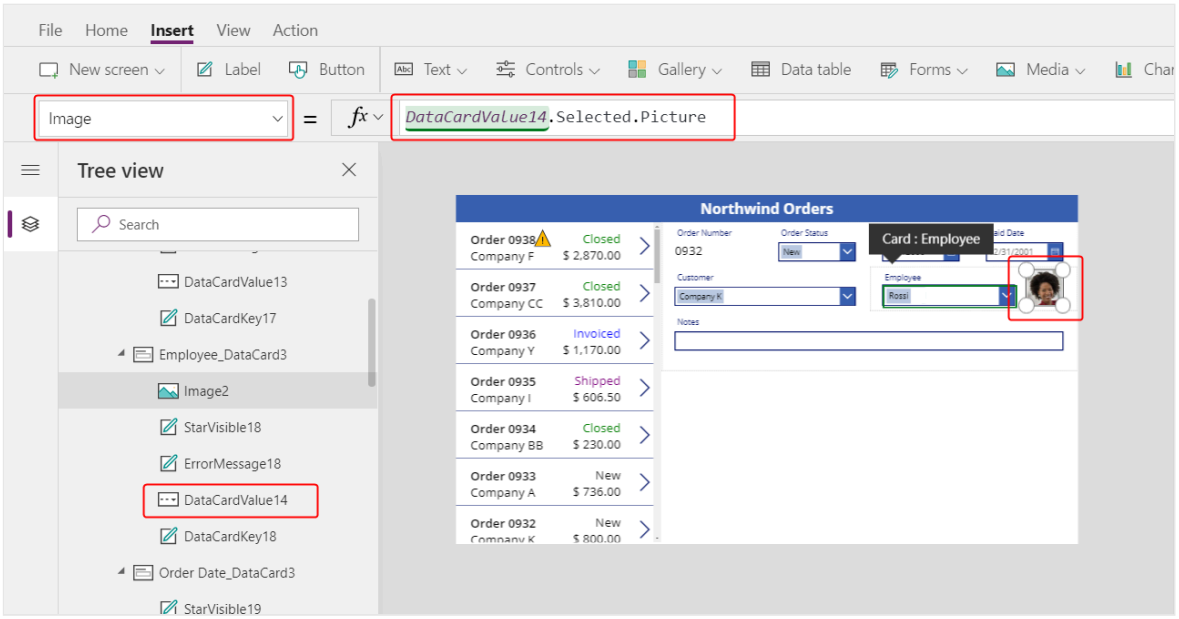
5. Resize the image, and move it to the right of the combo box:



6. Set the **Image** property of the image to this formula, replacing the number at the end of DataCardValue if necessary:

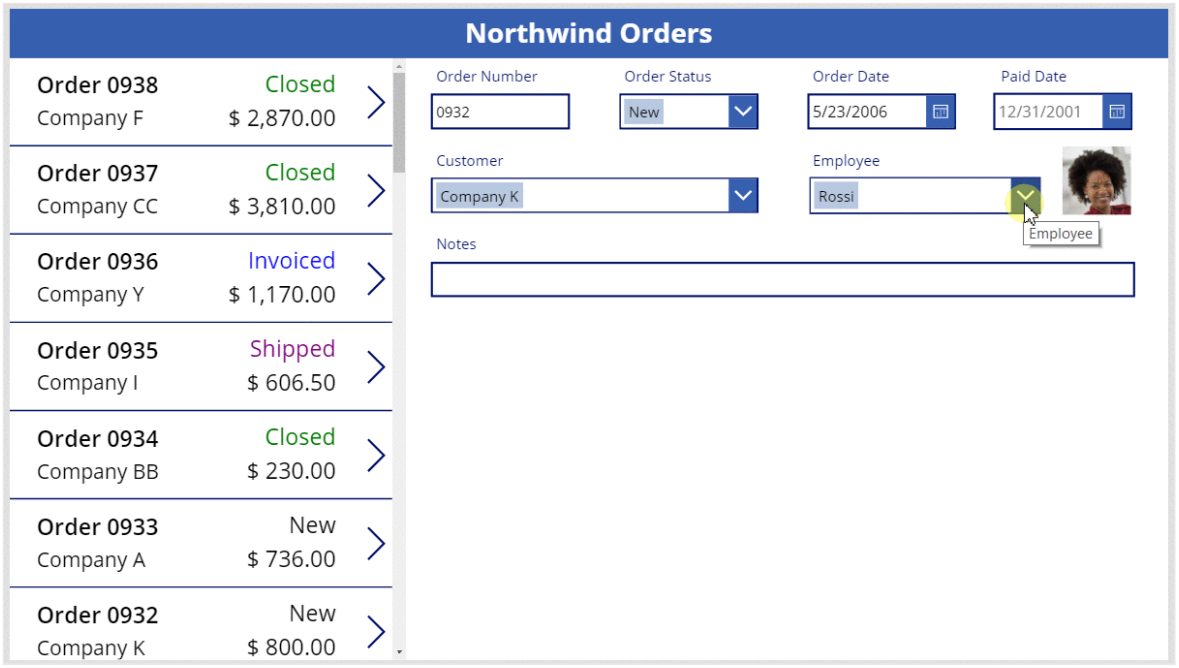
Power Fx

```
DataCardValue7.Selected.Picture
```



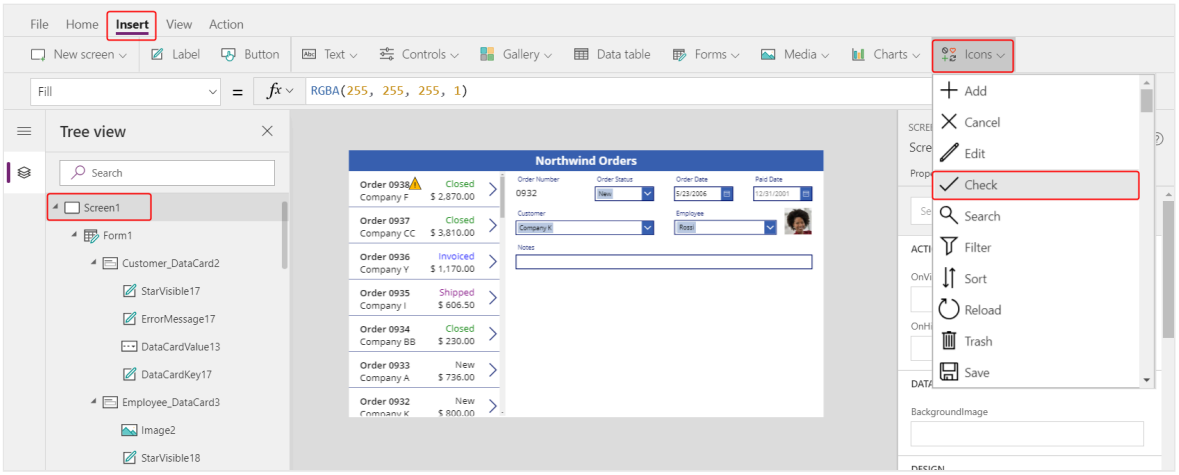
The picture of the selected employee appears.

7. While holding down the Alt key, select a different employee in the combo box to confirm that the picture also changes.

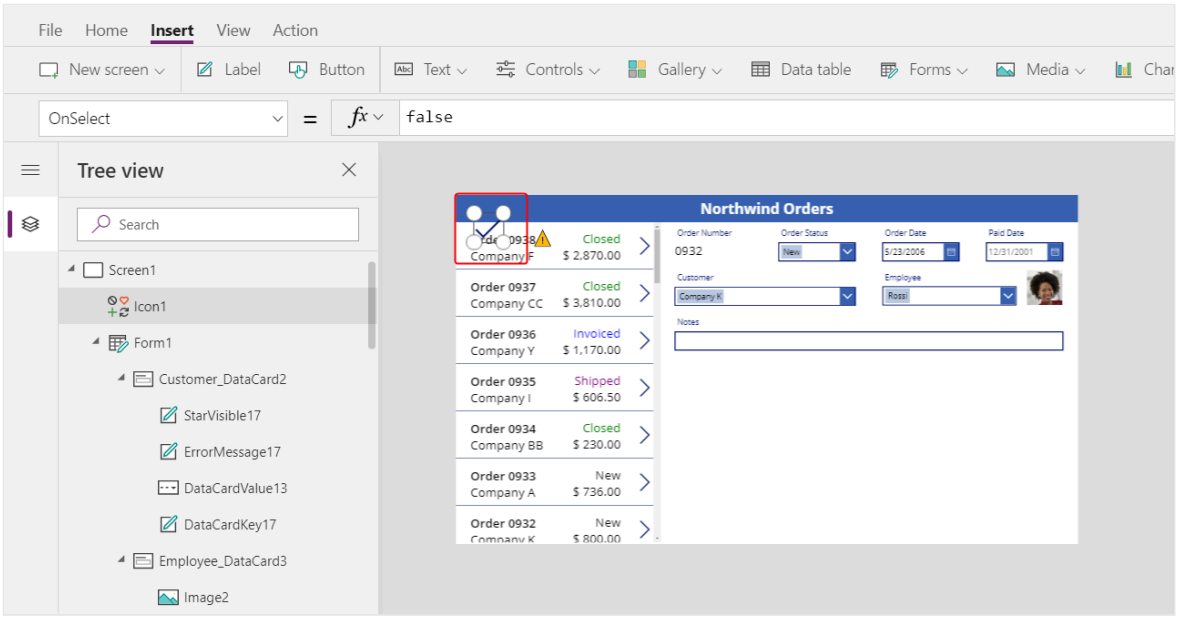


Add a Save icon

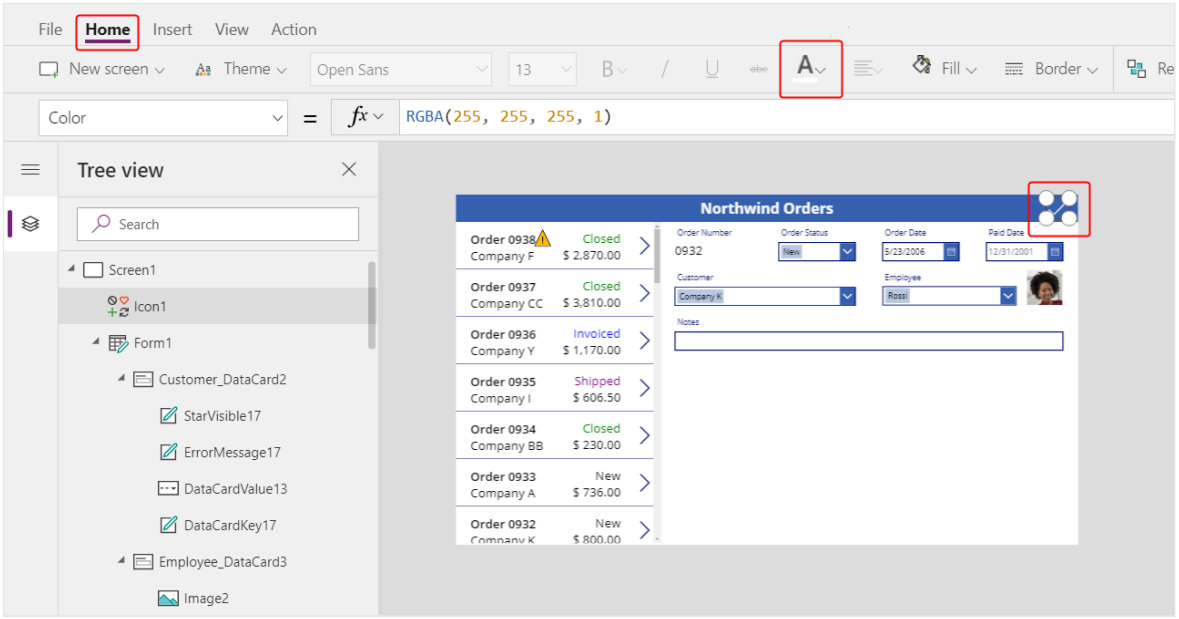
1. In the **Tree view** pane, select **Screen1**, and then select **Insert** > **Icons** > **Check**:



The **Check** icon appears in the upper-left corner by default, where other controls might make the icon difficult to find:



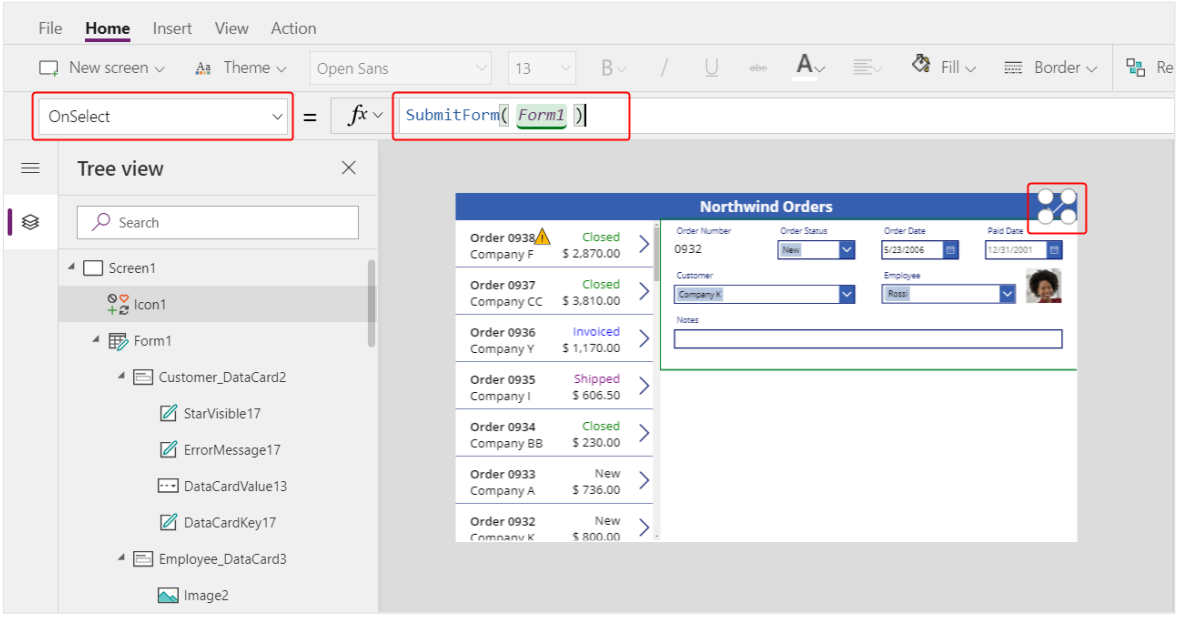
2. On the **Home** tab, change the **Color** property of the icon to white, resize the icon, and move it near the right edge of the title bar:



3. In the **Tree view** pane, confirm that the form's name is **Form1**, and then set the icon's **OnSelect** property to this formula:

```
Power Fx

SubmitForm( Form1 )
```

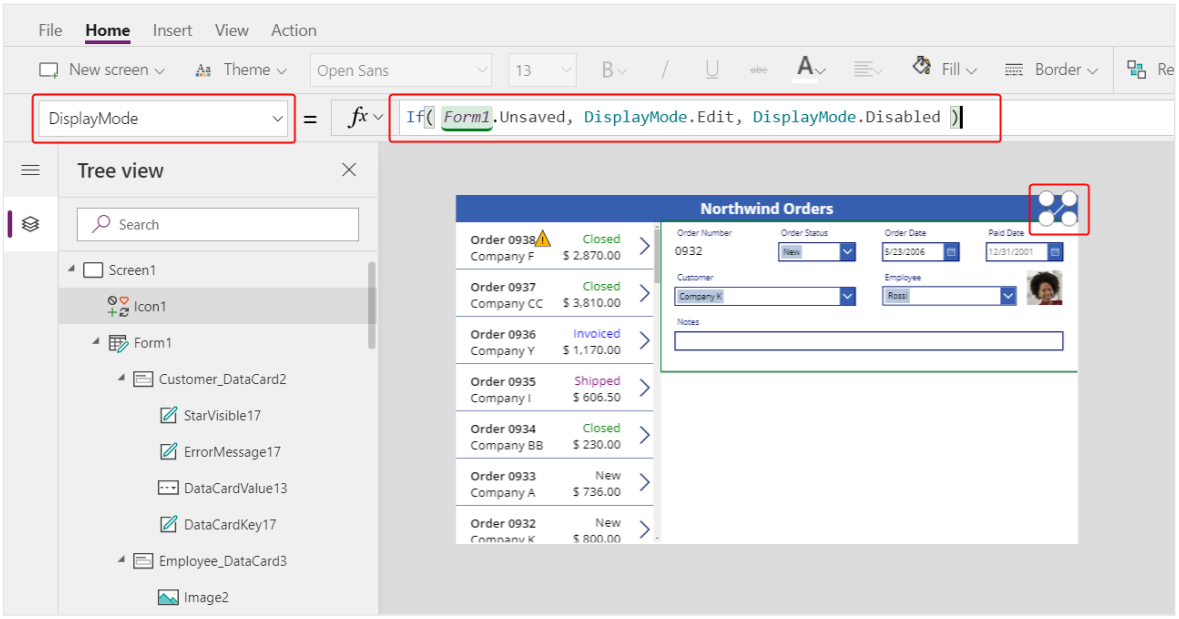


When the user selects the icon, the **SubmitForm** function gathers any changed values in the form and submits them to the data source. Dots march across the top of the screen as the data is submitted, and the order gallery reflects the changes after the process finishes.

4. Set the icon's **DisplayMode** property to this formula:

```
Power Fx

If( Form1.Unsaved, DisplayMode.Edit, DisplayMode.Disabled )
```

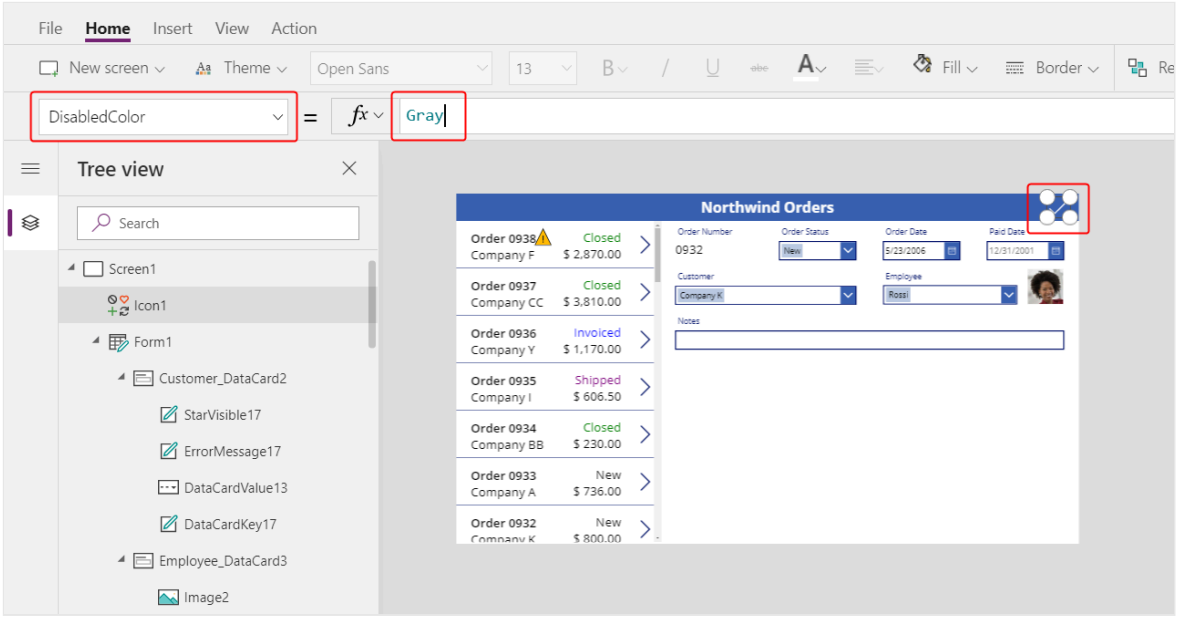


If all changes in the form have been saved, the icon is disabled and appears in the **DisabledColor**, which you'll set next.

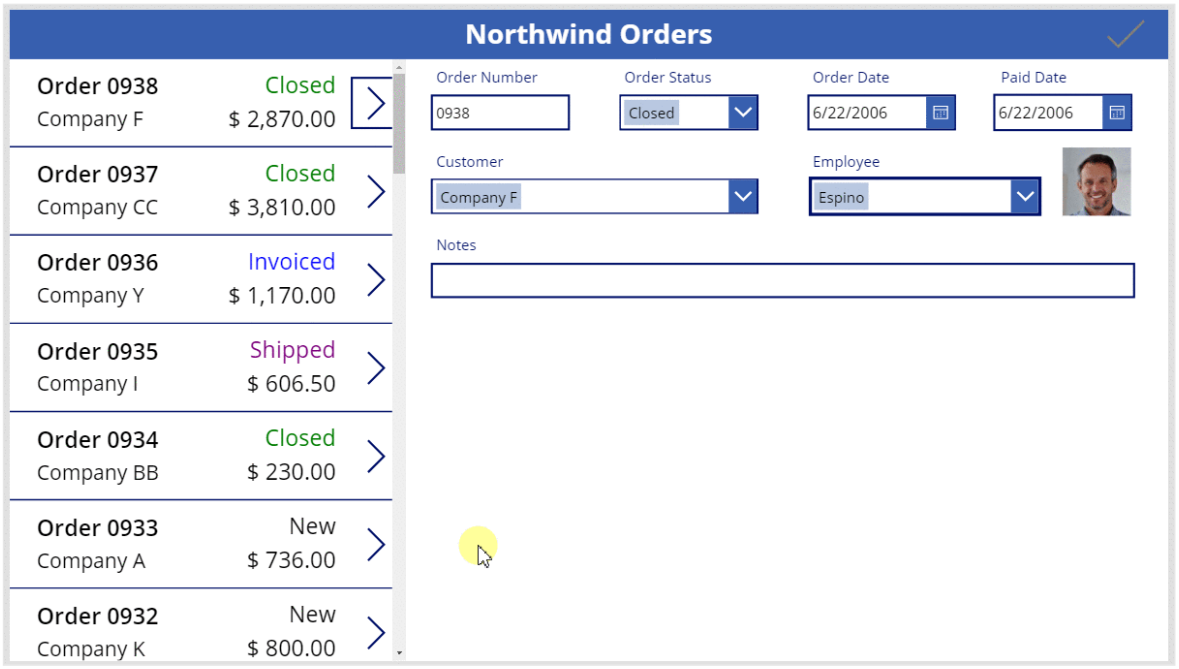
5. Set the icon's **DisabledColor** property to this value:

```
Power Fx

Gray
```

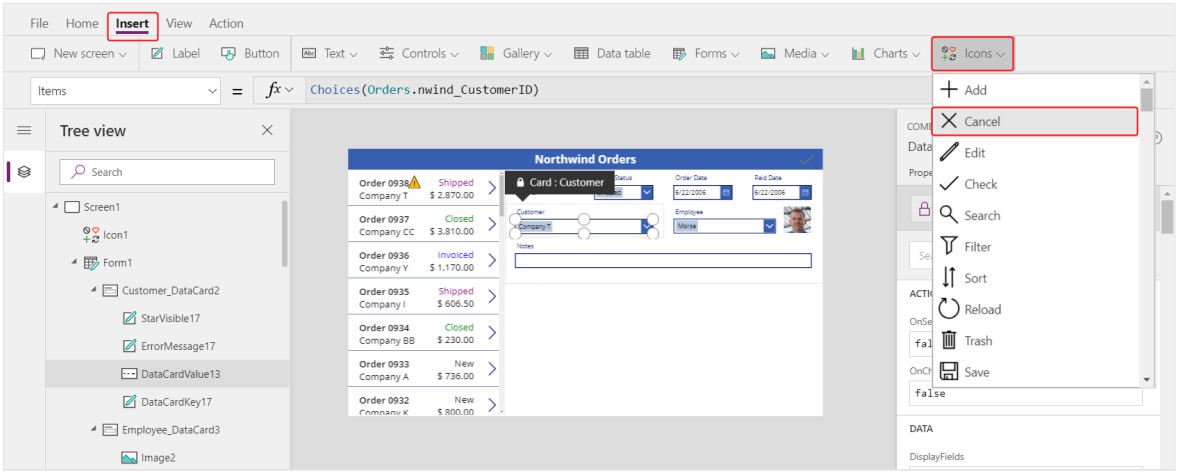


The user can save changes to an order by selecting the Check icon, which is then disabled and dimmed until the user makes another change:

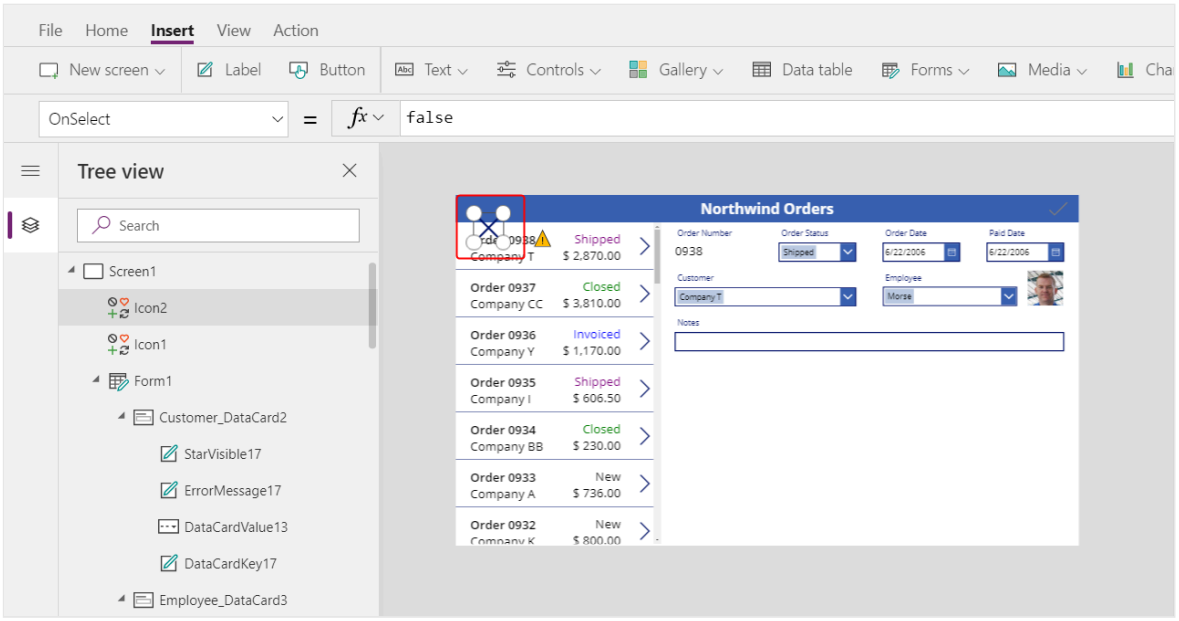


Add a Cancel icon

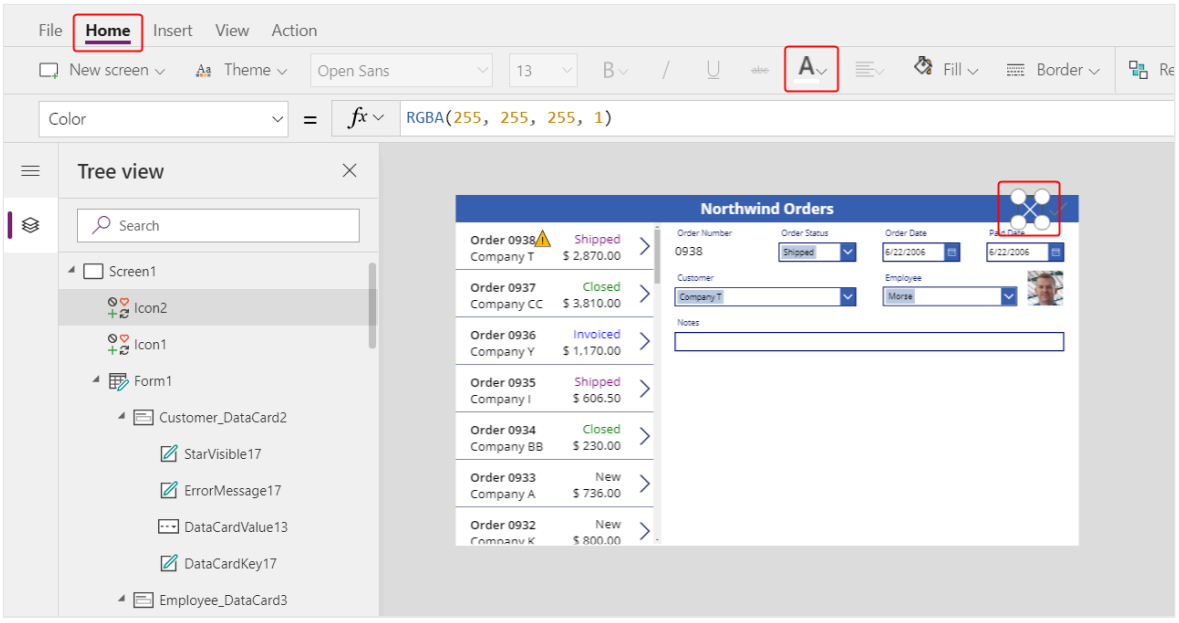
1. On the **Insert** tab, select **Icons** > **Cancel**:



The icon appears in the upper-left corner by default, where other controls might make the icon difficult to find:



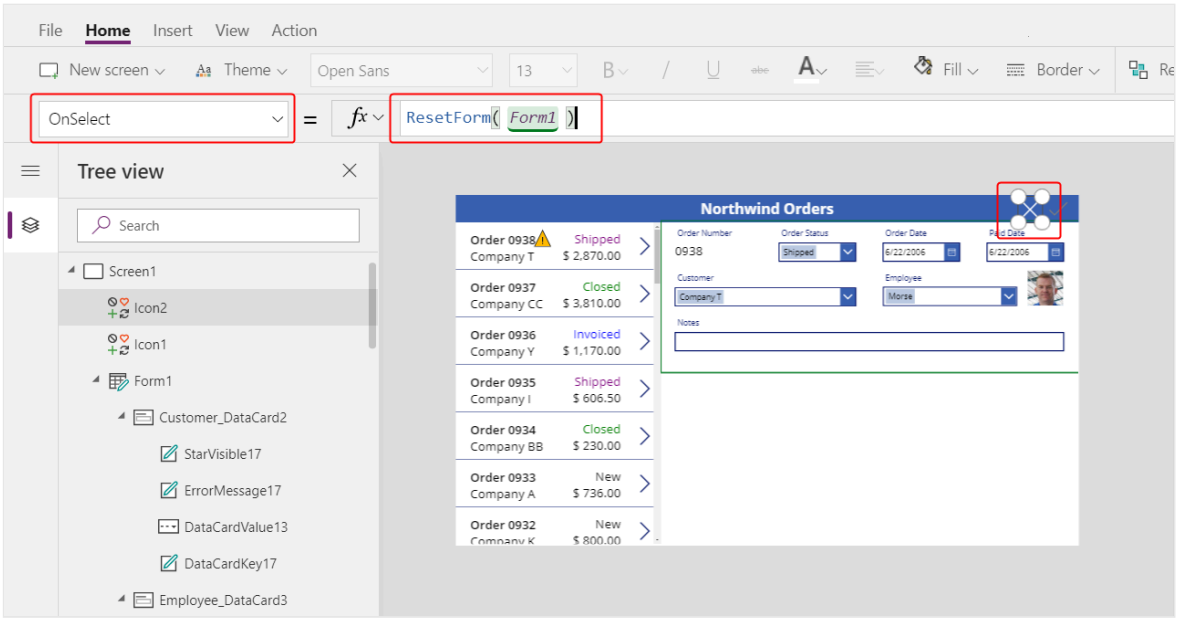
2. On the **Home** tab, change the icon's **Color** property to white, resize the icon, and move it to the left of the Check icon:



3. Set the Cancel icon's **OnSelect** property to this formula:

```
Power Fx

ResetForm( Form1 )
```

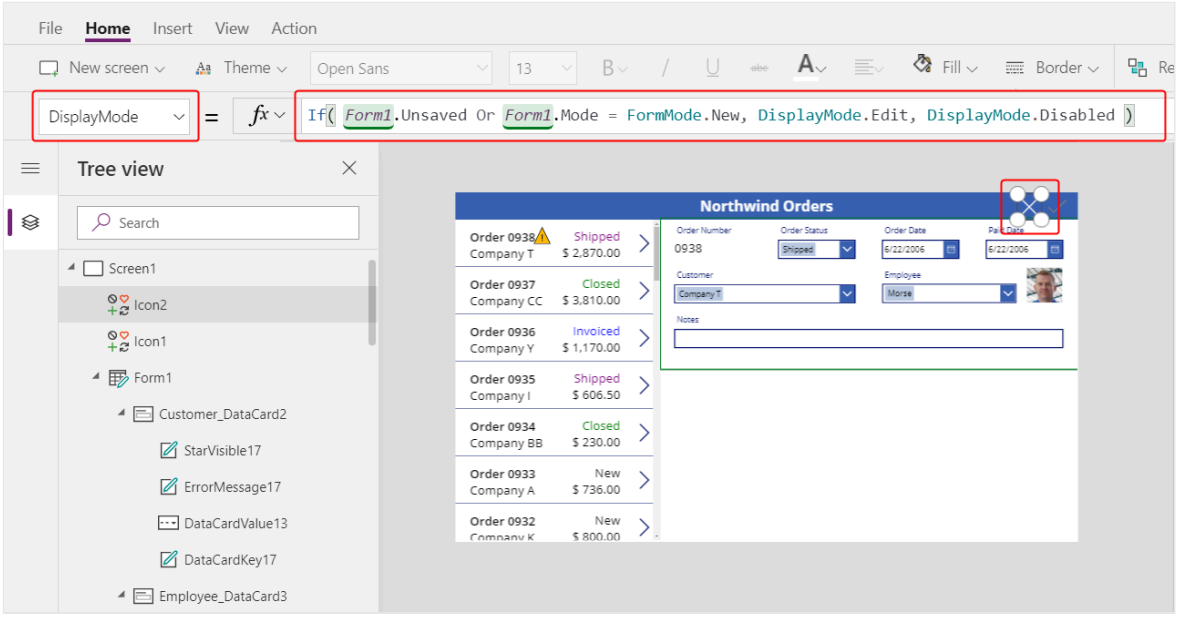


The ResetForm function discards all changes in the form, which returns it to its original state.

4. Set the Cancel icon's **DisplayMode** property to this formula:

```
Power Fx

If( Form1.Unsaved Or Form1.Mode = FormMode.New, DisplayMode.Edit,
DisplayMode.Disabled )
```

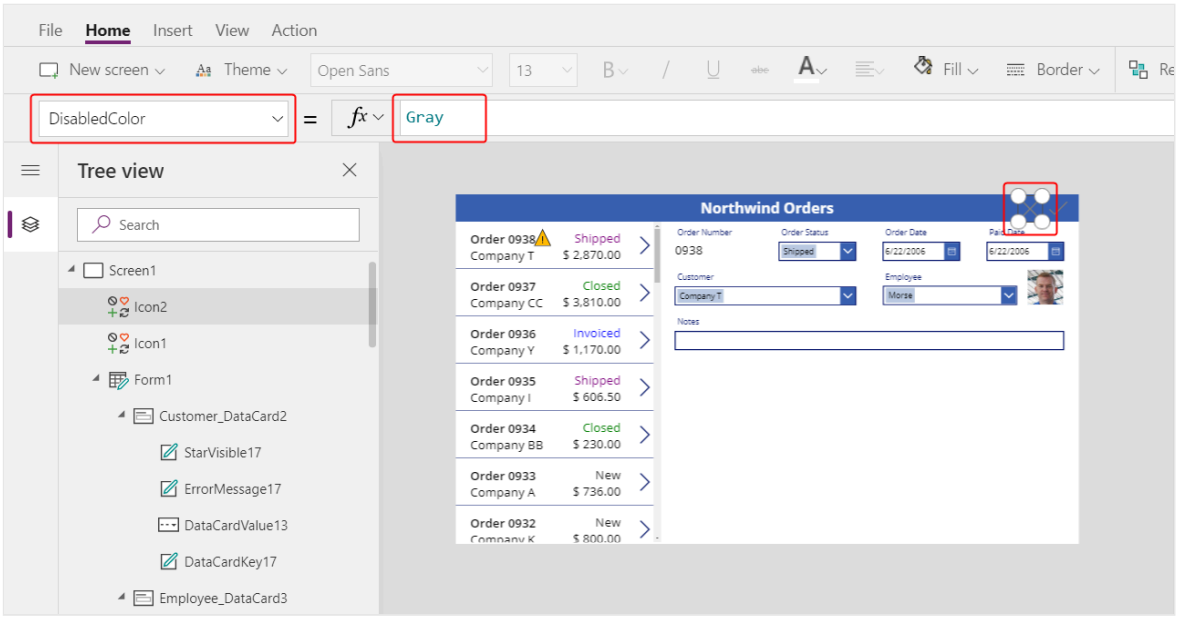


This formula differs slightly from the one for the Check icon. The Cancel icon is disabled if all changes have been saved or the form is in **New** mode, which you'll enable next. In that case, **ResetForm** discards the new record.

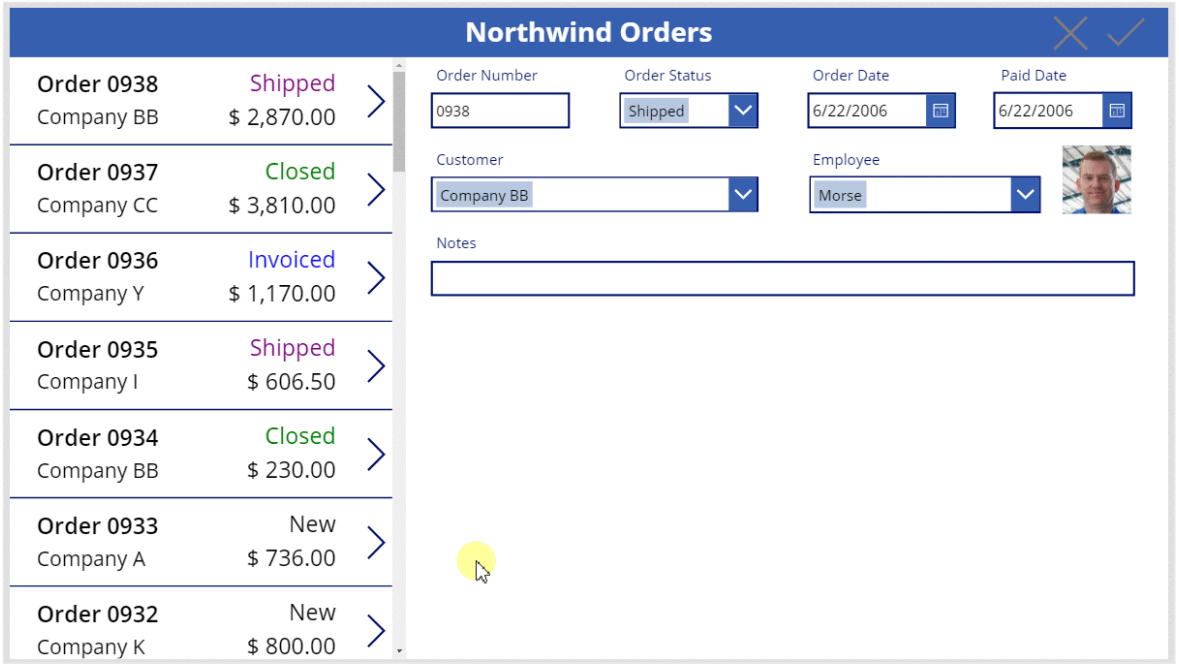
5. Set the Cancel icon's **DisabledColor** property to this value:

Power Fx

```
Gray
```

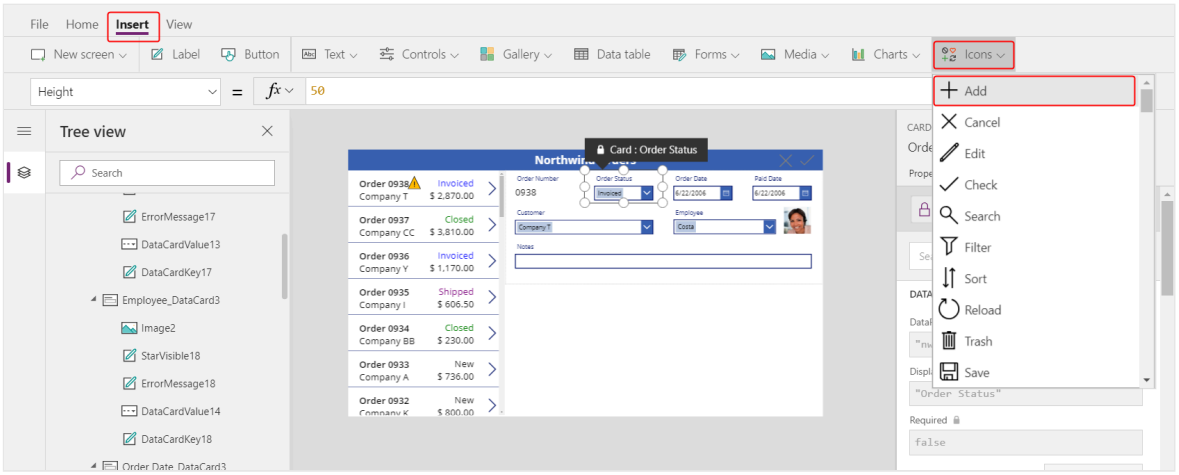


The user can cancel changes to an order, and the Check and Cancel icons are disabled and dimmed if all changes have been saved:

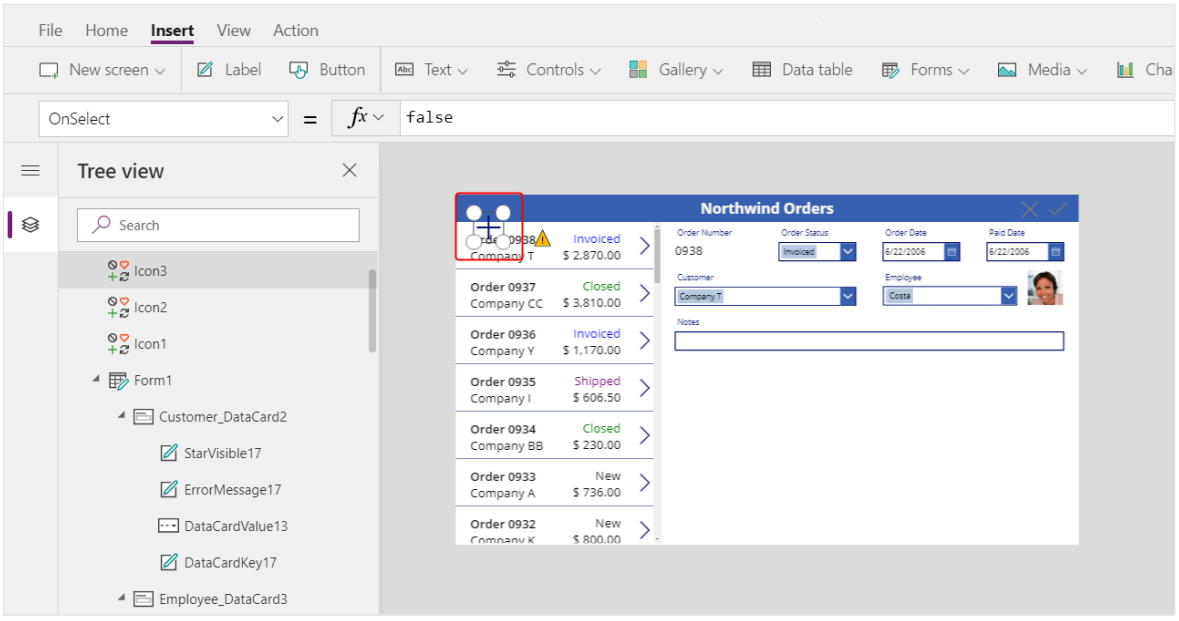


Add an Add icon

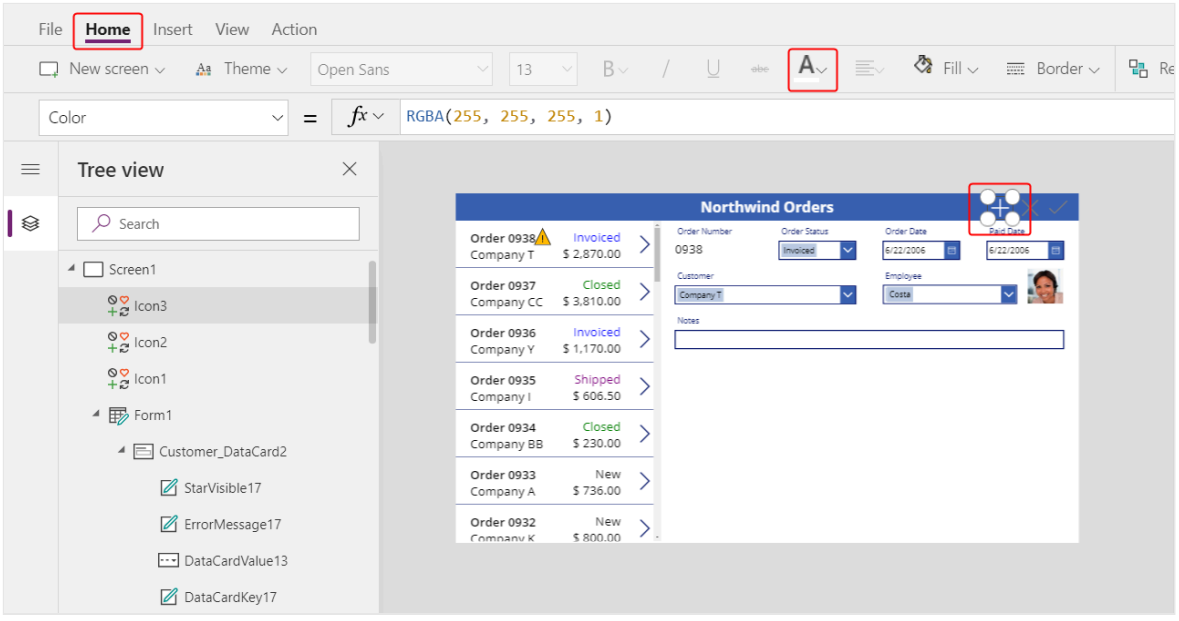
1. On the **Insert** tab, select **Icons** > **Add**.



The **Add** icon appears in the upper-left corner by default, where other controls might make it difficult to find:



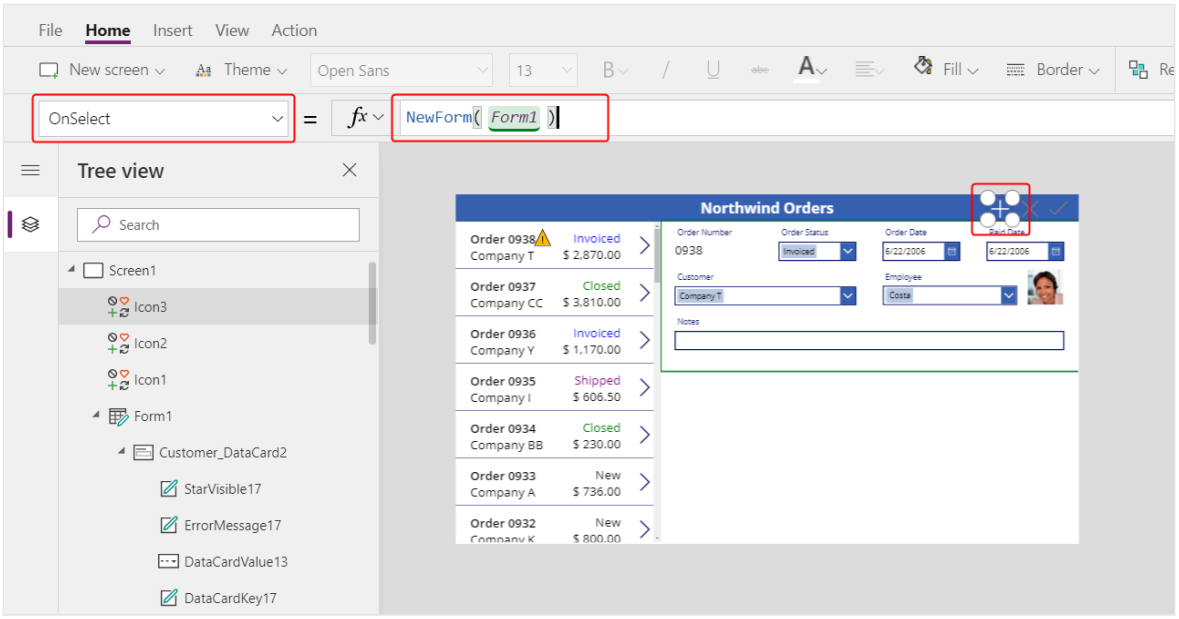
2. On the **Home** tab, set the **Color** property of the Add icon to white, resize the icon, and move it to the left of the Cancel icon:



3. Set the Add icon's **OnSelect** property to this formula:

```
Power Fx

NewForm( Form1 )
```

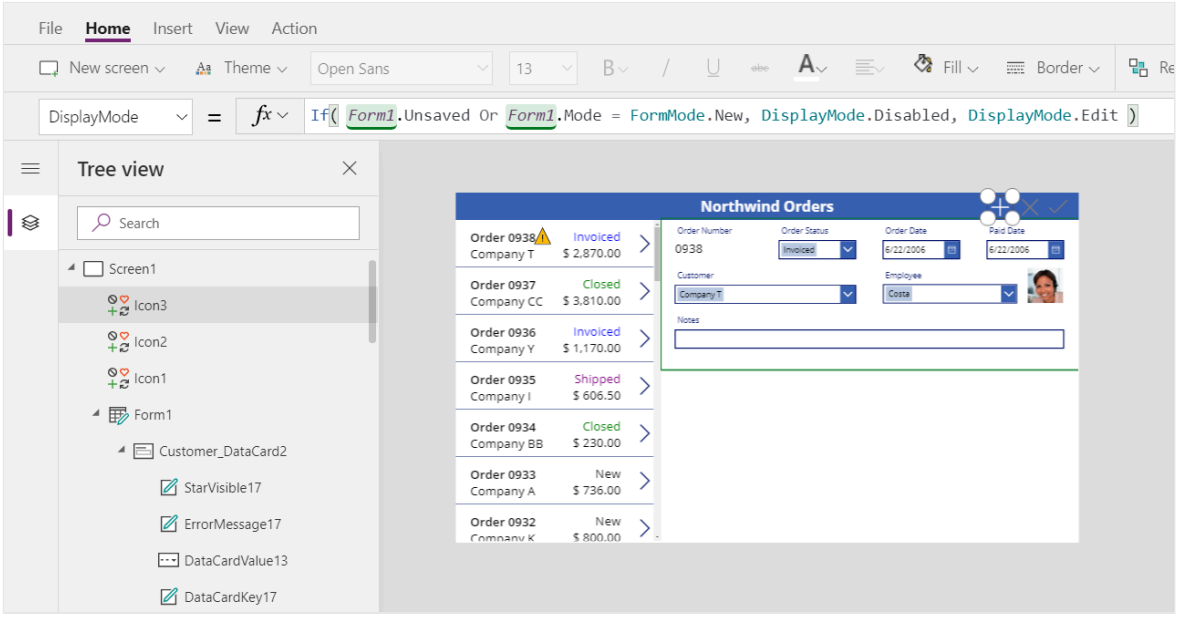


The NewForm function shows a blank record in the form.

4. Set the Add icon's **DisplayMode** property to this formula:

```
Power Fx

If( Form1.Unsaved Or Form1.Mode = FormMode.New, DisplayMode.Disabled,
DisplayMode.Edit )
```



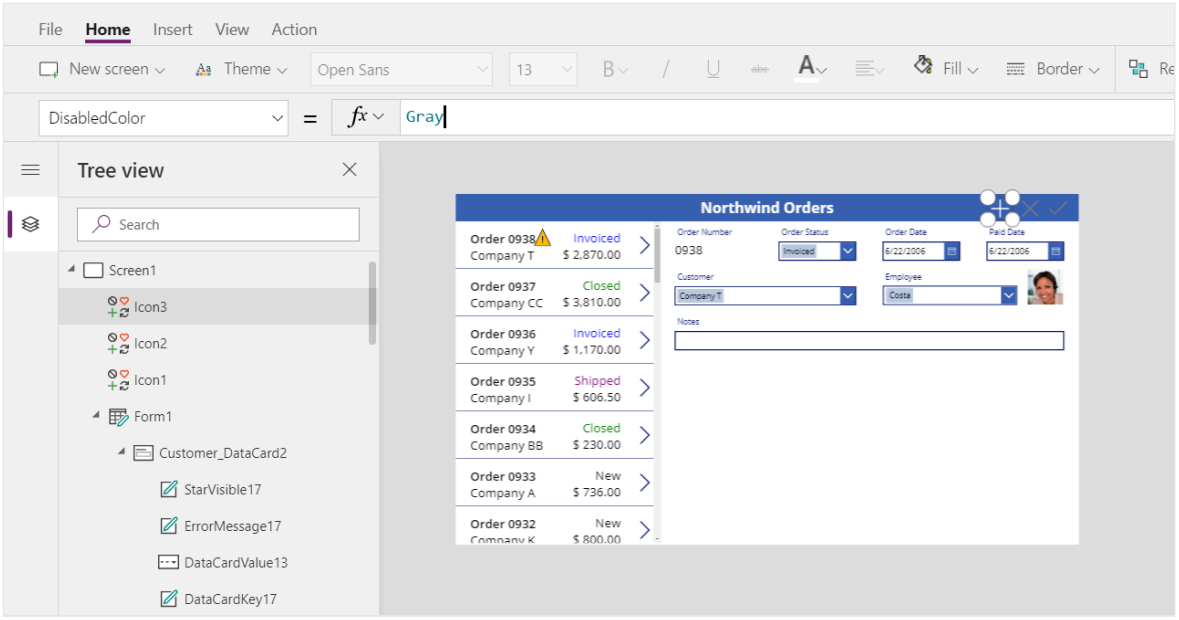
The formula disables the Add icon under these conditions:

- The user makes changes but doesn't save or cancel them, which is the opposite behavior from the Check and Cancel icons.
- The user selects the Add icon but makes no changes.

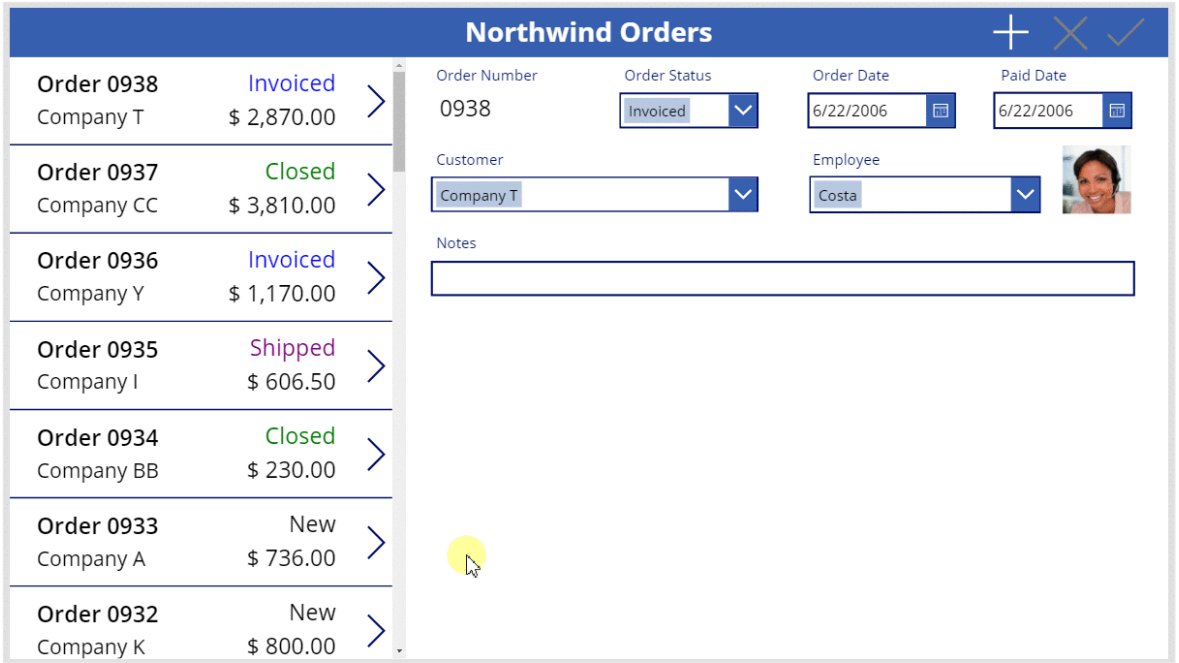
5. Set the Add icon's **DisabledColor** property to this value:

```
Power Fx

Gray
```



The user can create an order if they make no changes or they save or cancel any changes they've made. (If the user selects this icon, they can't select it again until they make one or more changes and then save or cancel those changes):

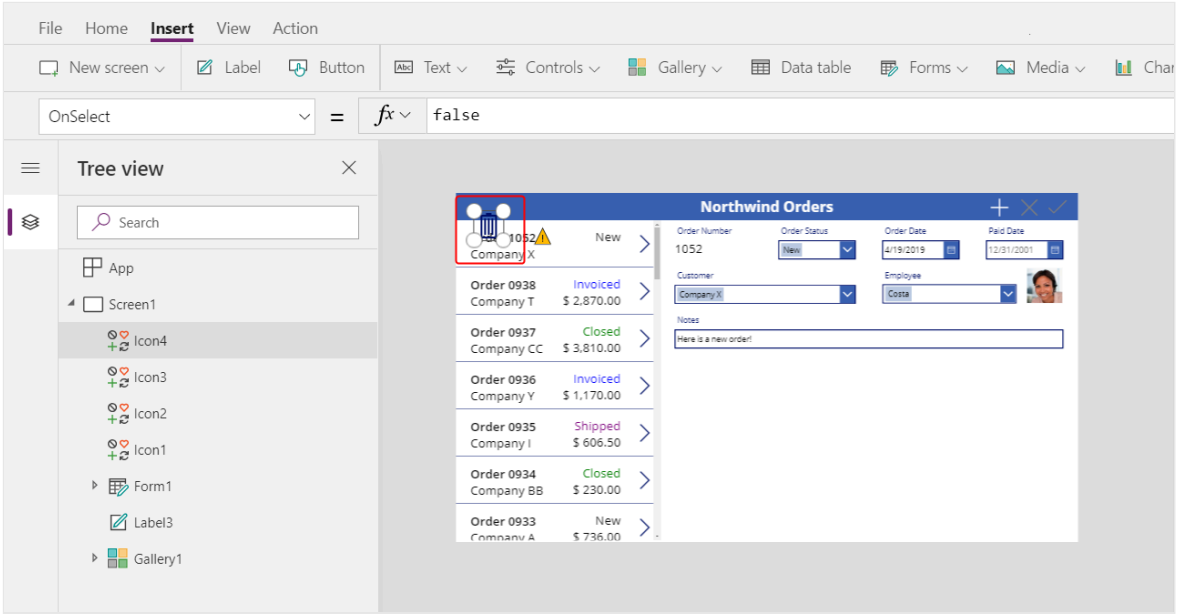


> **Note**
>
> If you create and save an order, you might need to scroll down in the order gallery to show your new order. It won't have a total price because you haven't added any order details yet.

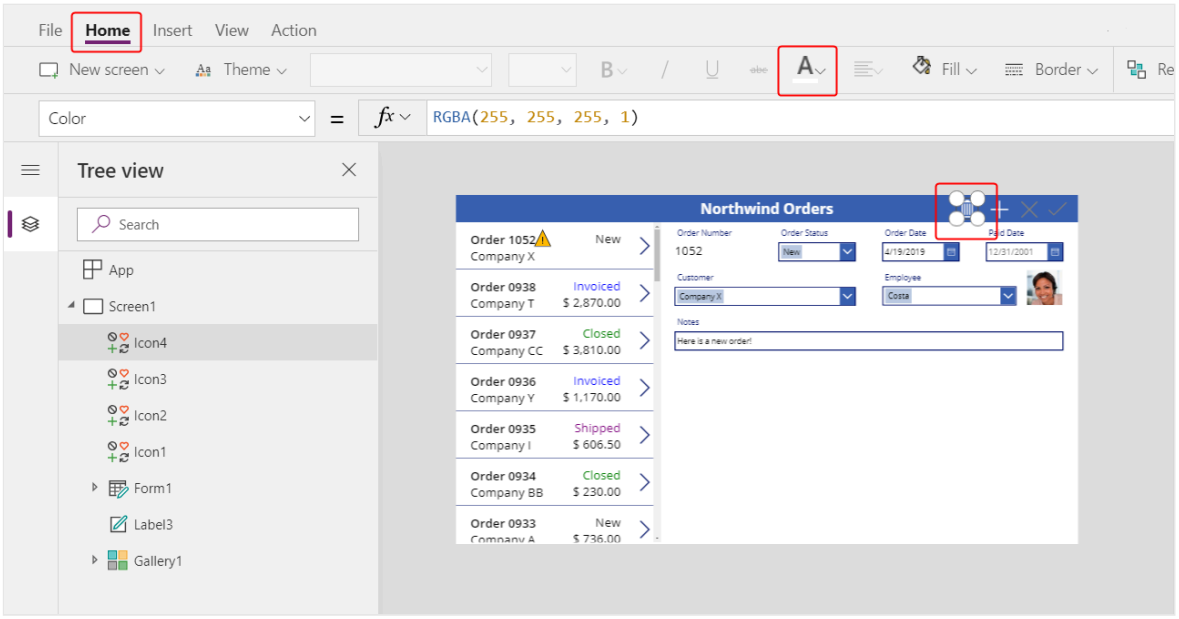
Add a Trash icon

1. On the **Insert** tab, select **Icons** > **Trash**.

   The **Trash** icon appears in the upper-left corner by default, where other controls might make it difficult to find:



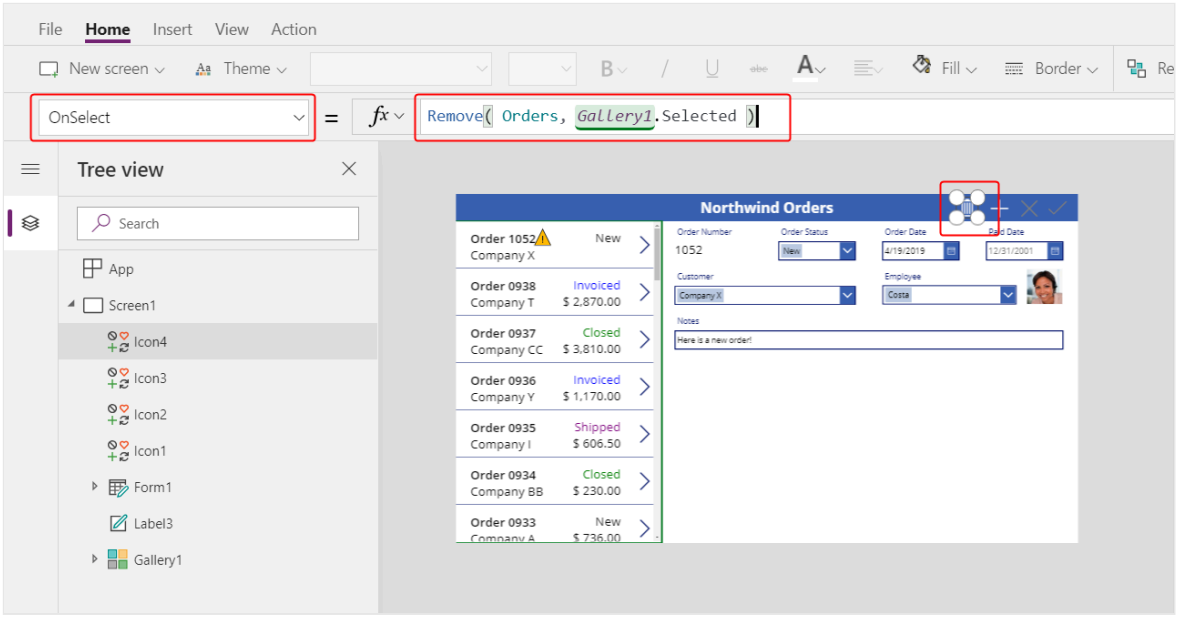
2. On the **Home** tab, change the Trash icon's **Color** property to white, resize the icon, and move it to the left of the Add icon:



3. Set the Trash icon's **OnSelect** property to this formula:

```
Power Fx

Remove( Orders, Gallery1.Selected )
```

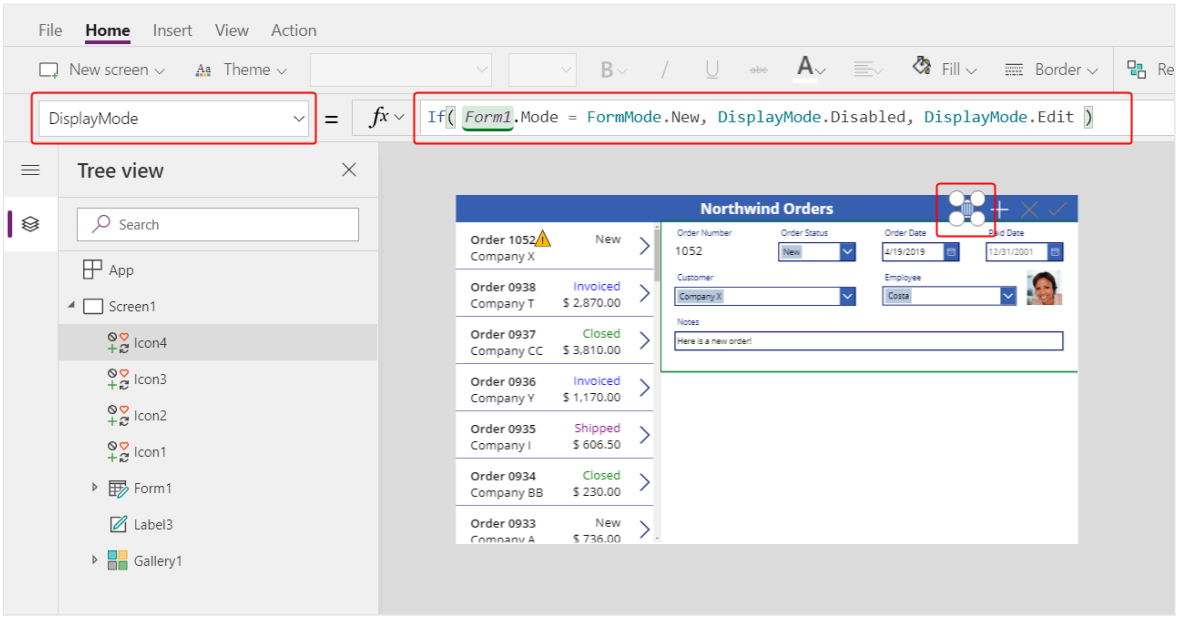


The **Remove** function removes a record from a data source. In this formula, the function removes the record that's selected in the order gallery. The Trash icon appears near the summary form (not the order gallery) because the form shows more details about the record, so the user can more easily identify the record that the formula will delete.

4. Set the Trash icon's **DisplayMode** property to this formula:

```
Power Fx
```

```
If( Form1.Mode = FormMode.New, DisplayMode.Disabled, DisplayMode.Edit )
```

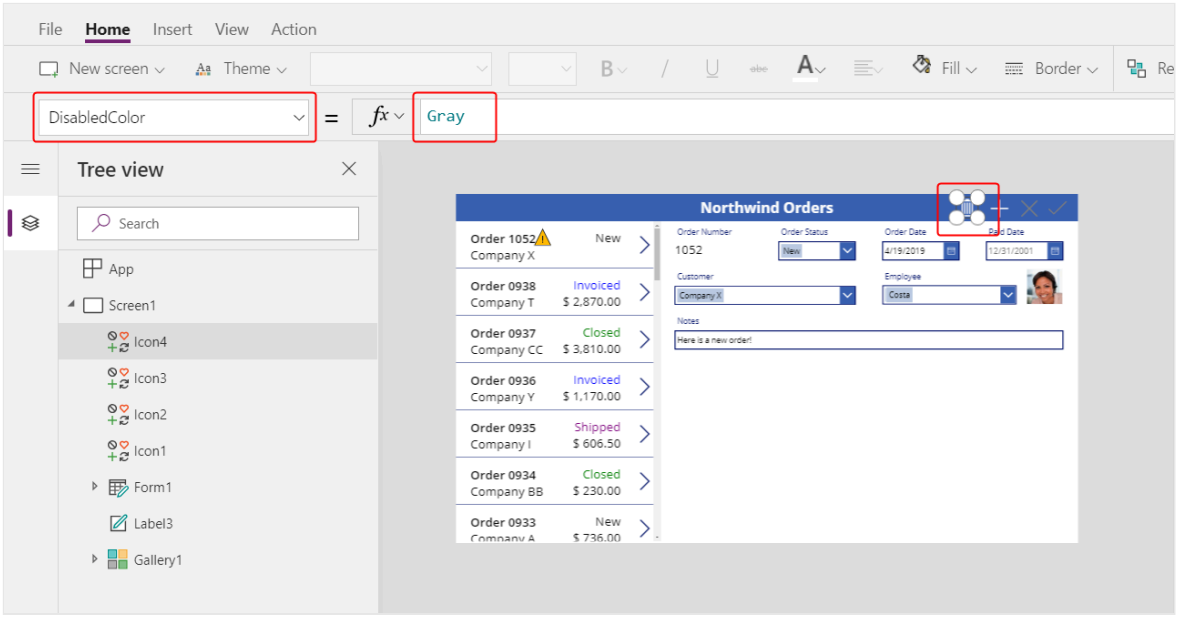


This formula disables the Trash icon if the user is creating a record. Until the user saves the record, the **Remove** function has no record to delete.

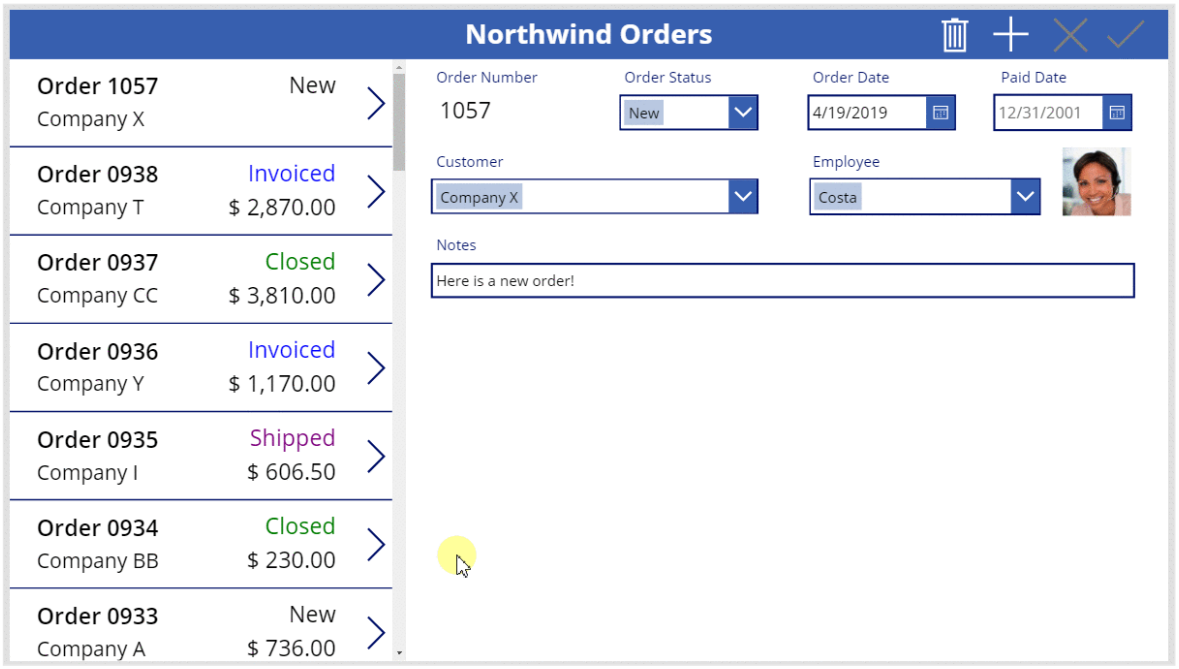
5. Set the Trash icon's **DisabledColor** property to this value:

```
Power Fx

Gray
```



The user can delete an order.



Summary

To recap, you added a form in which the user can show and edit a summary of each order, and you used these elements:

- A form that shows data from the **Orders** table: **Form1.DataSource** = `Orders`
- A connection between the form and the order gallery: **Form1.Item** = `Gallery1.Selected`
- An alternate control for the **Order number** field: **View text**
- A many-to-one relationship to show the employee's picture in the **Employee** data card: `DataCardValue1.Selected.Picture`
- An icon to save changes to an order: `SubmitForm( Form1 )`
- An icon to cancel changes to an order: `ResetForm( Form1 )`
- An icon to create an order: `NewForm( Form1 )`
- An icon to delete an order: `Remove( Orders, Gallery1.Selected )`

Next step

In the next topic, you'll add another gallery to show the products in each order, and you'll change those details by using the **Patch** function.

Create the detail gallery

Create a detail gallery in a canvas app

Article • 12/16/2022

Follow step-by-step instructions to create a detail gallery in a canvas app for managing fictitious data in the Northwind Traders database. This topic is part of a series that explains how to build a business app on relational data in Microsoft Dataverse. For best results, explore these topics in this sequence:

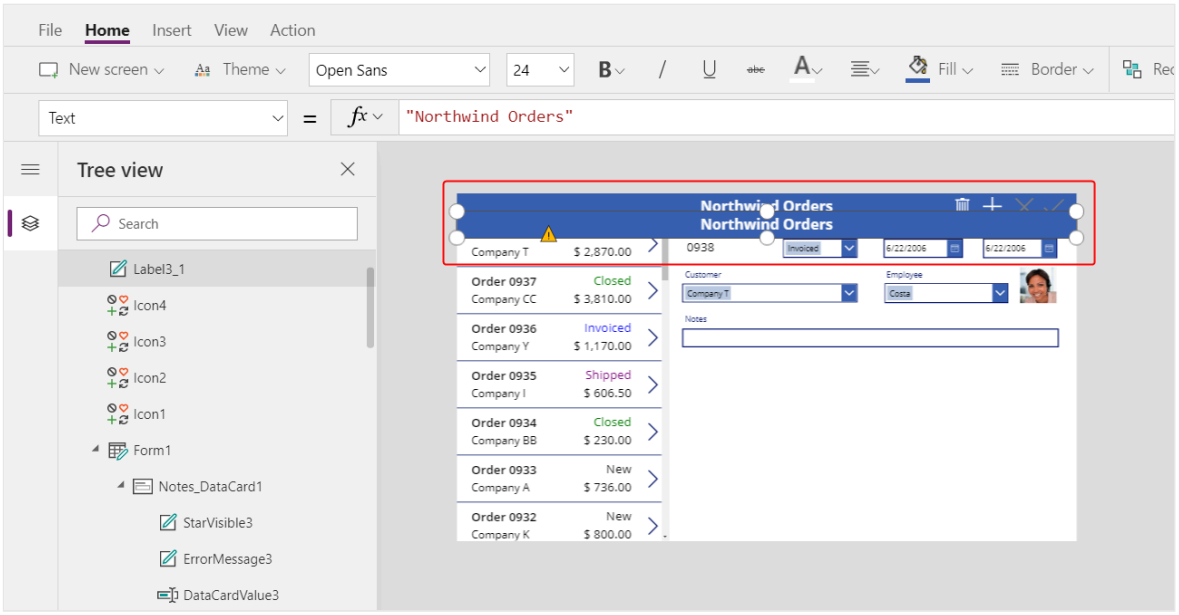
1. Create an order gallery.
2. Create a summary form.
3. Create a detail gallery (**this topic**).

Prerequisites

Before you start this topic, you must install the database as described earlier in this topic. You must then either create the order gallery and the summary form or open the **Northwind Orders (Canvas) - Begin Part 3** app, which already contains that gallery and that form.

Create another title bar

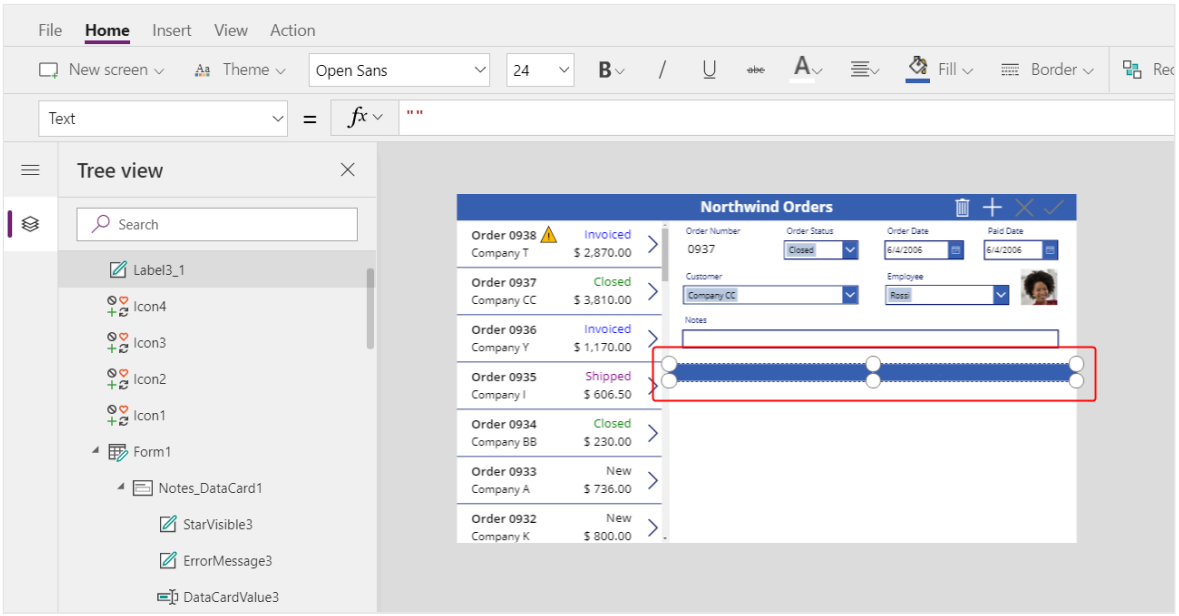
1. At the top of the screen, select the **Label** control that acts as a title bar, copy it by pressing Ctrl-C, and then paste it by pressing Ctrl-V:



2. Resize and move the copy so that it appears just under the summary form.

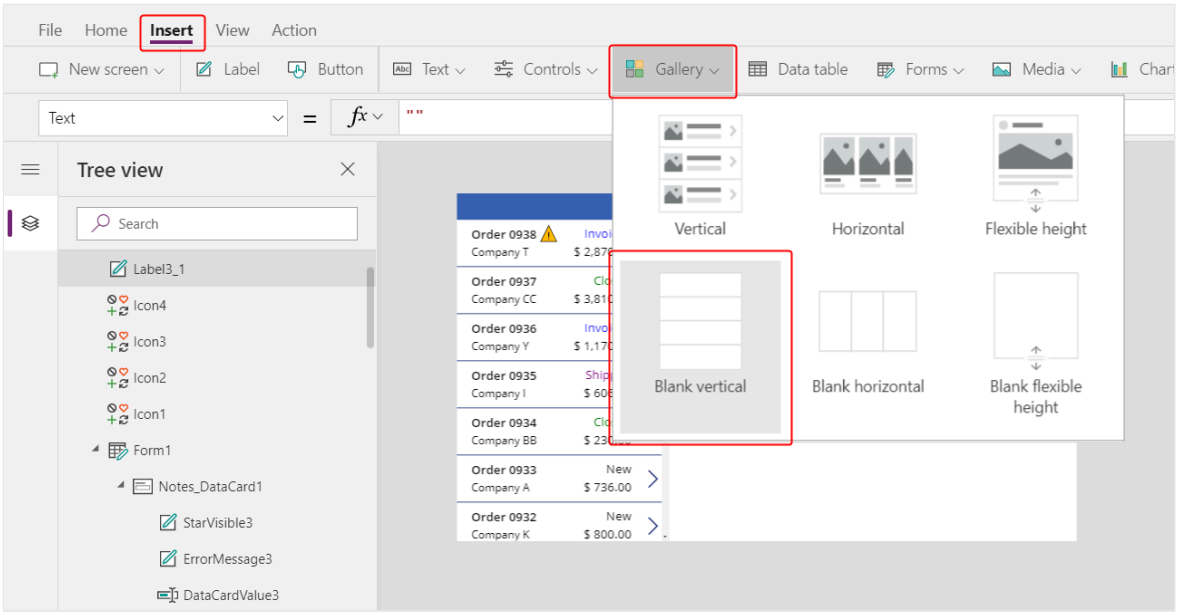
3. Remove the text from the copy in either of these ways:

   - Double-click the text to select it, and then press Delete.
   - Set the label's **Text** property to an empty string ("").



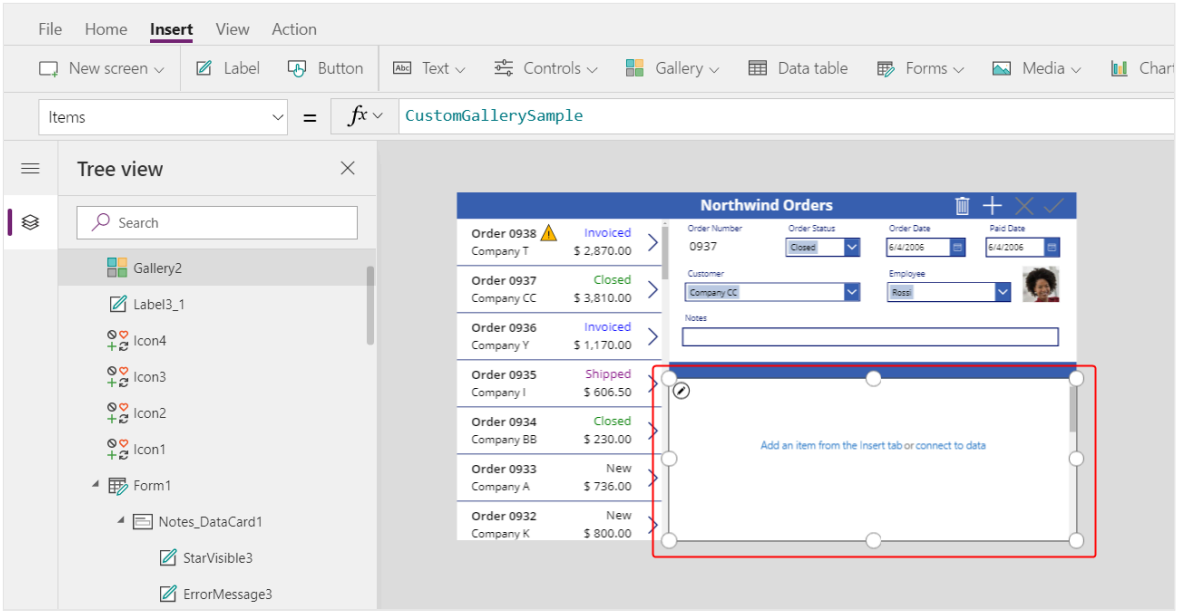
Add a gallery

1. Insert a Gallery control with a **Blank vertical** layout:



The new gallery, which will show order details, appears in the upper-left corner.

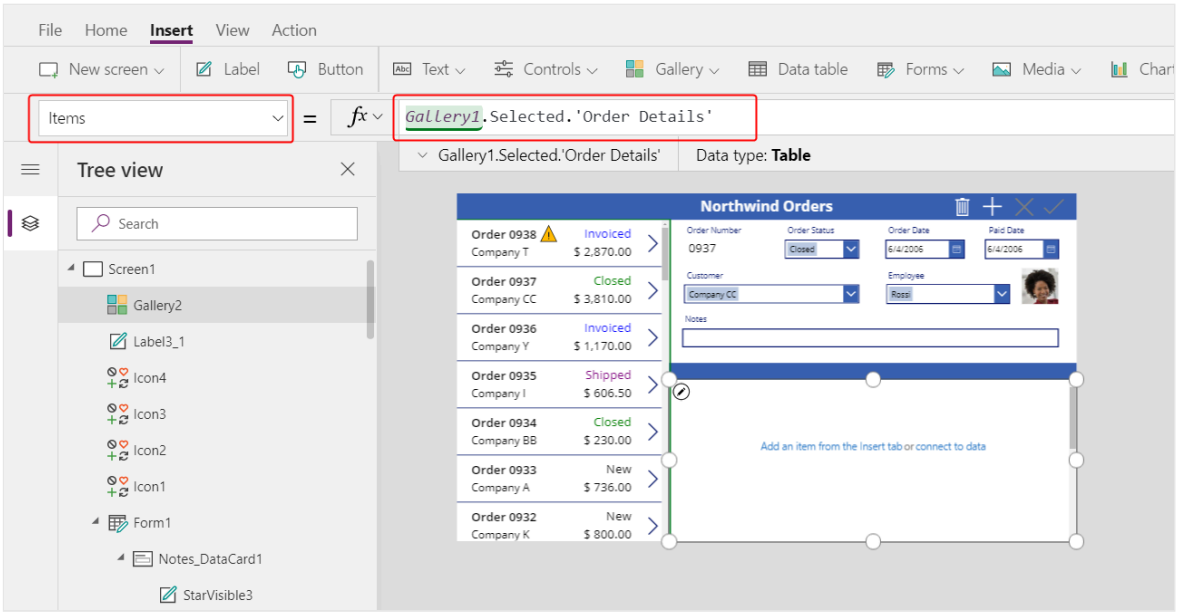
2. Close the fly out data source dialog, and then resize and move the detail gallery to the lower-right corner, below the new title bar:



3. Set the **Items** property of the detail gallery to this formula:

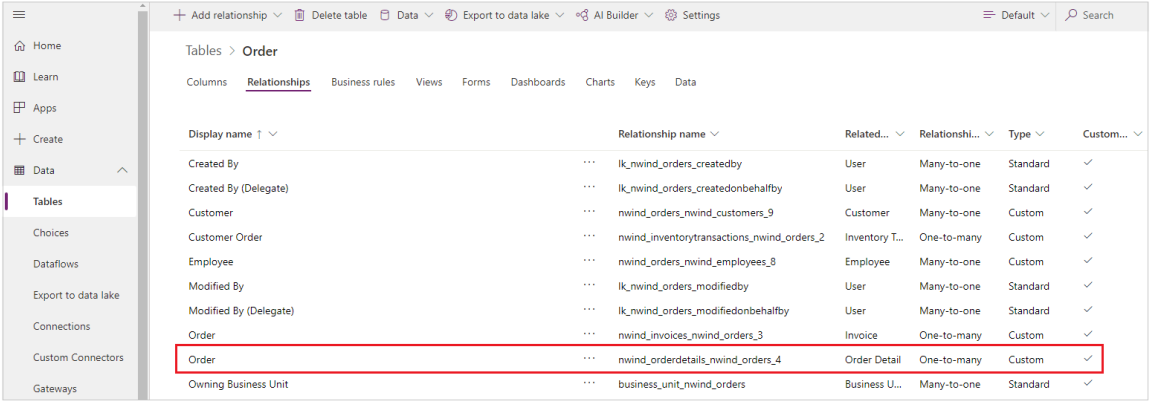
Power Fx

```
Gallery1.Selected.'Order Details'
```



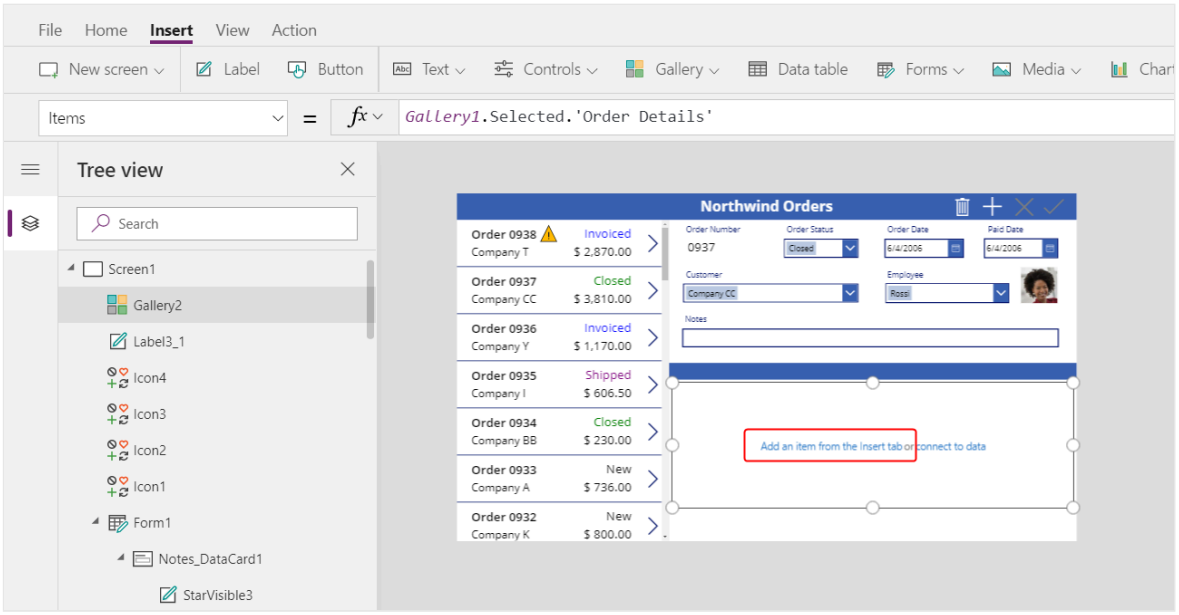
If an error appears, confirm that the order gallery is named **Gallery1** (in the **Tree view** pane near the left edge). If that gallery has a different name, rename it **Gallery1**.

You've just linked the two galleries. When the user selects an order in the order gallery, that selection identifies a record in the **Orders** table. If that order contains one or more line items, the record in the **Orders** table is linked to one or more records in the **Order details** table, and data from those records appears in the detail gallery. This behavior reflects the one-to-many relationship that was created for you between the **Orders** and **Order Details** tables. The formula that you specified "walks" that relationship by using dot notation:



Show product names

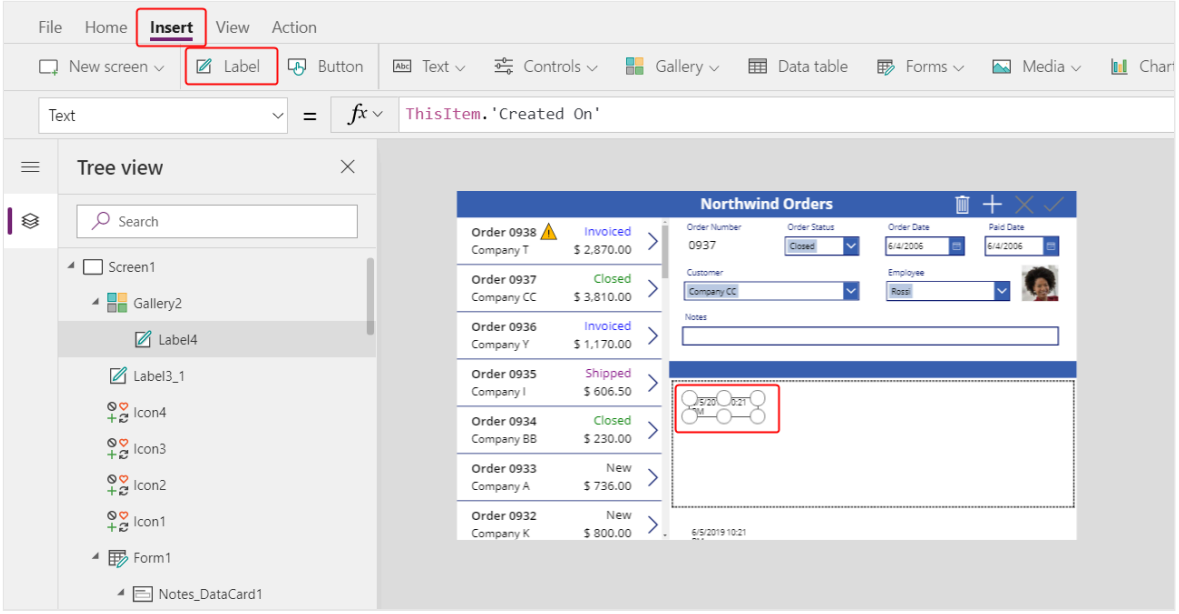
1. In the detail gallery, select **Add an item from the Insert tab** to select the gallery template:



Ensure that you've selected the gallery template instead of the gallery itself. The bounding box should be slightly inside the gallery's boundary and probably shorter than the gallery's height. As you insert controls into this template, they are repeated for each item in the gallery.

2. On the **Insert** tab, insert a label into the detail gallery.

   The label should appear within the gallery; if it doesn't, try again, but make sure to select the gallery's template before you insert the label.



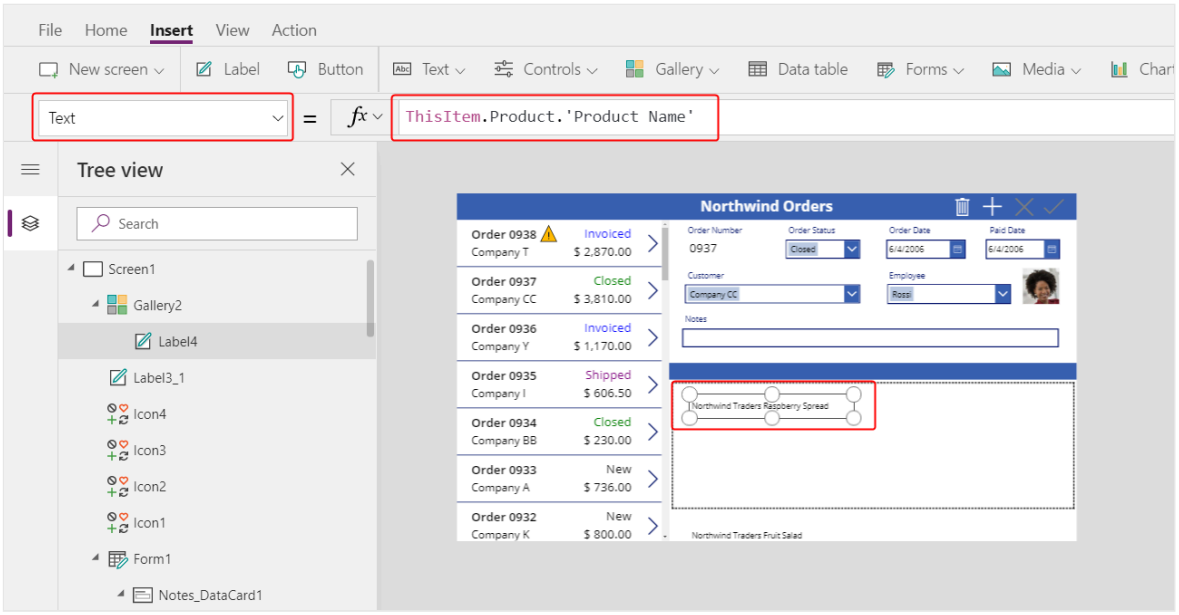
3. Set the new label's **Text** property to this formula:

```
Power Fx

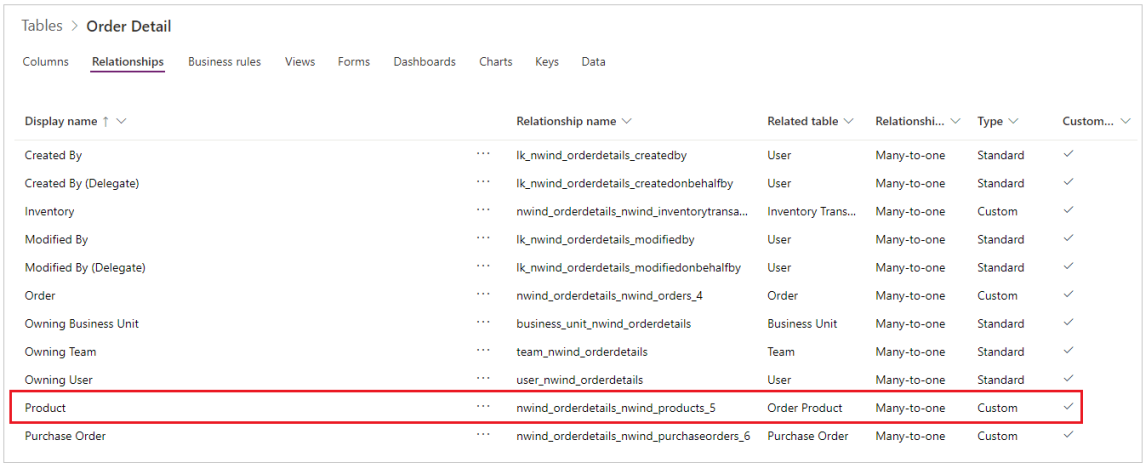
ThisItem.Product.'Product Name'
```

If no text appears, select the arrow for **Order 0901** near the bottom of the order gallery.

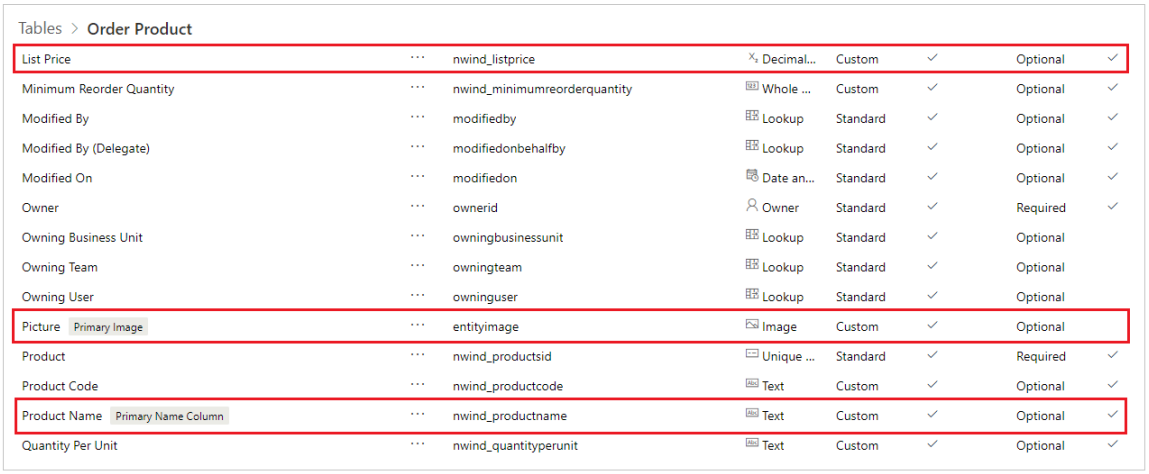
4. Resize the label so that the full text appears:



This expression walks from a record in the **Order Details** table. The record is held in **ThisItem** over to the **Order Products** table through a many-to-one relationship:

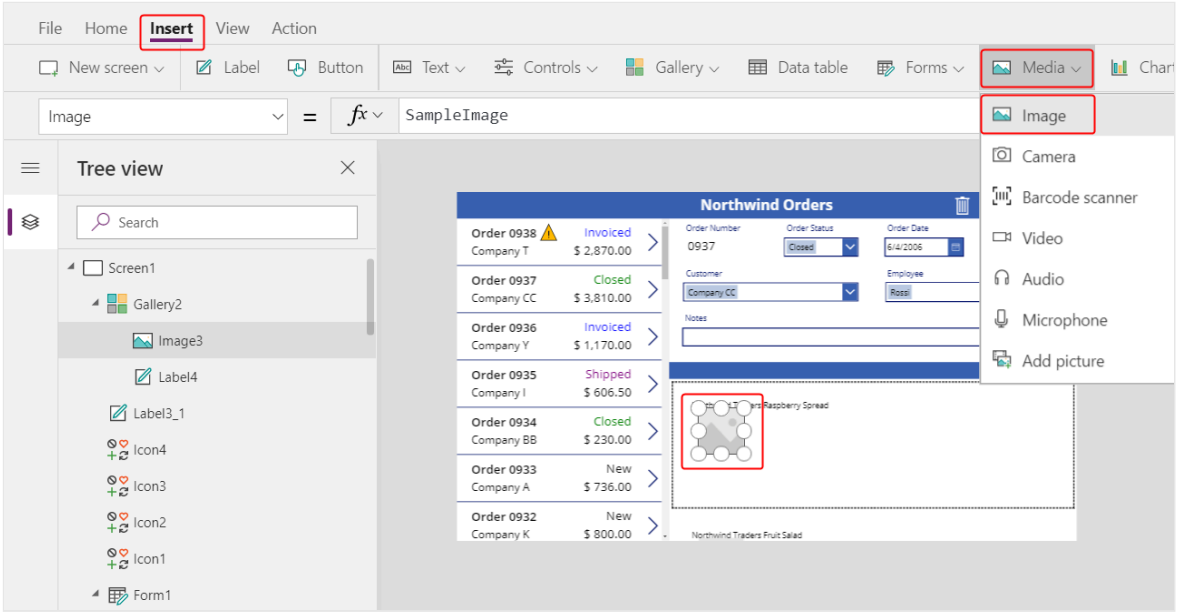


The **Product Name** column (and other columns that you're about to use) are extracted:



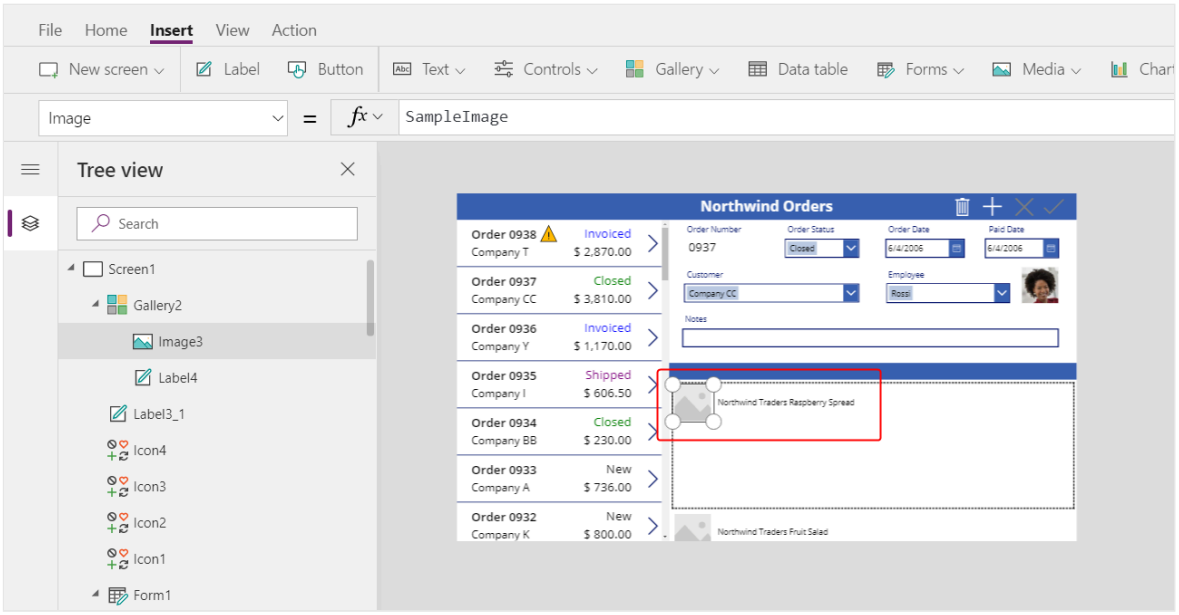
Show product images

1. On the **Insert** tab, insert an **Image** control into the detail gallery:



2. Resize and move the image and the label to be side by side.

> **Tip**
>
> For fine-grained control over the size and the position of a control, start to resize or move it without pressing the Alt key, and then continue to resize or move the control while you hold down the Alt key:

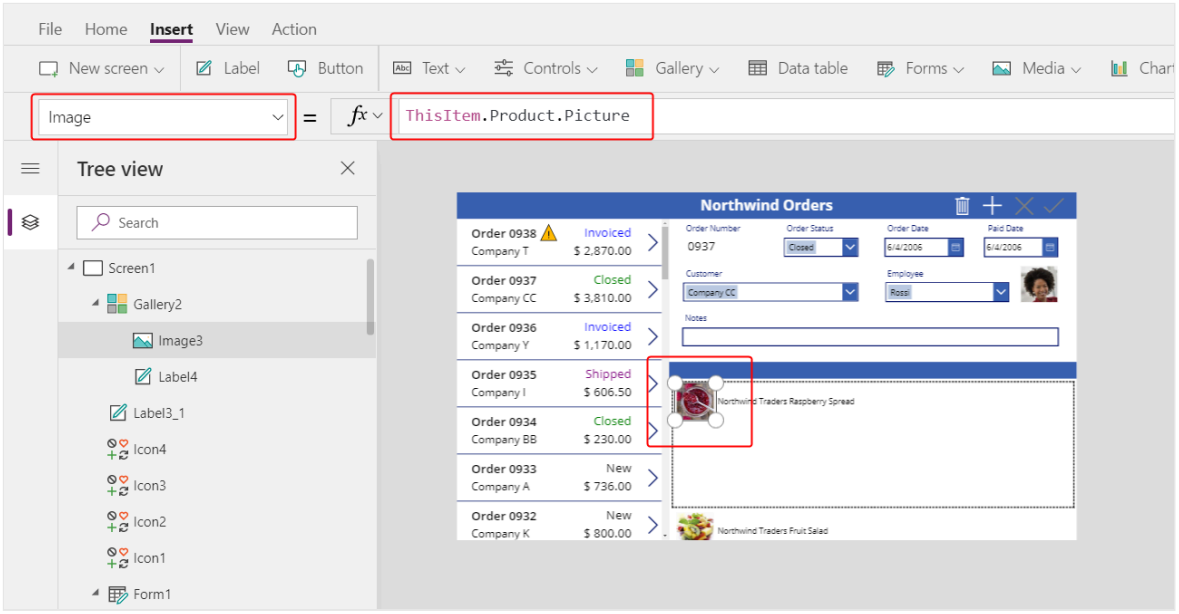


3. Set the image's **Image** property to this formula:

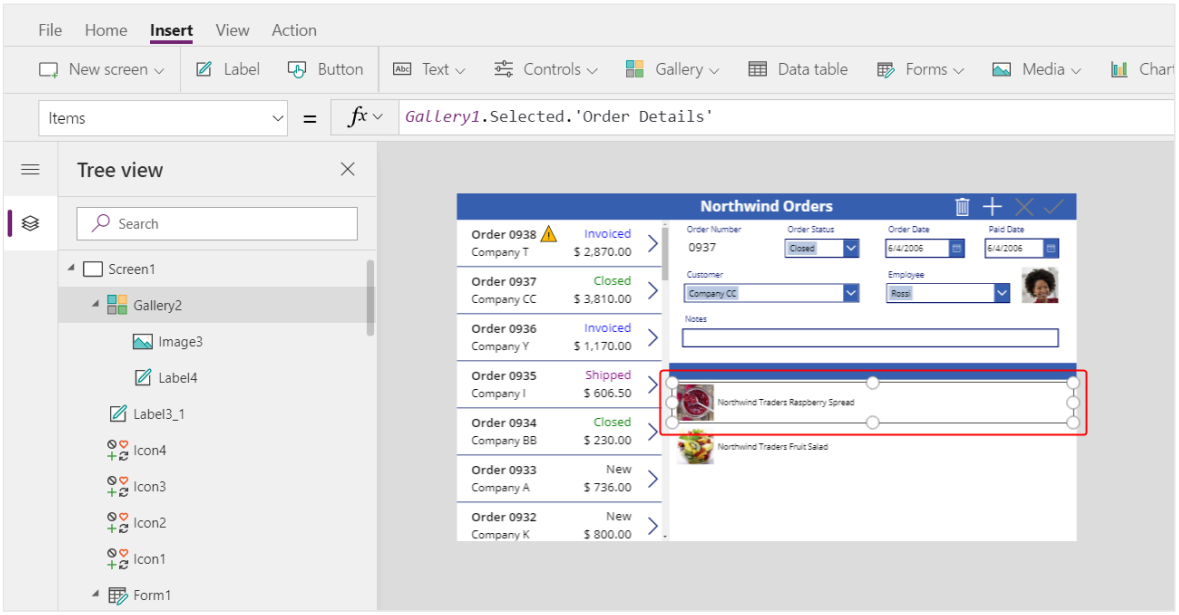
```
Power Fx

ThisItem.Product.Picture
```

Again, the expression references a product that's associated with this order detail and extracting the **Picture** field to display.



4. Reduce the height of the gallery's template so that more than one **Order Detail** record appears at a time:



Show product quantity and cost

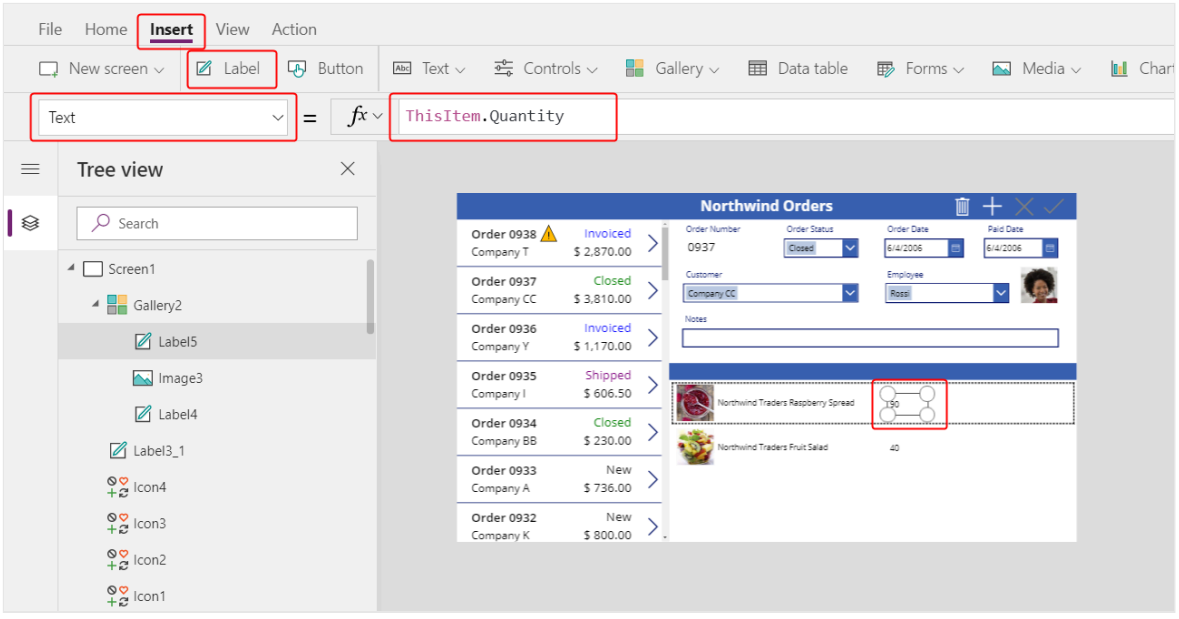
1. On the **Insert** tab, insert another label into the detail gallery, and then resize and move the new label to the right of the product information.

2. Set the new label's **Text** property to this expression:

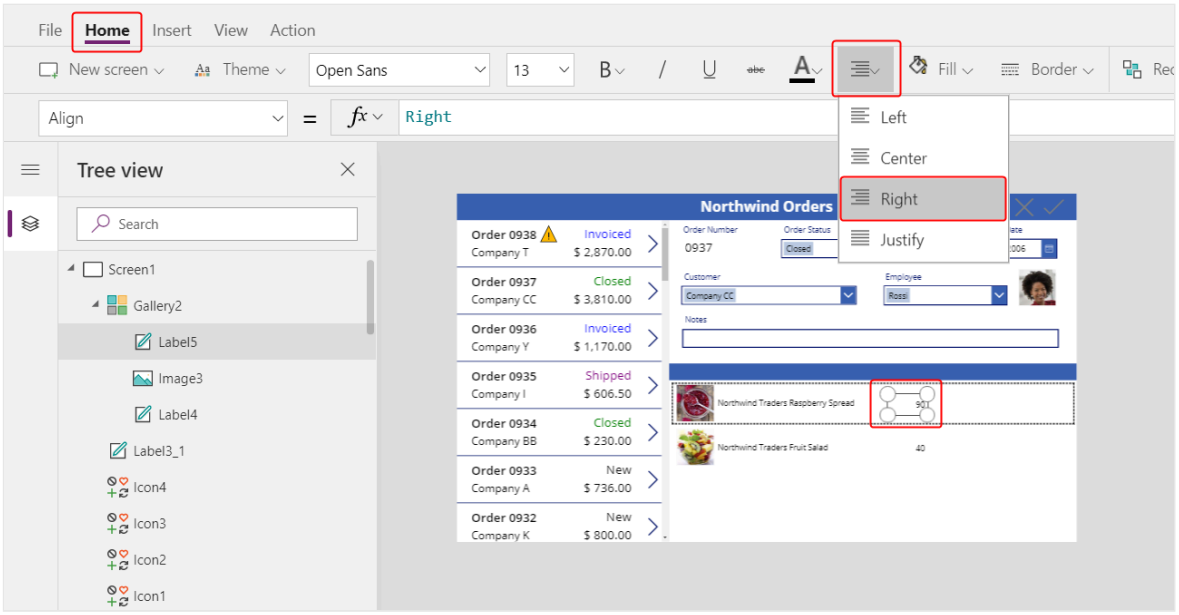
```
Power Fx

ThisItem.Quantity
```

   This formula pulls information directly from the **Order Details** table (no relationship required).



3. On the **Home** tab, change the alignment of this control to **Right**:



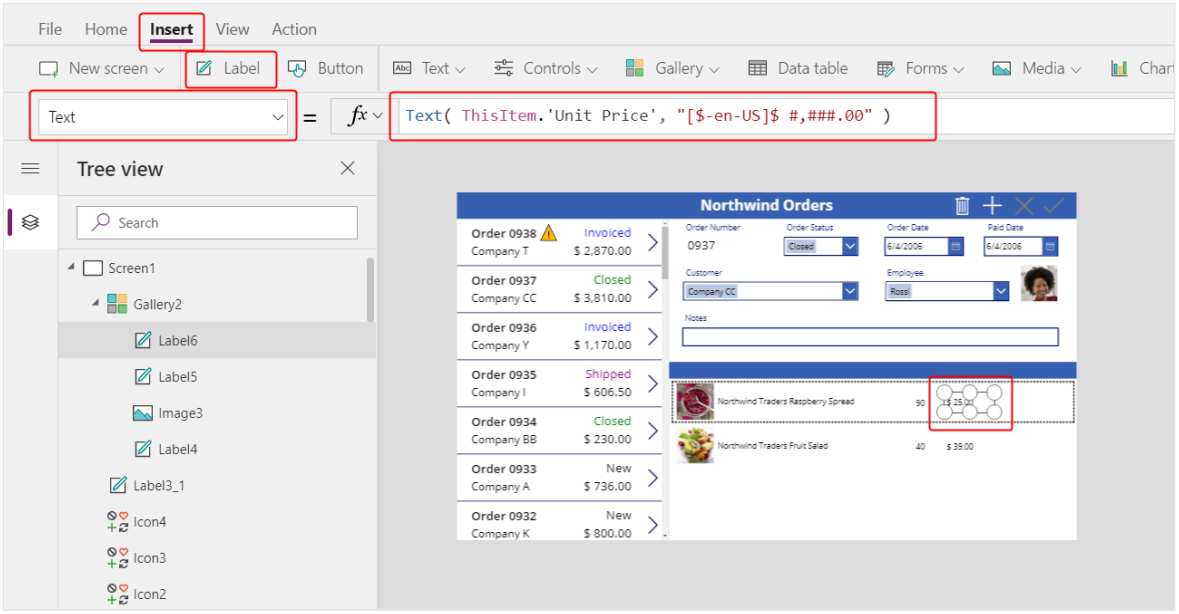
4. On the **Insert** tab, insert another label into the detail gallery, and then resize and move the label to the right of the quantity label.

5. Set the new label's **Text** property to this formula:

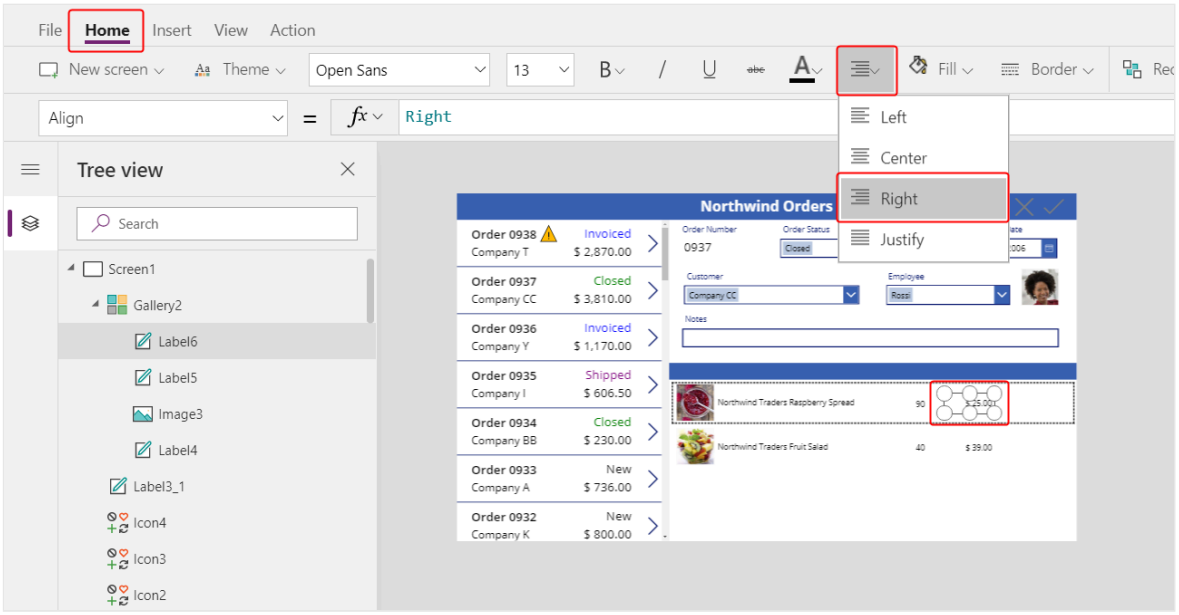
```
Power Fx

Text( ThisItem.'Unit Price', "[$-en-US]$ #,###.00" )
```

If you don't include the language tag (**[$-en-US]**), it will be added for you based on your language and region. If you use a different language tag, you'll want to remove the **$** just after the close square bracket (**]**), and then add your own currency symbol in that position.



6. On the **Home** tab, change the alignment of this control to **Right**:



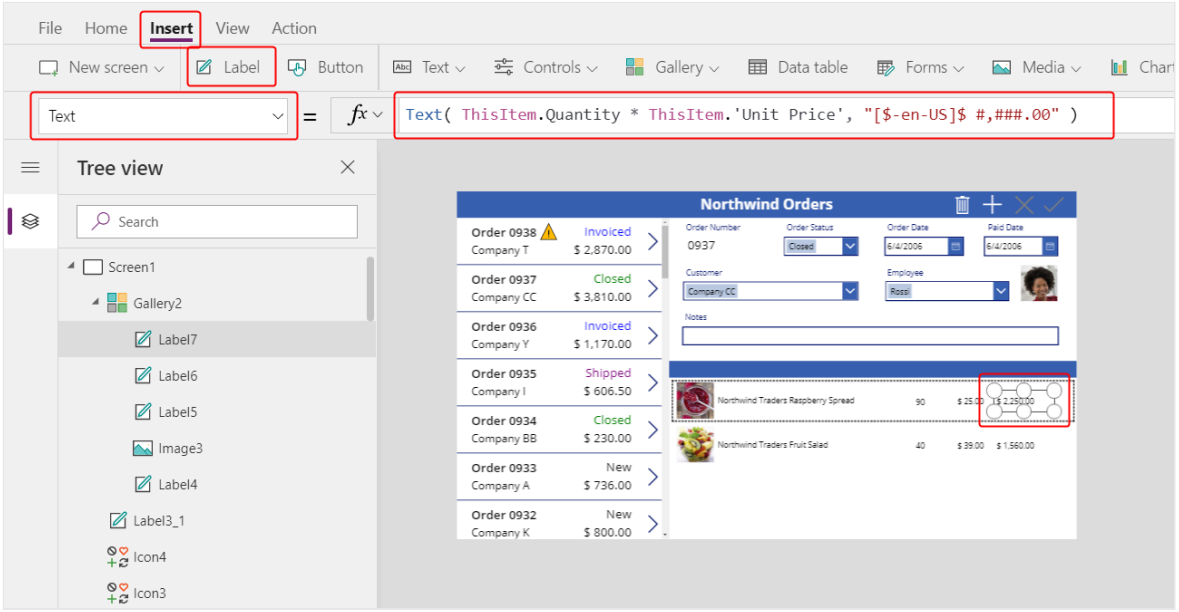
7. On the **Insert** tab, insert another label control into the detail gallery, and then resize and move the new label to the right of the unit price.

8. Set the new label's **Text** property to this formula:

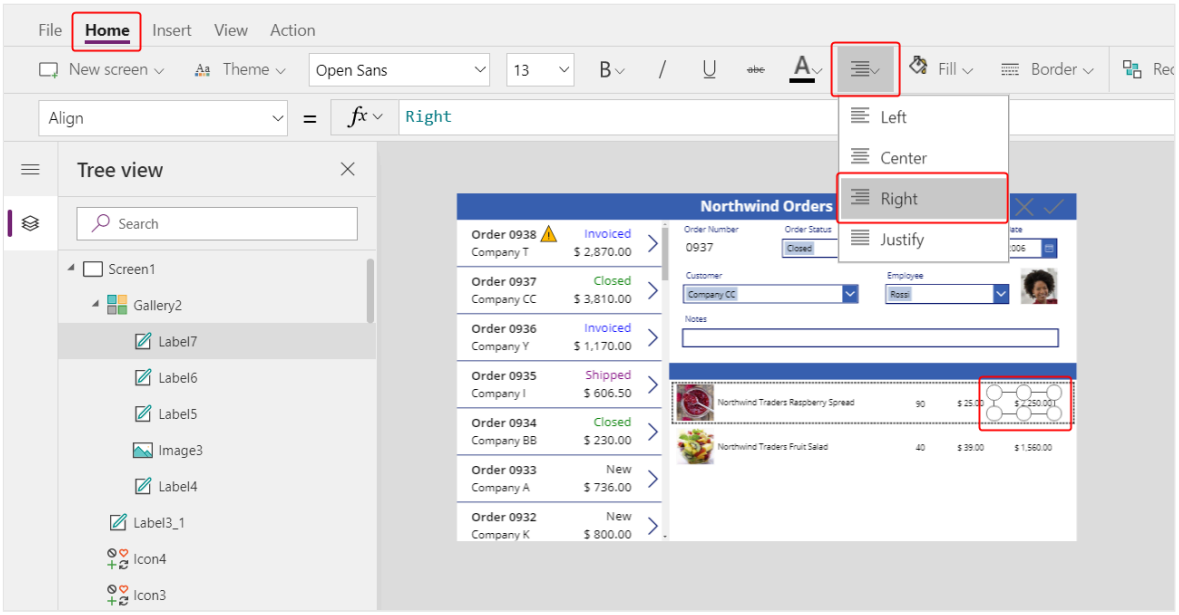
```
Power Fx

Text( ThisItem.Quantity * ThisItem.'Unit Price', "[$-en-US]$ #,###.00"
)
```

Again, if you don't include the language tag (**[$-en-US]**), it will be added for you based on your language and region. If the tag is different, you'll want to use your own currency symbol instead of the **$** just after the close square bracket (**]**).



9. On the **Home** tab, change the alignment of this control to **Right**:

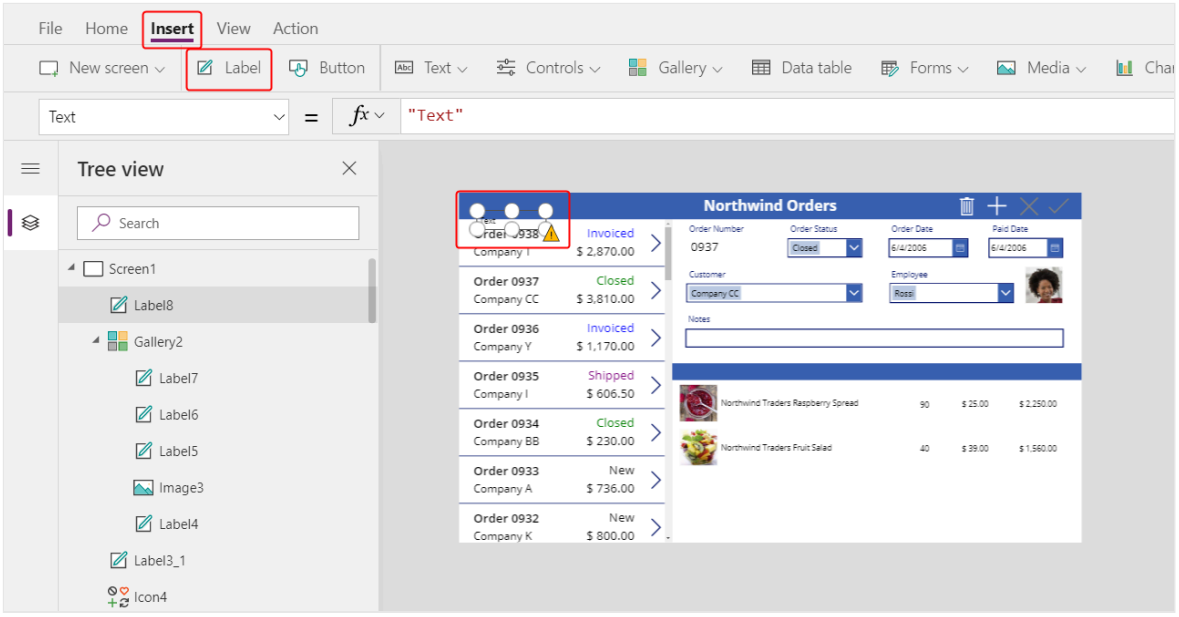


You're done adding controls to the detail gallery for now.

10. In the **Tree view** pane, select **Screen1** to ensure that the detail gallery is no longer selected.

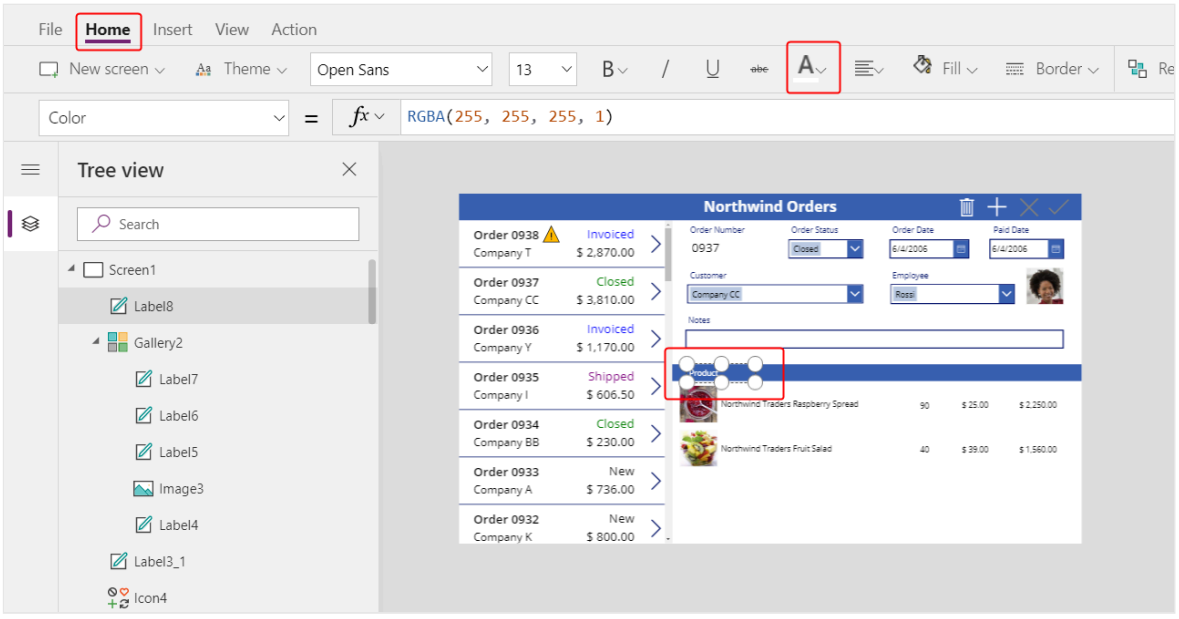
Add text to the new title bar

1. On the **Insert** tab, insert another label on to the screen:



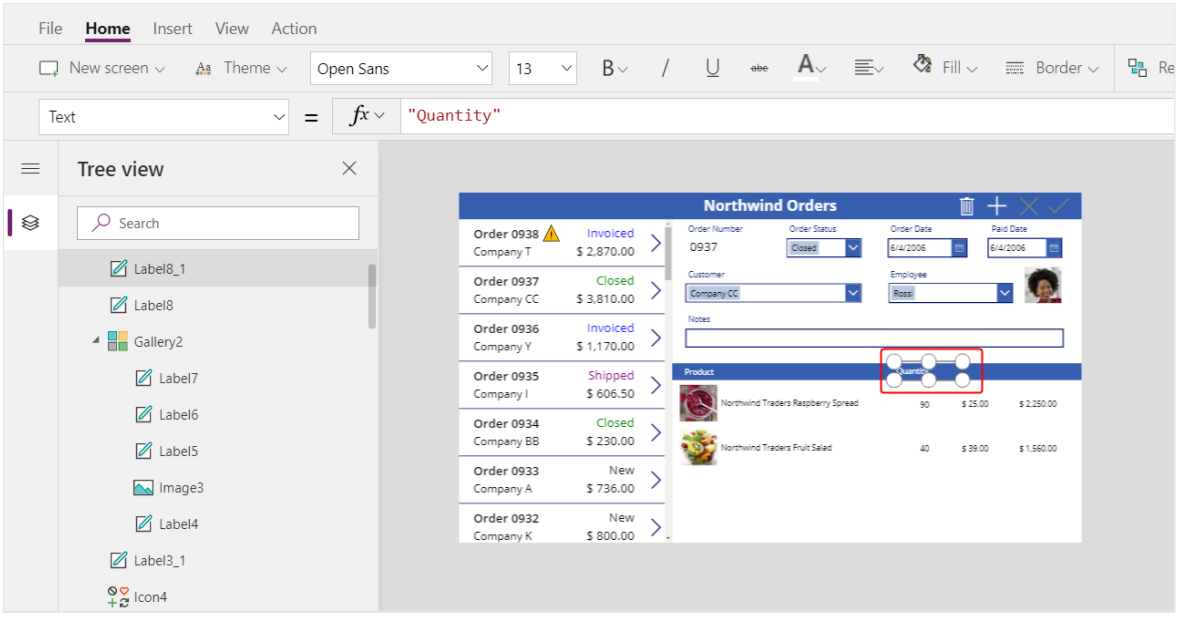
2. Resize and move the new label above the pictures of the products in the second title bar, and then change the text's color to white on the **Home** tab.

3. Double-click the label's text, and then type **Product**:



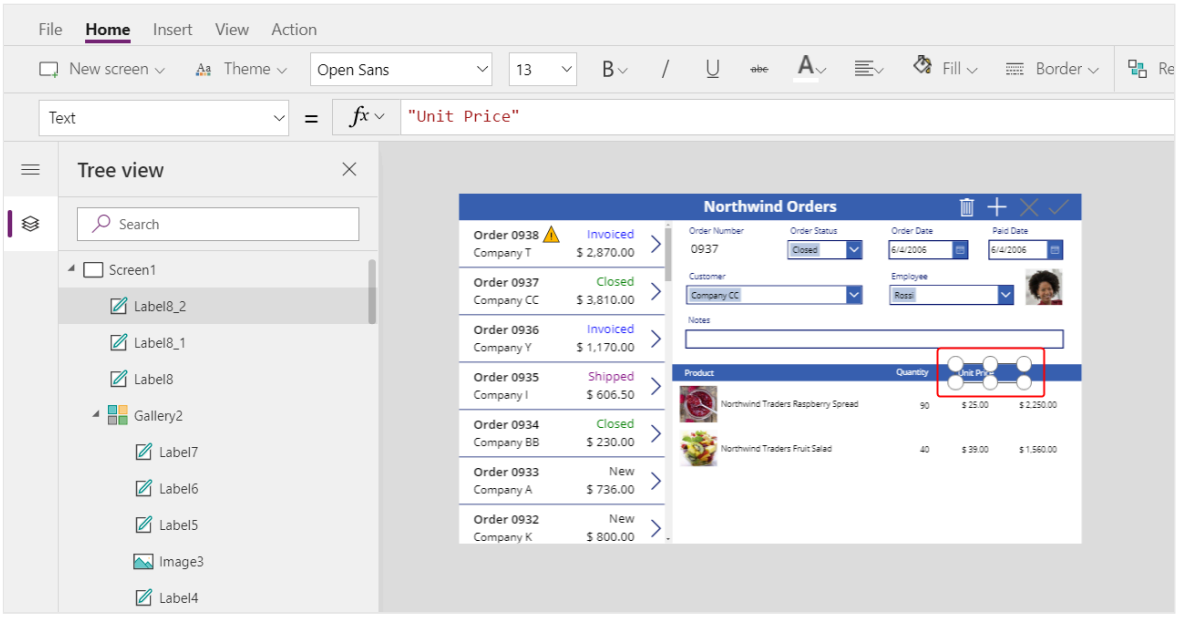
4. Copy and paste the product label, and then resize and move the copy above the quantity column.

5. Double-click the new label's text, and then type **Quantity**:



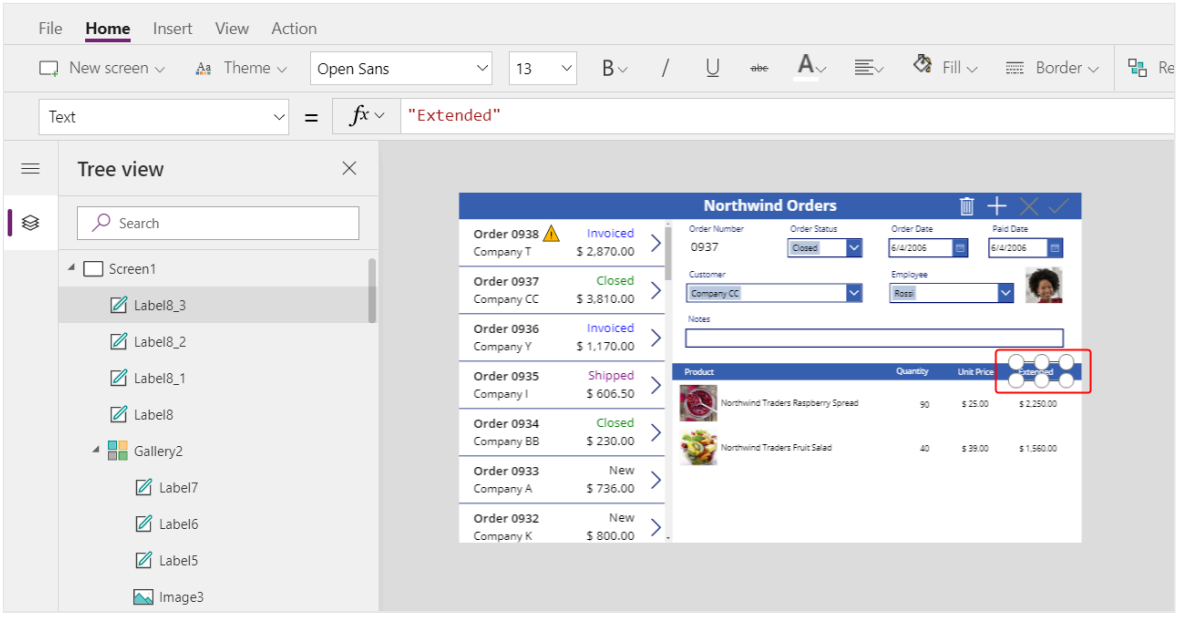
6. Copy and paste the quantity label, and then resize and move the copy above the unit-price column.

7. Double-click the new label's text, and then type **Unit Price**:



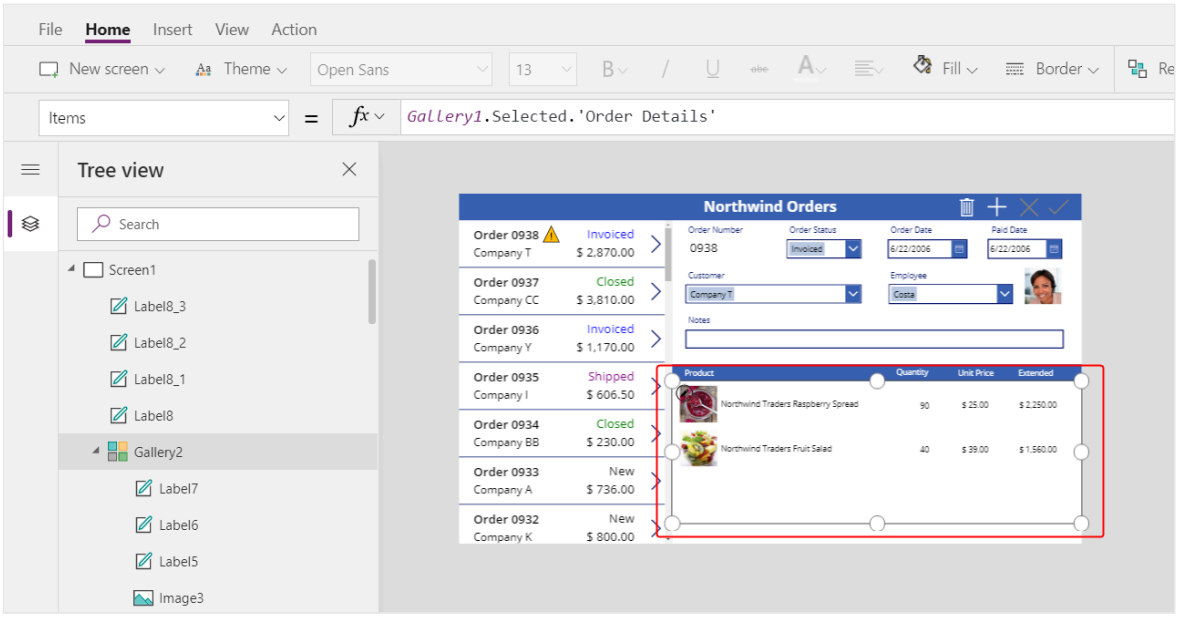
8. Copy and paste the unit-price label, and then resize and move the copy above the extended-price column.

9. Double-click the text of the new label, and then type **Extended**:

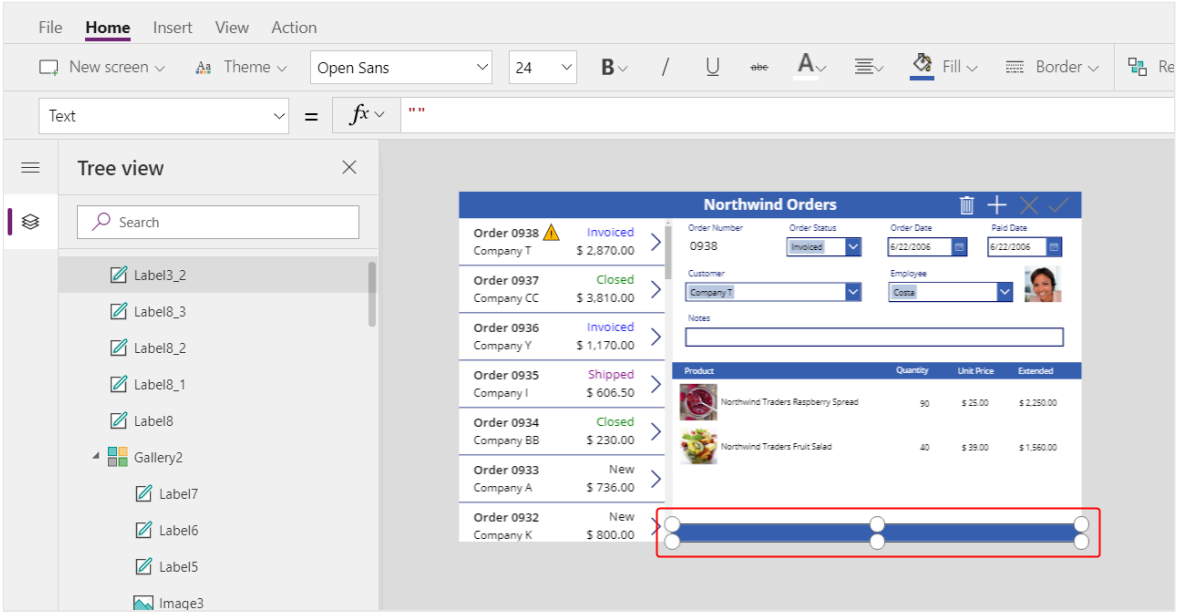


Display order totals

1. Reduce the height of the detail gallery to make room for the order totals at the bottom of the screen:

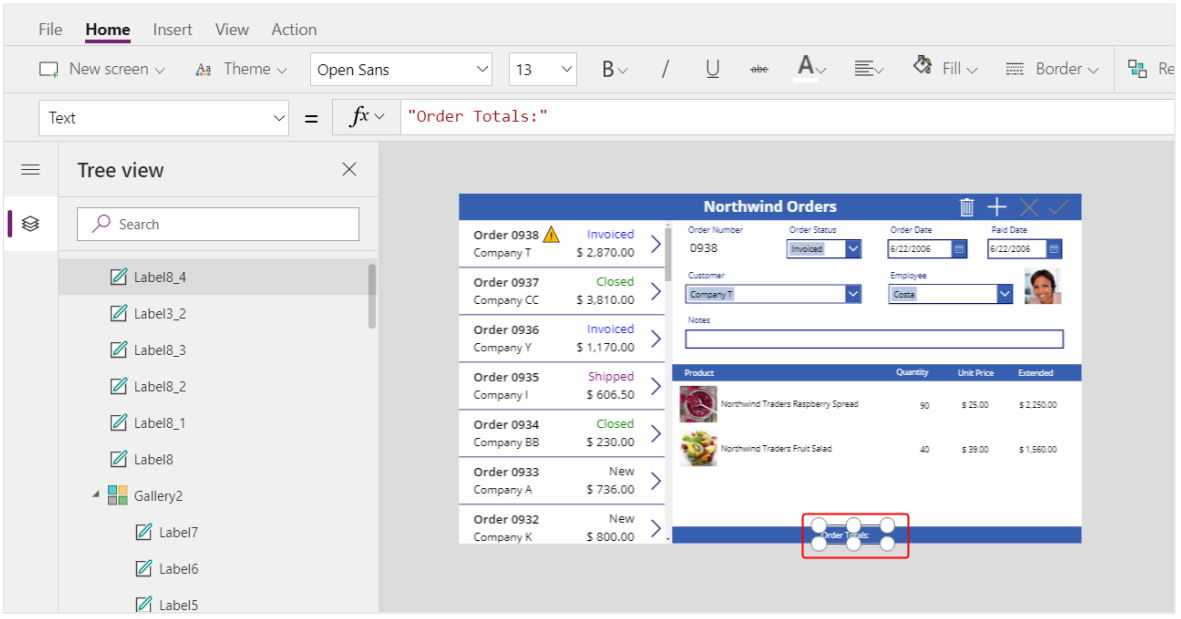


2. Copy and paste the title bar in the middle of the screen, and then move the copy to the bottom of the screen:



3. Copy and paste the product label from the middle title bar, and then move the copy to the bottom title bar, just to the left of the **Quantity** column.

4. Double-click the new label's text, and then type this text:
   Order Totals:



5. Copy and paste the order-totals label, and then resize and move the copy to the right of the order-totals label.

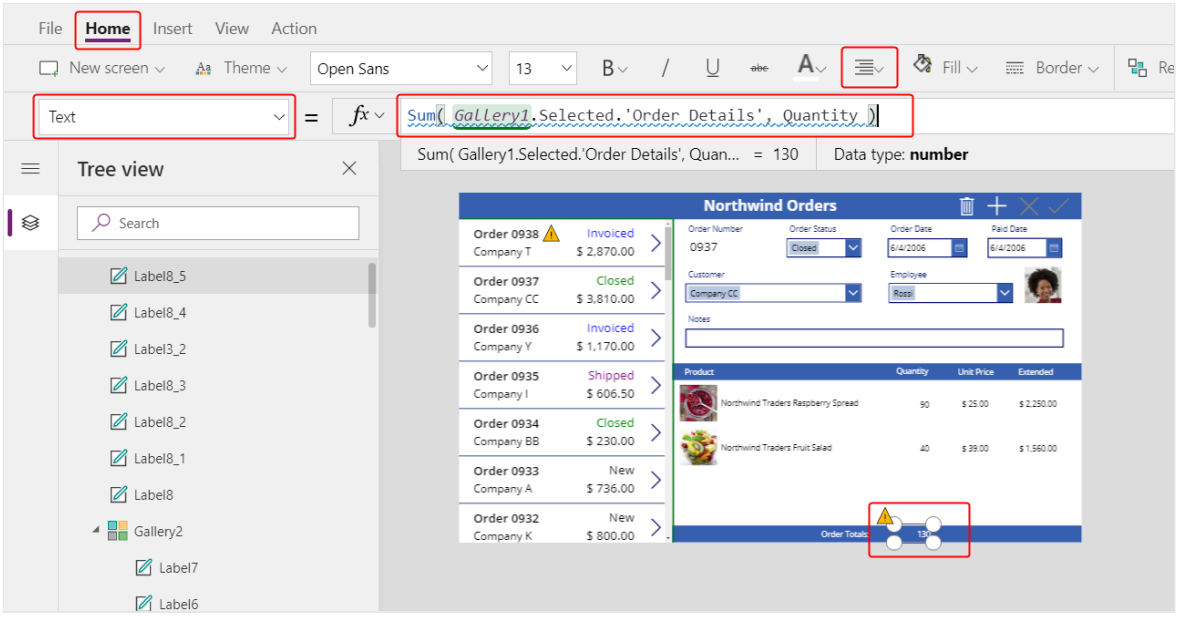
6. Set the new label's **Text** property to this formula:

```
Power Fx

Sum( Gallery1.Selected.'Order Details', Quantity )
```

   This formula shows a delegation warning, but you can ignore it because no single order will contain more than 500 products.

7. On the **Home** tab, set the new label's text alignment to **Right**:



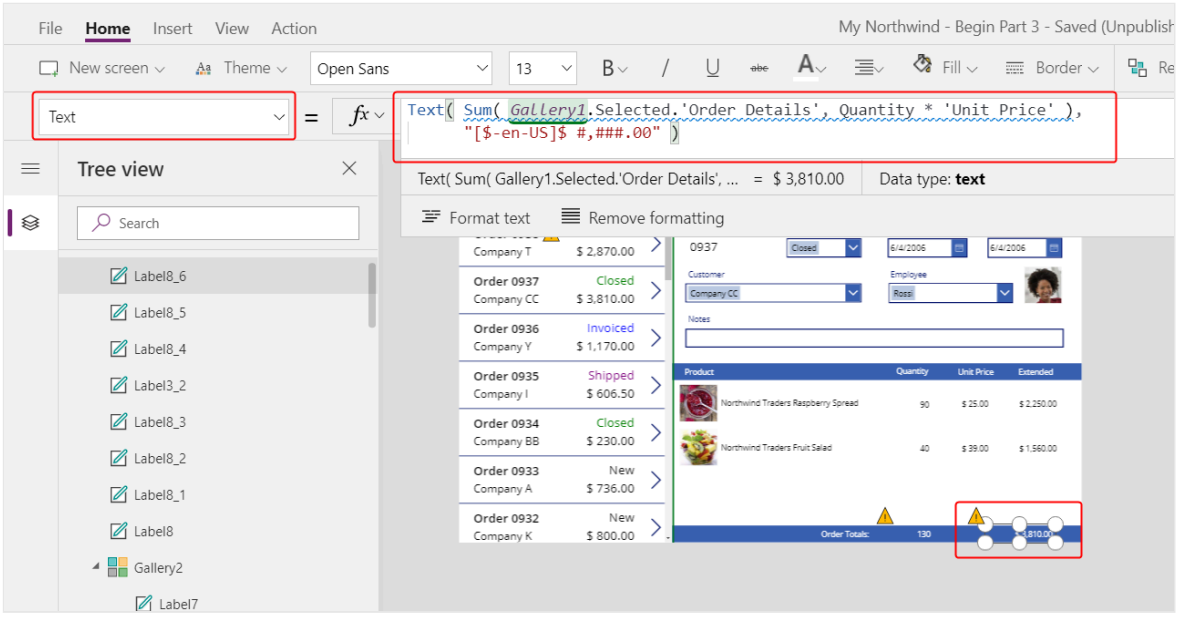
8. Copy and paste this label control, and then resize and move the copy under the **Extended** column.

9. Set the copy's **Text** property to this formula:

```
Power Fx

Text( Sum( Gallery1.Selected.'Order Details', Quantity * 'Unit Price'
), "[$-en-US]$ #,###.00" )
```

This formula shows a delegation warning, but you can ignore it because no single order will contain more than 500 products.

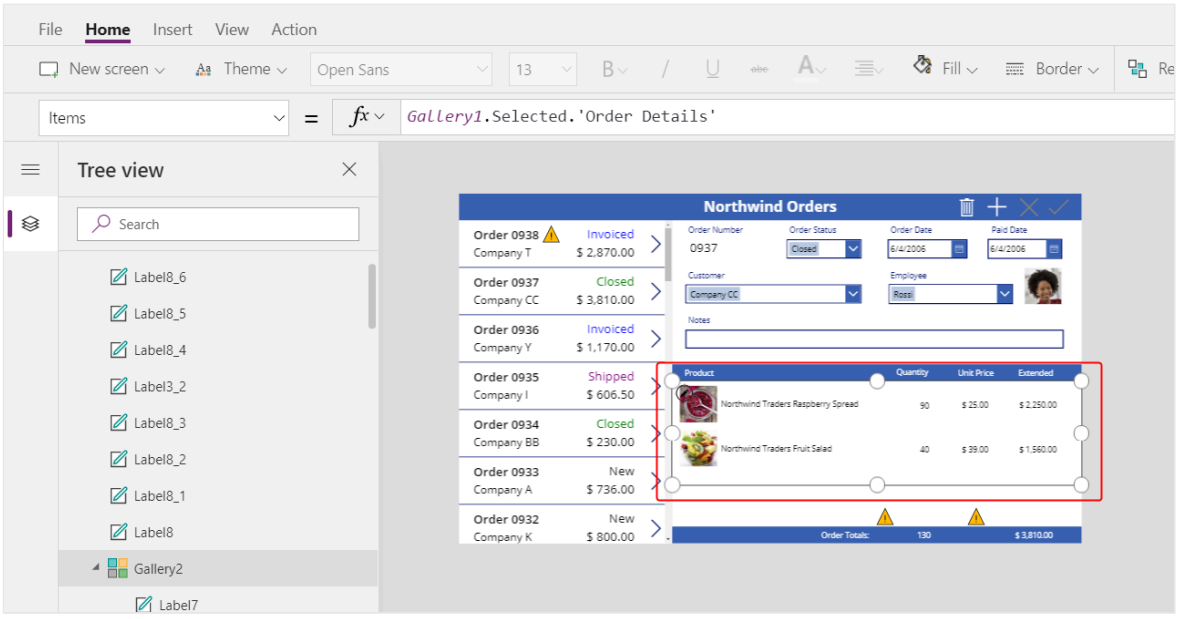


Add space for new details

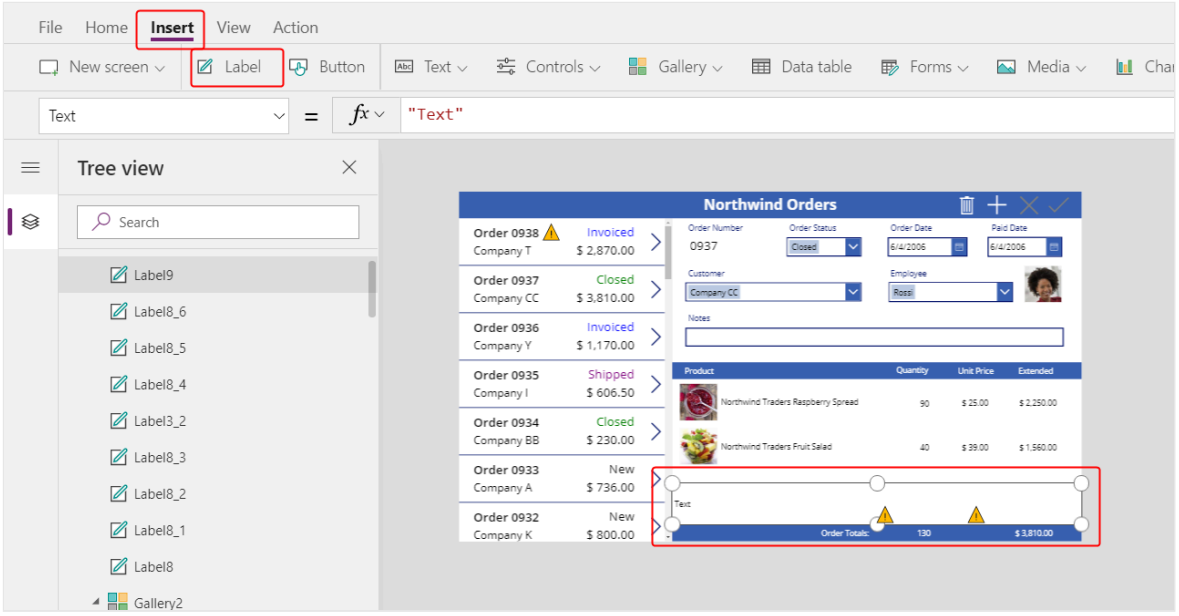
In any gallery, you can show data but you can't update it or add records. Under the detail gallery, you'll add an area where the user can configure a record in the **Order Details** table and insert that record into an order.

1. Reduce the height of the detail gallery enough to make room for a single-item editing space under that gallery.

   In this space, you'll add controls so that the user can add an order detail:

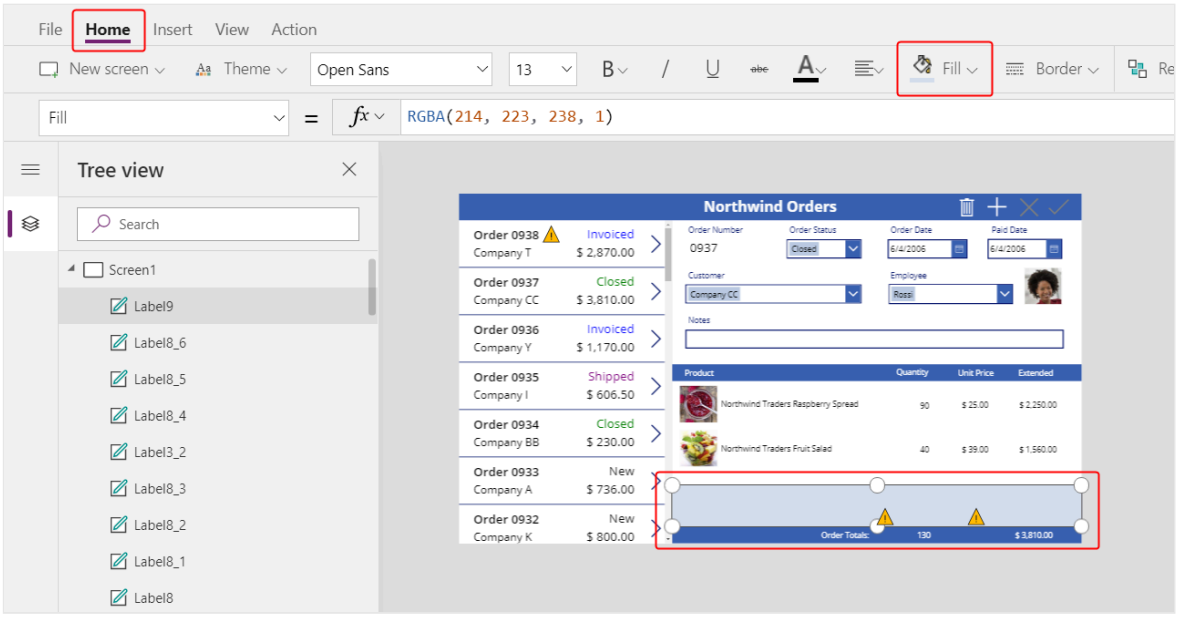


2. On the **Insert** tab, insert a label, and then resize and move it under the detail gallery.



3. Double-click the text of the new label, and then press Delete.

4. On the **Home** tab, set the new label's **Fill** color to **LightBlue**:



Select a product

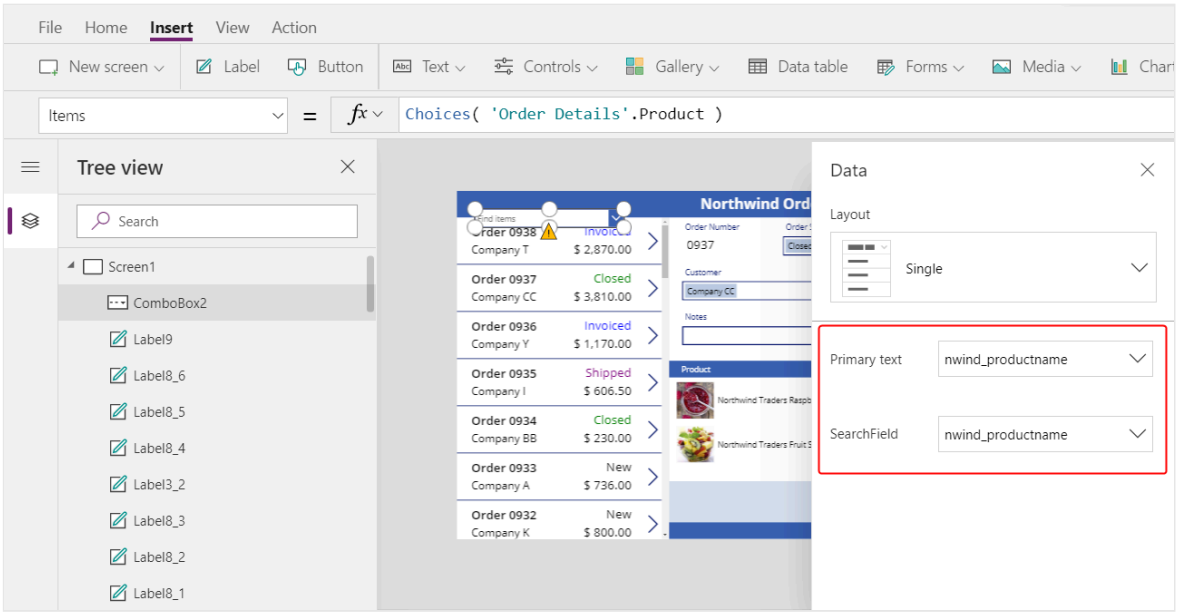
1. On the **Insert** tab, select **Controls** > **Combo box**:

   The Combo box control appears in the upper-left corner.

2. In the fly out dialog, select the **Order Products** data source.

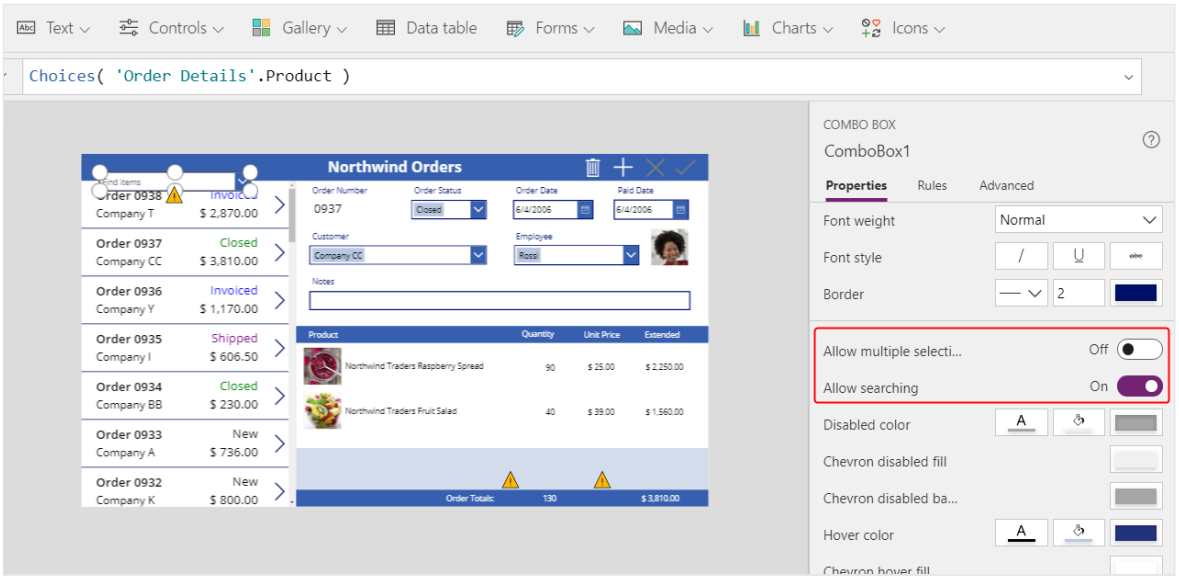
3. In the **Properties** tab for the combo box, select **Edit** (next to **Fields**) to open the **Data** pane. Ensure that the **Primary text** and **SearchField** are set to **nwind_productname**.

   You specify the logical name because the **Data** pane doesn't support display names in this case yet:

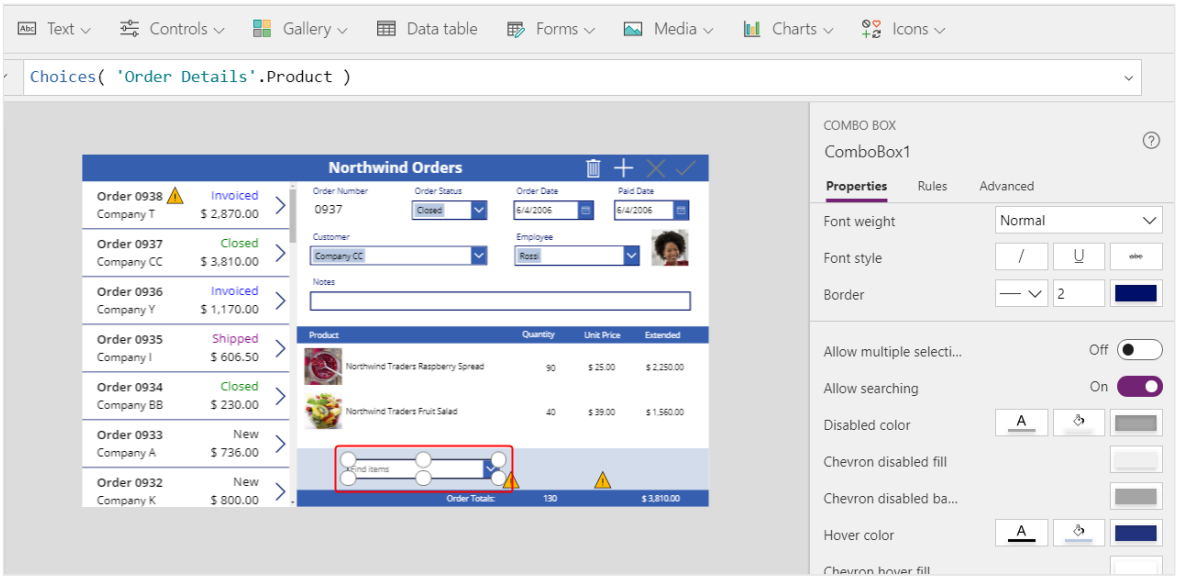


4. Close the **Data** pane.

5. In the **Properties** tab near the right edge, scroll down, turn off **Allow multiple selection**, and ensure that **Allow searching** is turned on:



6. Resize and move the combo box to the light-blue area, just under the product-name column in the detail gallery:

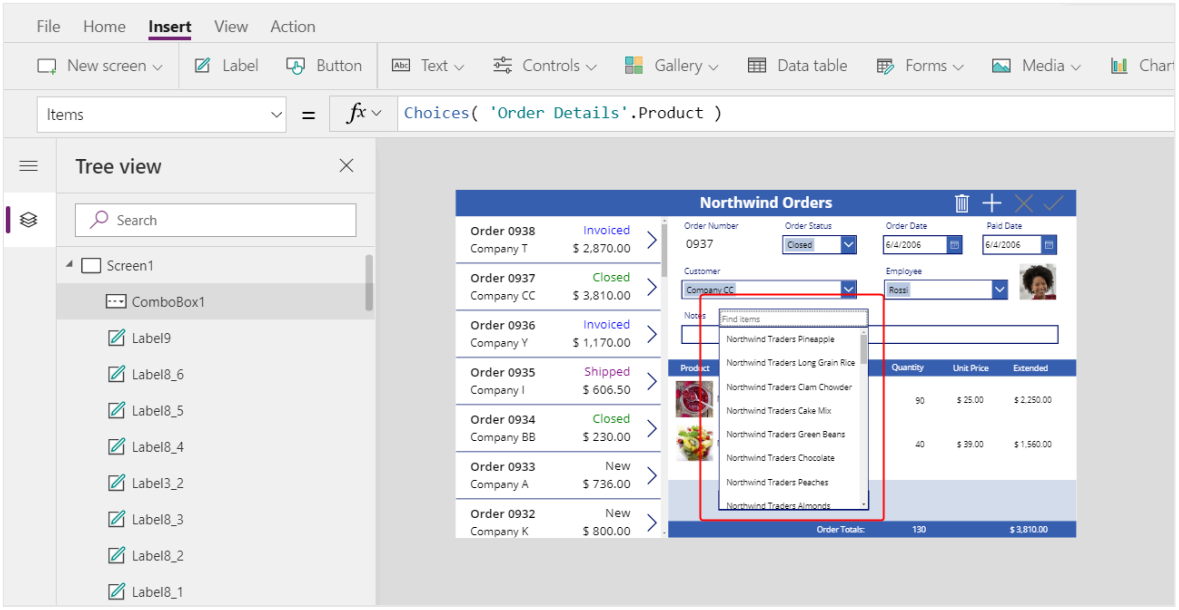


In this combo box, the user will specify a record in the **Product** table for the **Order Details** record that the app will create.

7. While holding down the Alt key, select the combo box's down arrow.

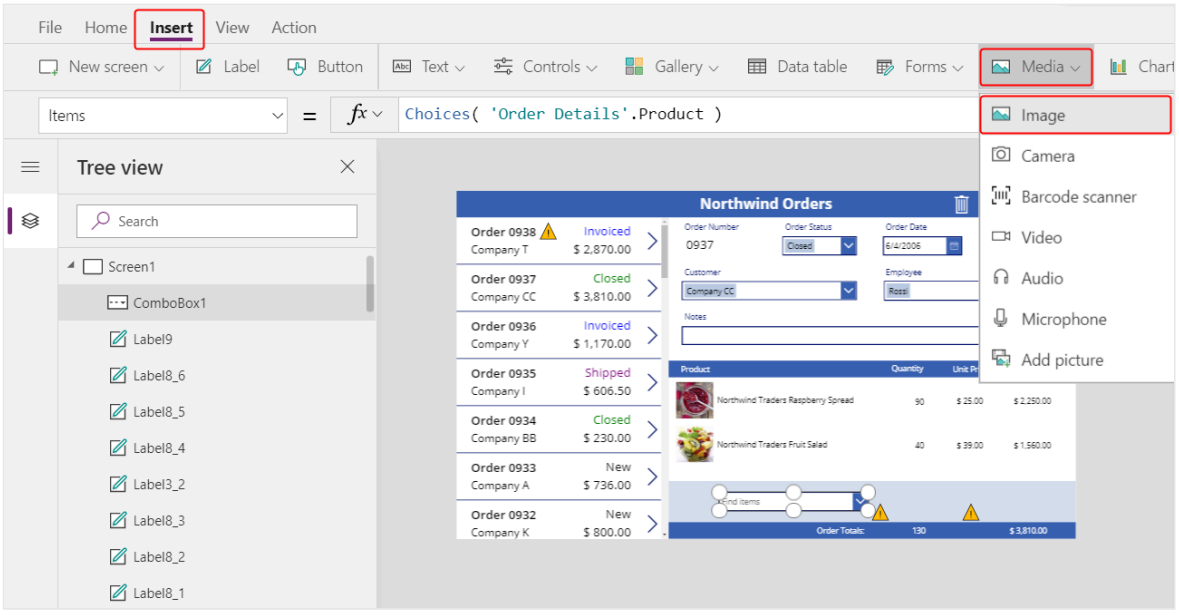
> **Tip**
>
> By holding down the Alt key, you can interact with controls in Power Apps Studio without opening Preview mode.

8. In the list of products that appears, select a product:

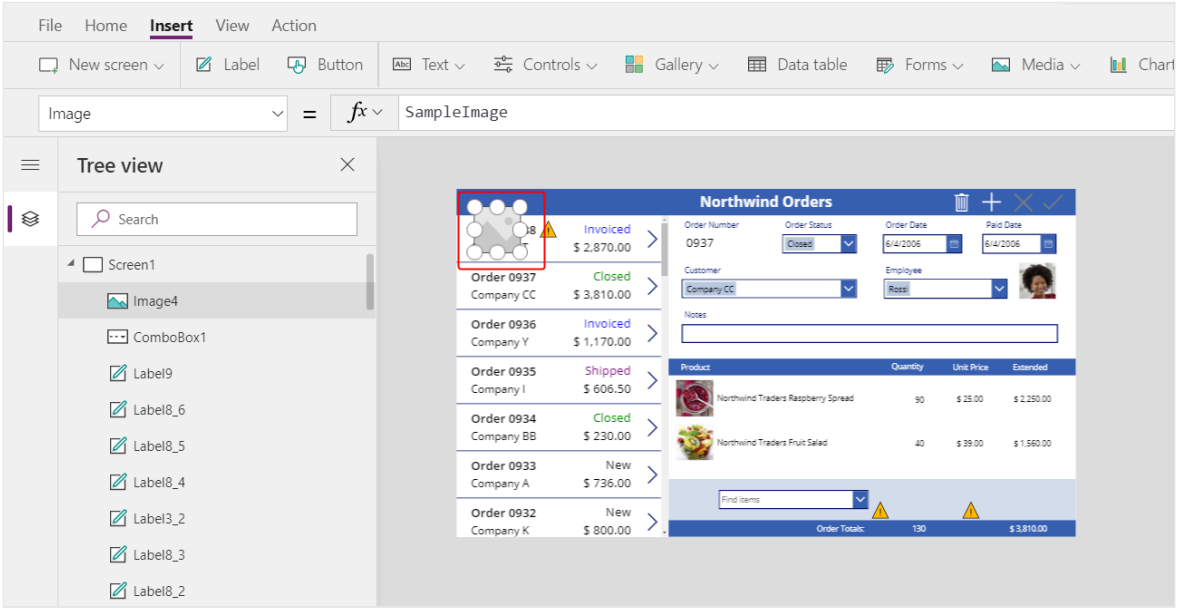


Add a product image

1. On the **Insert** tab, select **Media** > **Image**:



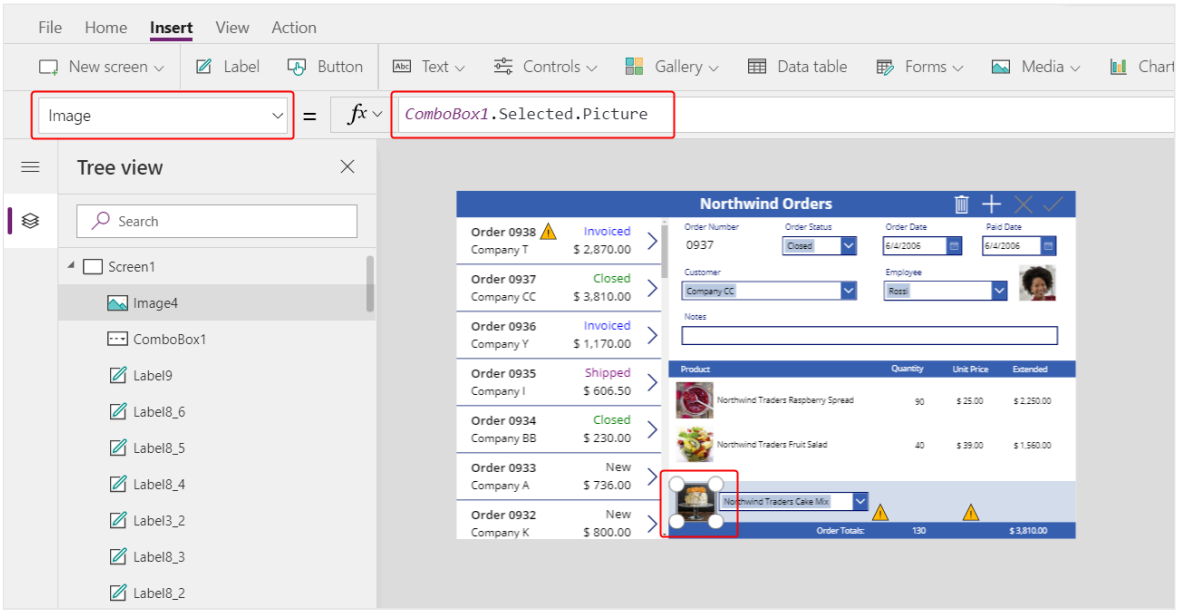
The **Image** control appears in the upper-left corner:



2. Resize and move the image to the light-blue area under the other product images and next to the combo box.

3. Set the **Image** property of the image to:

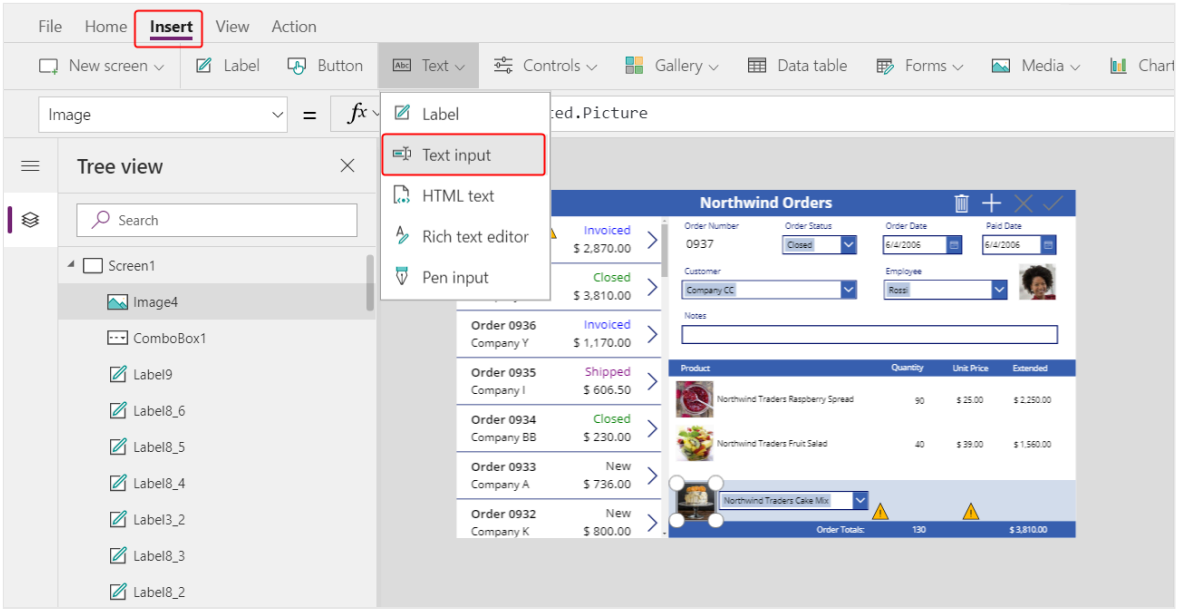
```
ComboBox1.Selected.Picture
```



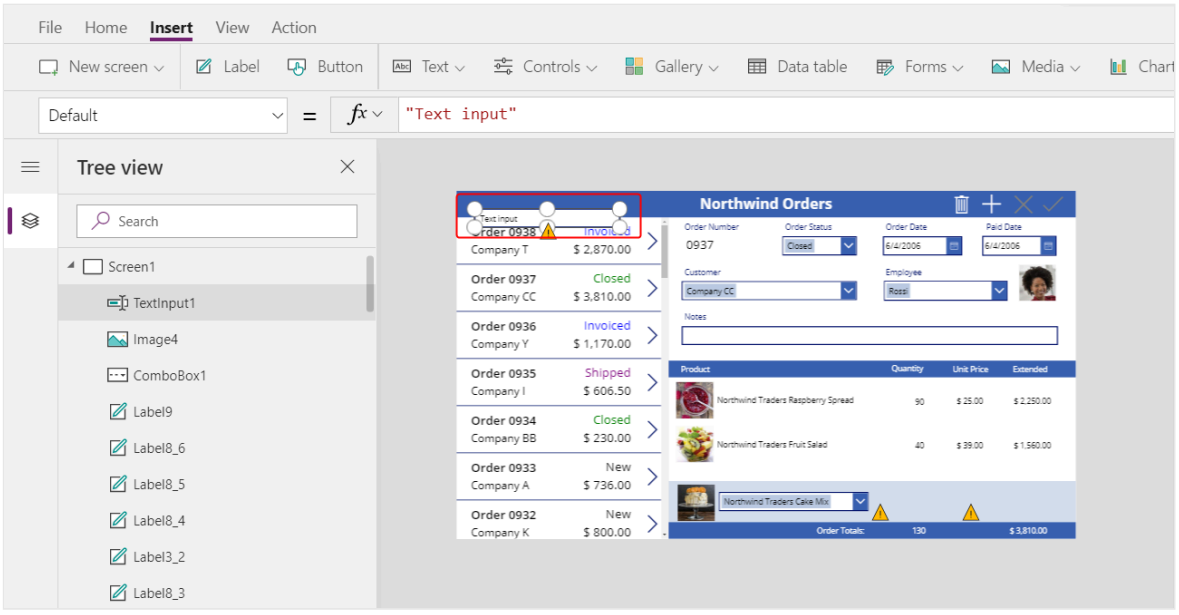
You're using the same trick as you used to show the employee picture in the summary form. The **Selected** property of the combo box returns the entire record of whatever product the user selects, including the **Picture** field.

Add a quantity box

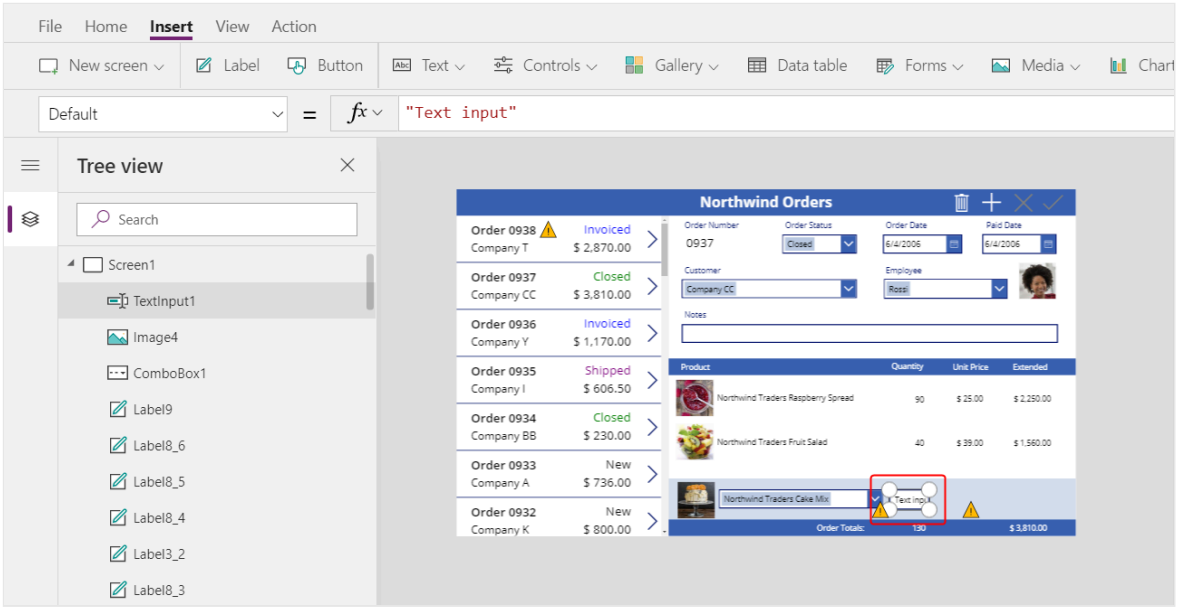
1. On the **Insert** tab, select **Text** > **Text input**:



The Text input control appears in the upper-left corner:

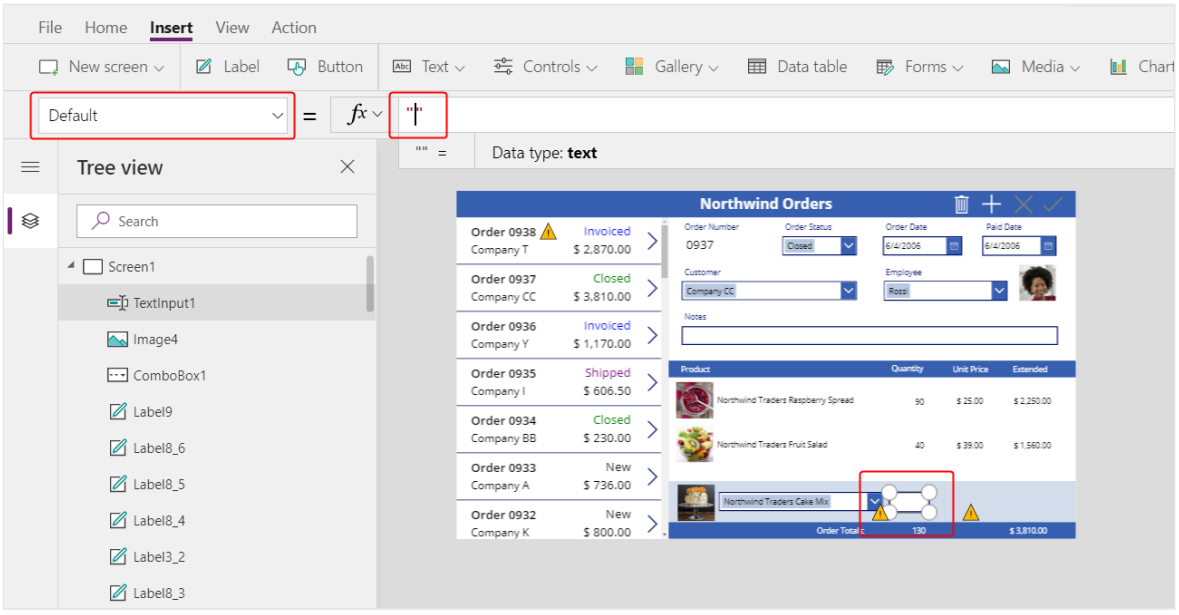


2. Resize and move the text-input box to the right of the combo box, under the quantity column in the detail gallery:

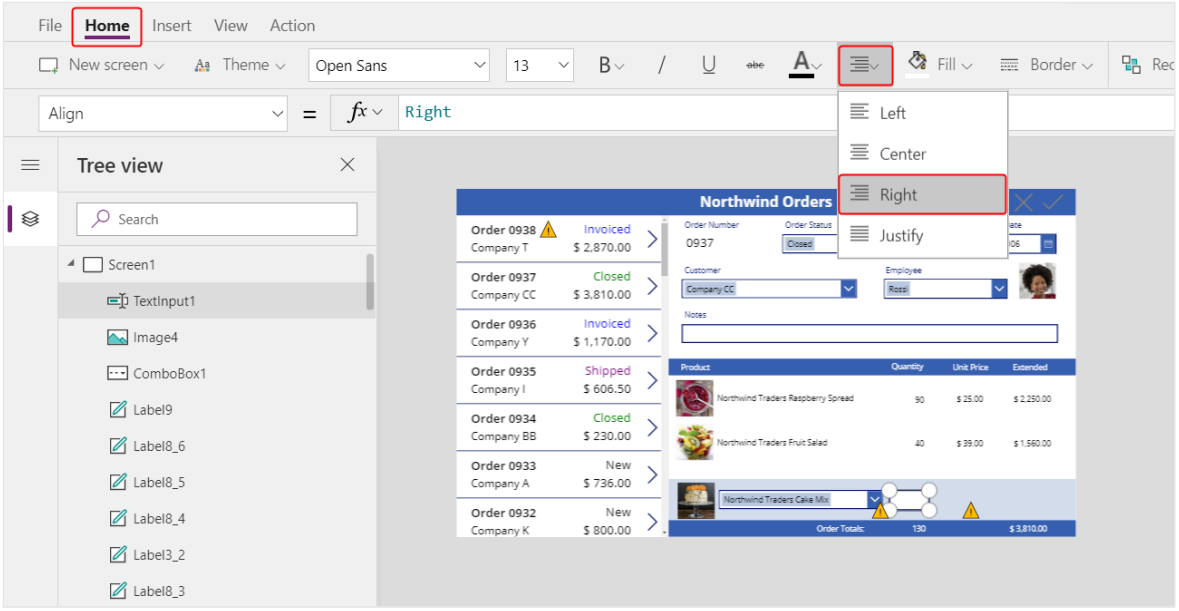


By using this text-input box, the user will specify the **Quantity** field of the **Order Details** record.

3. Set the **Default** property of this control to "":



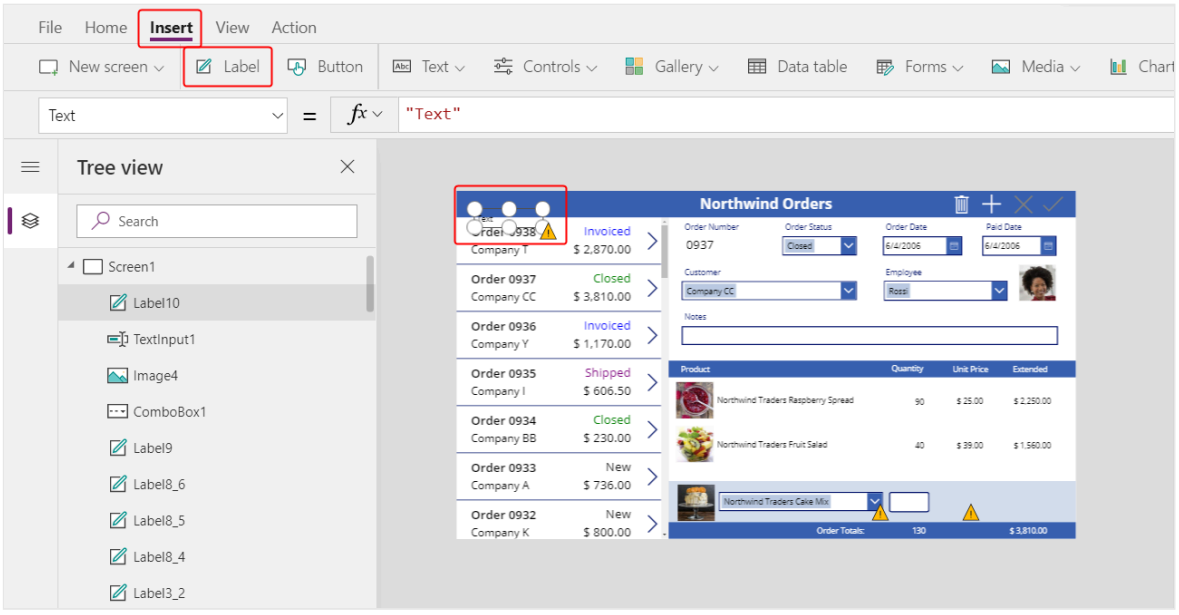
4. On the **Home** tab, set the text alignment of this control to **Right**:



Show the unit and extended prices

1. On the **Insert** tab, insert a **Label** control.

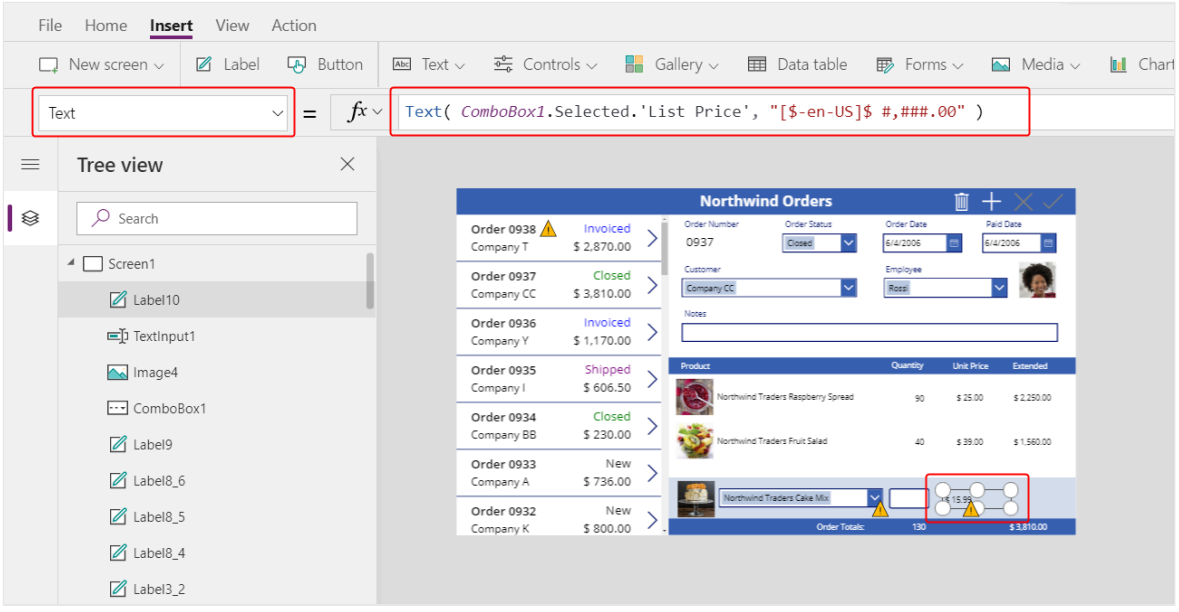
   The label appears in the upper-left corner of the screen:



2. Resize and move the label to the right of the text-input control, and set the label's **Text** property to this formula:

```
Power Fx

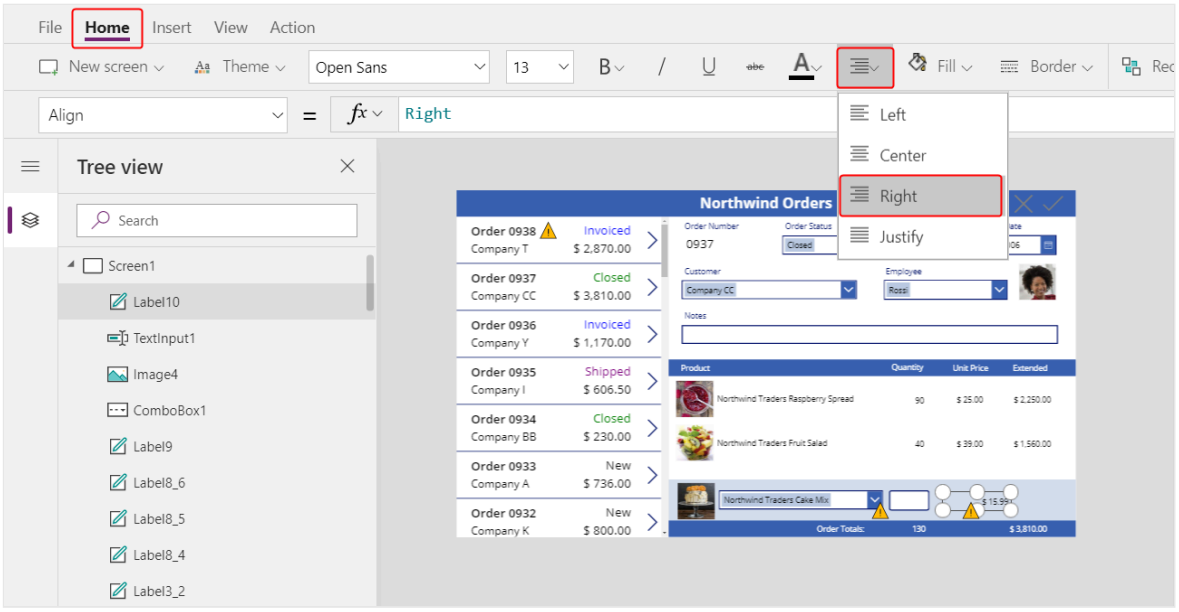
Text( ComboBox1.Selected.'List Price', "[$-en-US]$ #,###.00" )
```



This control shows the **List Price** from the **Order Products** table. This value will determine the **Unit Price** field in the **Order Details** record.

> ⓘ **Note**
>
> For this scenario, the value is read-only, but other scenarios might call for the app user to modify it. In that case, use a **Text input** control, and set its **Default** property to **List Price**.

3. On the **Home** tab, set the text alignment of the list-price label to **Right**:

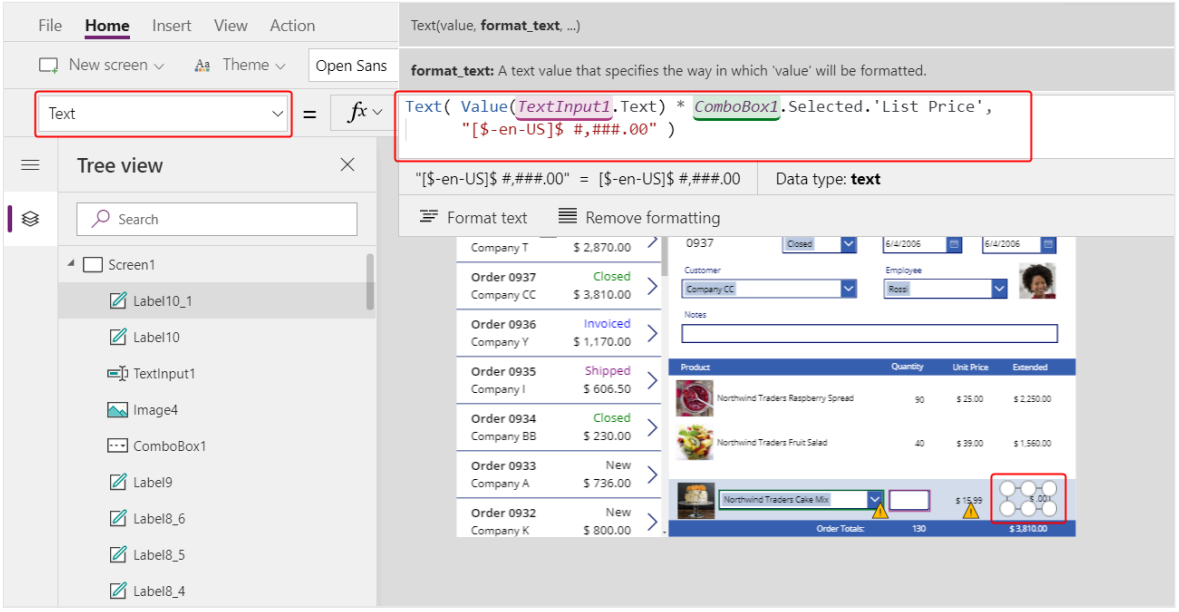


4. Copy and paste the list-price label, and then resize and move the copy to the right of the list-price label.

5. Set the new label's **Text** property to this formula:

```
Power Fx

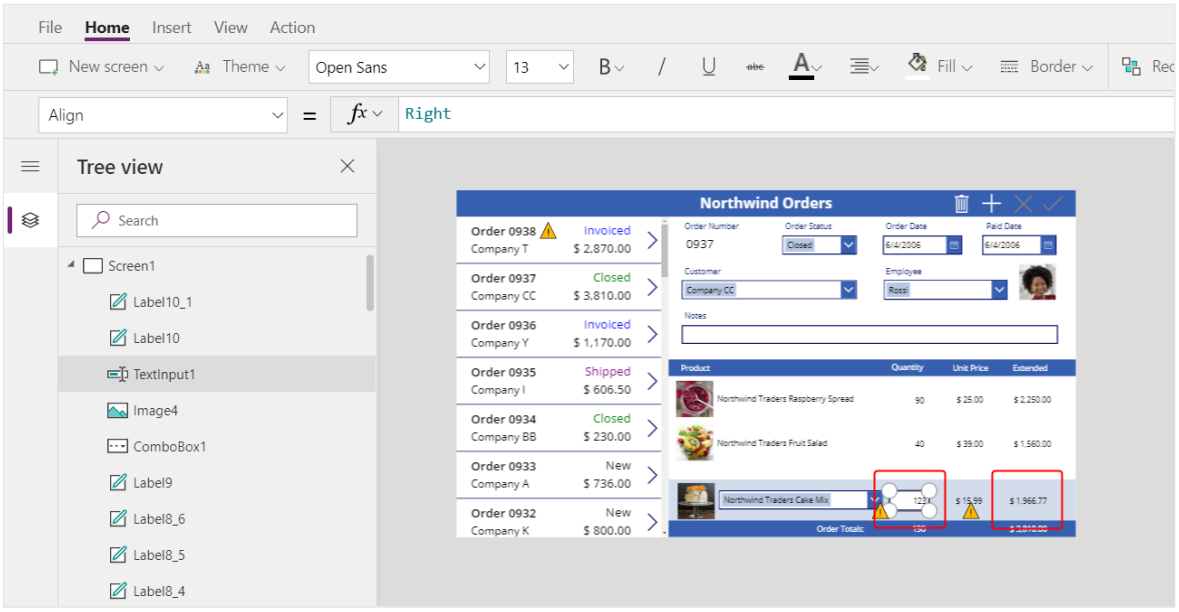
Text( Value(TextInput1.Text) * ComboBox1.Selected.'List Price', "[$-en-US]$ #,###.00" )
```



This control shows the extended price based on the quantity that the app user specified and the list price of the product that the app user selected. It's purely informational for the app user.

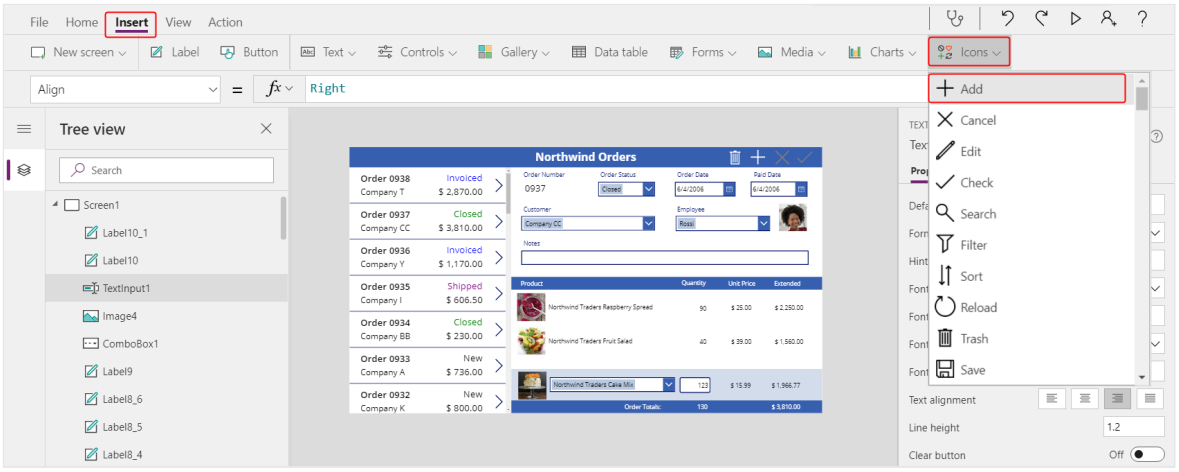
6. Double-click the text-input control for quantity, and then type a number.

The **Extended** price label recalculates to show the new value:

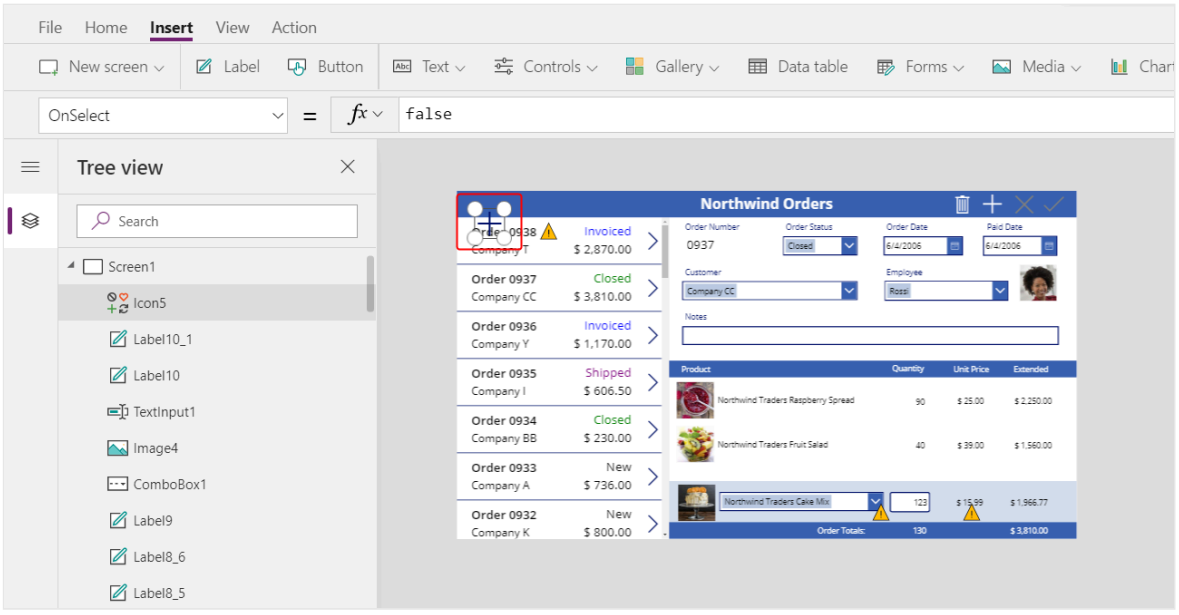


Add an Add icon

1. On the **Insert** tab, select **Icons** > **Add**:



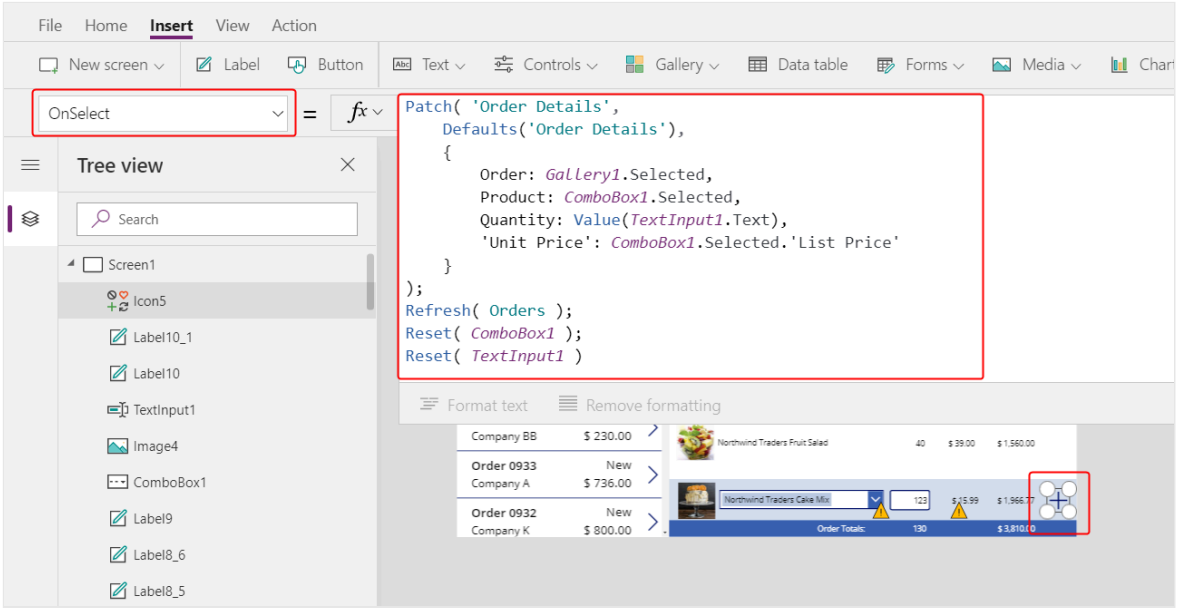
The icon appears in the upper-left corner of the screen.



2. Resize and move this icon to the right edge of the light-blue area, and then set the icon's **OnSelect** property to this formula:

Power Fx

```
Patch( 'Order Details',
    Defaults('Order Details'),
    {
        Order: Gallery1.Selected,
        Product: ComboBox1.Selected,
        Quantity: Value(TextInput1.Text),
        'Unit Price': ComboBox1.Selected.'List Price'
    }
);
Refresh( Orders );
Reset( ComboBox1 );
Reset( TextInput1 )
```



In general, the **Patch** function updates and creates records, and the specific arguments in this formula determine the exact changes that the function will make.

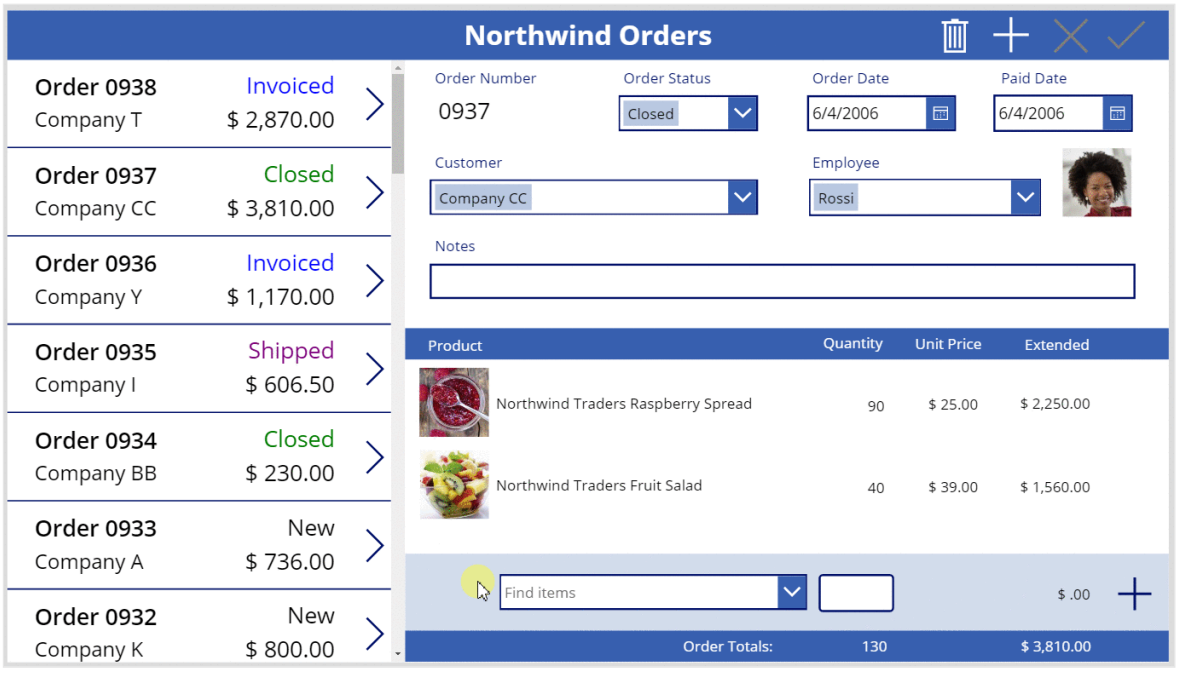
- The first argument specifies the data source (in this case, the **Order Details** table) in which the function will update or create a record.
- The second argument specifies that the function will create a record with the default values for the **Order Details** table unless otherwise specified in the third argument.
- The third argument specifies that four columns in the new record will contain values from the user.
  - The **Order** column will contain the number of the order that the user selected in order gallery.
  - The **Product** column will contain the name of the product that the user selected in the combo box that shows products.
  - The **Quantity** column will contain the value that the user specified in the text-input box.
  - The **Unit Price** column will contain the list price of the product that the user selected for this order detail.

> ⓘ Note
>
> You can build formulas that use data from any column (in the **Order Products** table) for whatever product the app user selects in the combo box that shows products. When the user selects a record in the **Order Products** table, not only does the product's name appear in that combo box but also the product's unit price appears in a label. Each lookup value in a canvas app references an entire record, not just a primary key.

The **Refresh** function ensures that the **Orders** table reflects the record that you've just added to the **Order Details** table. The **Reset** function clears the product, quantity, and unit-price data so that the user can more easily create another order detail for the same order.

3. Press F5, and then select the **Add** icon.

   The order reflects the information that you specified:

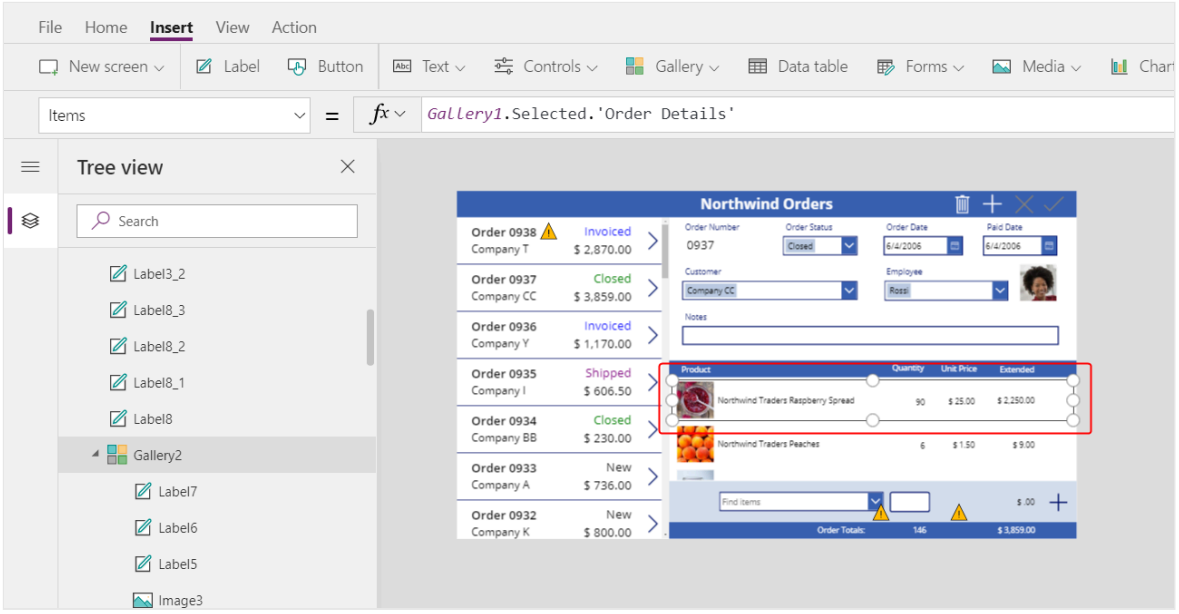


4. (optional) Add another item to the order.

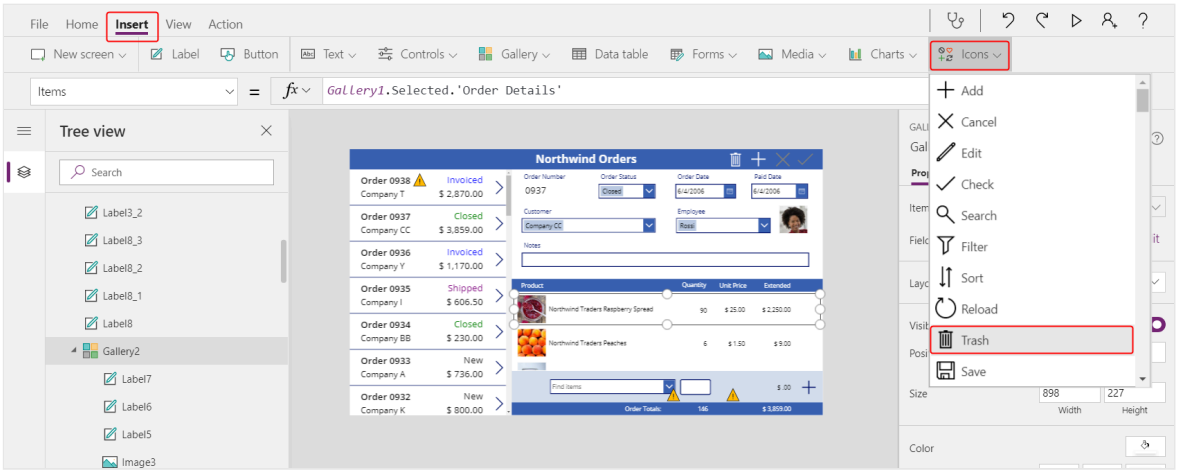
5. Press Esc to close Preview mode.

Remove an order detail

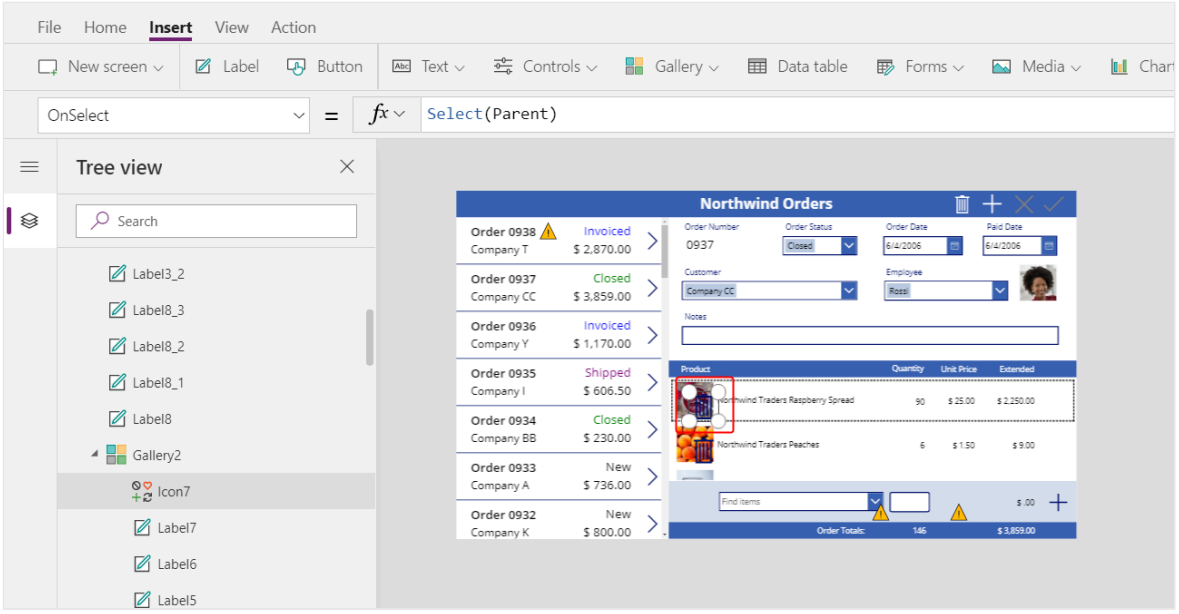
1. In the center of the screen, select the template of the detail gallery:



2. On the **Insert** tab, select **Icons** > **Trash**:



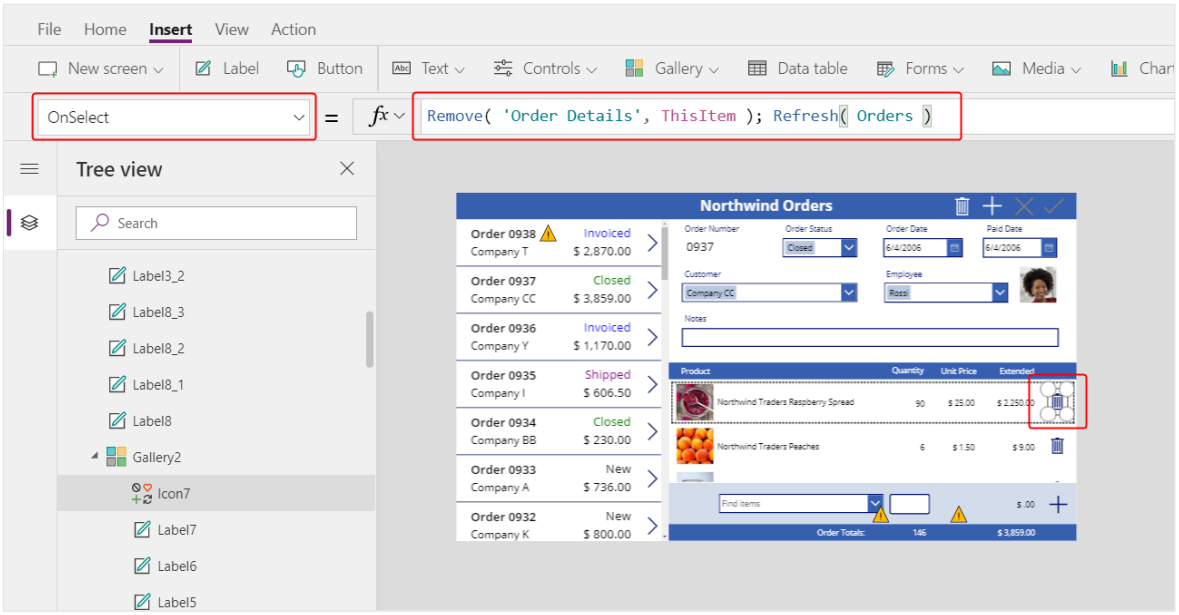
The Trash icon appears in the upper-left corner of gallery's template.



3. Resize and move the Trash icon to the right side of the detail gallery's template, and set the icon's **OnSelect** property to this formula:

Power Fx

```
Remove( 'Order Details', ThisItem ); Refresh( Orders )
```

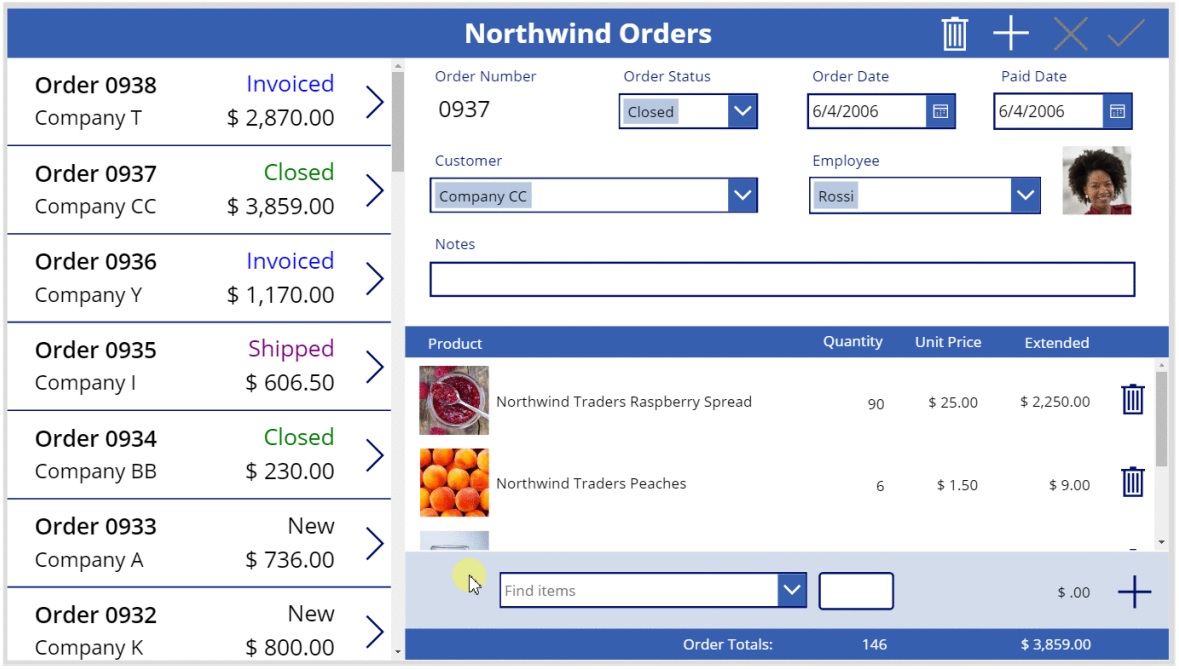


As of this writing, you can't remove a record directly from a relationship, so the **Remove** function removes a record directly from the related table. **ThisItem** specifies the record to remove, taken from the same record in the detail gallery where the Trash icon appears.

Again, the operation uses cached data, so the **Refresh** function informs the **Orders** table that the app has changed one of its related tables.

4. Press F5 to open Preview mode, and then select the Trash icon next to each **Order Details** record that you want to remove from the order.

5. Try adding and removing various order details from your orders:



In conclusion

To recap, you added another gallery to show order details and controls adding and removing an order detail in the app. You used these elements:

- A second gallery control, linked to the order gallery through a one-to-many relationship: **Gallery2.Items** = `Gallery1.Selected.'Order Details'`
- A many-to-one relationship from the **Order Details** table to the **Order Products** table: `ThisItem.Product.'Product Name'` and `ThisItem.Product.Picture`
- The **Choices** function to get a list of products: `Choices( 'Order Details'.Product' )`
- The **Selected** property of a combo box as the complete many-to-one related record: `ComboBox1.Selected.Picture` and `ComboBox1.Selected.'List Price'`
- The **Patch** function to create an **Order Details** record: `Patch( 'Order Details', Defaults( 'Order Details' ), ... )`
- The **Remove** function to delete an **Order Details** record: `Remove( 'Order Details', ThisItem )`

This series of topics has been a quick walkthrough of using Dataverse relationships and choices in a canvas app for educational purposes. Before you release any app to production, you should consider field validation, error handling, and many other factors.

Build global support into canvas apps

Article • 12/16/2022

Power Apps is a global product. You can build and use canvas apps in many different languages and regions.

Both while building and running apps, the text displayed by Power Apps has been translated into different kinds of languages. You'll see menu items, dialog boxes, ribbon tabs, and other text in your native language. Typing in and displaying dates and numbers is also adapted for your particular language and region. For example, some regions of the world use a **.** (dot or period) as the decimal separator while others use a **,** (comma).

The apps you create can be globally aware as well. Use the **Language**, **Text**, **Value**, **DateValue**, and other functions to adapt what is displayed and used as input in different languages.

Language settings

When using the native studio or a native player, the language used is provided by the host operating system. For Windows, this setting can be controlled under "All Settings" and then "Time & language" settings. Windows also allows you to specify the characters to use for the decimal separator, overriding the language setting.

When using the web experiences, the language used is provided by the browser. Most browser default to the host operating system's setting with some also providing a way to set the language manually.

Authoring environment

The authoring environment adapts to the language setting of the author. The app itself is stored in a language agnostic manner, so that authors using different languages can edit the same app.

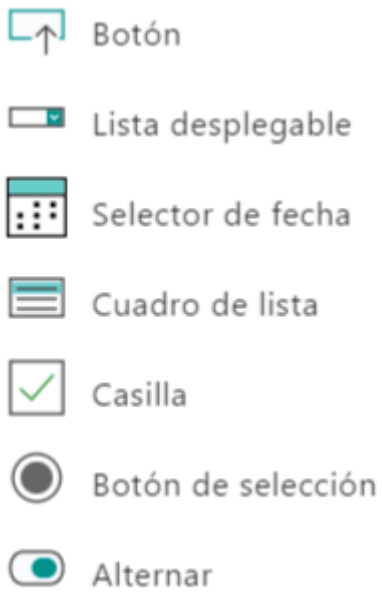
Names in formulas

Most elements in formula are always in English:

- Function names: **If**, **Navigate**, **Collect**, and so on.
- Control property names: **Screen.Fill**, **Button.OnSelect**, **Textbox.Font**, and so on.

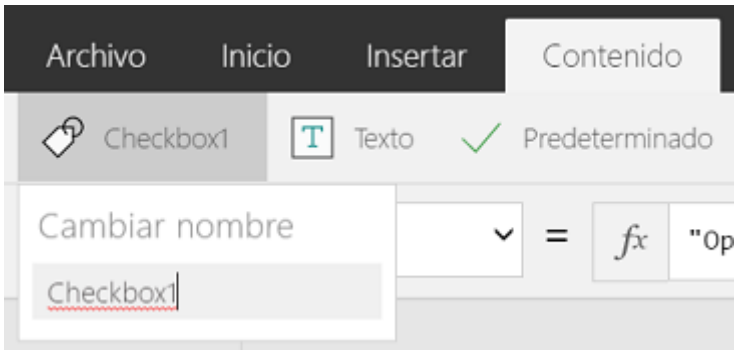
- Enumeration names: **Color.Aqua**, **DataSourceInfo.MaxValue**, **FontWeight.Bold**, and so on.
- Signal records: **Compass.Heading**, **Location. Latitude**, **App.ActiveScreen**, and so on.
- Operators: **Parent**, **in**, **exactIn**, and so on.

As the authoring experience is localized, control and other object names will appear in the native language of the author. In Spanish, some of the control names appear as:



When you insert one of these controls into your app, their name will default to English. This change is done for consistency with the control property names and the rest of the formula. For example, **Casilla** listed above is inserted as **Checkbox1**.

After a control is inserted, you can change the name to whatever you like. While selected, the far left-hand side of the "Content" ribbon displays the name of the control. Selecting this name drops down a text box where you can edit the name:



If you like, here you can rename the control to **Casilla1**. The red squiggly, in this case displayed by a browser, is because the name isn't a Spanish word and is of no concern.

You can use whatever names you like for:

- Control names
- Collection names
- Context variable names

Formula separators and chaining operator

Some separators and operators will shift based on the decimal separator of the author's language:

Expand table

Author's language decimal separator	Power Apps decimal separator	Power Apps list separator	Power Apps chaining operator
. (dot or period)	. (dot or period)	, (comma)	; (semi-colon)
, (comma)	, (comma)	; (semi-colon)	;; (double semi-colon)

The change in the Power Apps list separator is consistent with what happens to the Excel list separator. It impacts:

- Arguments in function calls.
- Fields in a record.
- Records in a table.

For example, consider the following formula expressed in a language and region that uses dot or period as the decimal separator, such as Japan or the United Kingdom:

```
If( Slider1.Value > 12.59,
      Notify( "Valid!", Success ); Navigate( "NextScreen", None ),
      Notify( "Invalid, try again", Error )
)
```

Now view this same formula in a language and region where a comma is used for the decimal separator, such as France or Spain:

```
If( Slider1.Value > 12,59;
      Notify( "Valid!"; Success );; Navigate( "NextScreen"; None );
      Notify( "Invalid, try again"; Error )
)
```

The highlight shows the operators that change between the two versions. The property selection operator . (dot or period) in **Slider1.Value** is always the same, no matter what the decimal separator is.

Internally the formula doesn't change, all that changes is how it's displayed and edited by the author. Two different authors using two different languages can view and edit the same formula, with each seeing the appropriate separators and operators for their language.

Creating a global app

The app you create can adapt to different languages, providing a great user experience for your users around the world.

Language function

The **Language** function returns the language tag of the current user. For example, this function returns **"en-GB"** for users in Great Britain and **"de-DE"** for users in Germany.

Among other things, you can use **Language** to display translated text for your users. Your app can include a table of translated values in your app:

TextID	LanguageTag	LocalizedText
"Hello"	"it"	"Ciao"
"Hello"	"fr"	"Salut"
"Hello"	*blank*	"Hello"
"Goodbye"	"it"	"Arrivederci"
"Goodbye"	"fr"	"Au revoir"
"Goodbye"	*blank*	"Goodbye"

And then use a formula such as the following to pull translated strings from the table:

Power Fx

```
LookUp( Table1, TextID = "Hello" && (LanguageTag = Left( Language(), 2 ) ||
IsBlank( LanguageTag ))).LocalizedText
```

Translated strings in other languages could be longer than they are in your language. In many cases, the labels and other elements that display the strings in your user interface will need to be wider to accommodate.

For more information, see the documentation for the **Language** function.

Formatting numbers, dates, and times

Numbers, dates, and times are written in different formats in different parts of the world. The meaning of commas, decimals, and the order of month, date, and year vary from location to location.

The Text function formats numbers and dates using the language setting of the user.

Text requires a format string to know how you want to format the number or date. This format string can take one of two forms:

- **A global aware enumeration.** For example, **Text(Now(), DateTimeFormat.LongDate)**. This formula will format the current date in a language appropriate format. This method is the preferred way to specify the format string.
- **A custom format string.** For example, **Text(Now(), "[$-en-US]dddd, mmmm dd, yyyy")** displays the same text as the enumeration when used in the language "en-US". The advantage of the custom format string is that you can specify exactly what you want.

The "[$-en-US]" on the front of the custom format string tells **Text** in which language to interpret the custom format string. This string is inserted for you and defaults to your authoring language. Normally you won't need to change this string. It's useful when authors from different languages are editing the same app.

The third argument to **Text** specifies which language to use for the result of the function. The default is the language setting of the current user.

For more information, see the documentation for the Text function.

Reading numbers, dates, and times

There are four functions for reading numbers, dates, and times provided by the user:

- Value: Converts a number in a text string to a number value.
- DateValue: Converts a date value in a text string to a date/time value. Anytime specified in the text string is ignored.
- TimeValue: Converts a time value in a text string to a date/time value. Any date specified in the text string is ignored.
- DateTimeValue: Converts a date and time value in a text string to a date/time value.

If you have used Excel, all of these functions are combined in the single **Value** function. They're broken out here since Power Apps has separate types for date/time values and numbers.

All of these functions have the same arguments:

- *String, required*: A string from the user. For example, a string types into a **Text input** control and read from the control with the **Text** property.
- *Language, optional*: The language in which to interpret the *String*. By default, the language setting of the user.

For example:

- **Value("12,345.678", "en-US")** or **Value("12,345.678")** when located where "en-US" is the user's language returns the number **12345.678**, ready for calculations.
- **DateValue("1/2/01", "es-ES")** or **DateValue("1/2/01")** when located where "es-ES" is the user's language returns the date/time value **February 1, 2001 at midnight**.
- **TimeValue("11:43:02", "fr-FR")** or **TimeValue("11:43:02")** when located where "fr-FR" is the user's language returns the date/time value **January 1, 1970 at 11:43:02**.
- **DateTimeValue("11:43:02 1/2/01", "de-DE")** or **DateTimeValue("11:43:02 1/2/01")** when located where "de-DE" is the user's language returns the date/time value **February 1, 2001 at 11:43:02**.

For more information, see the documentation for the **Value** and **DateValue, TimeValue, and DateTimeValue** functions and working with dates and times.

Calendar and Clock information

The **Calendar** and **Clock** functions provide calendar and clock information for the user's current language.

Among other things, use these functions to provide a **Dropdown** control with a list of choices.

For more information, see the documentation for the **Calendar** and **Clock** functions.

Build a multi-language app

Article • 03/03/2023

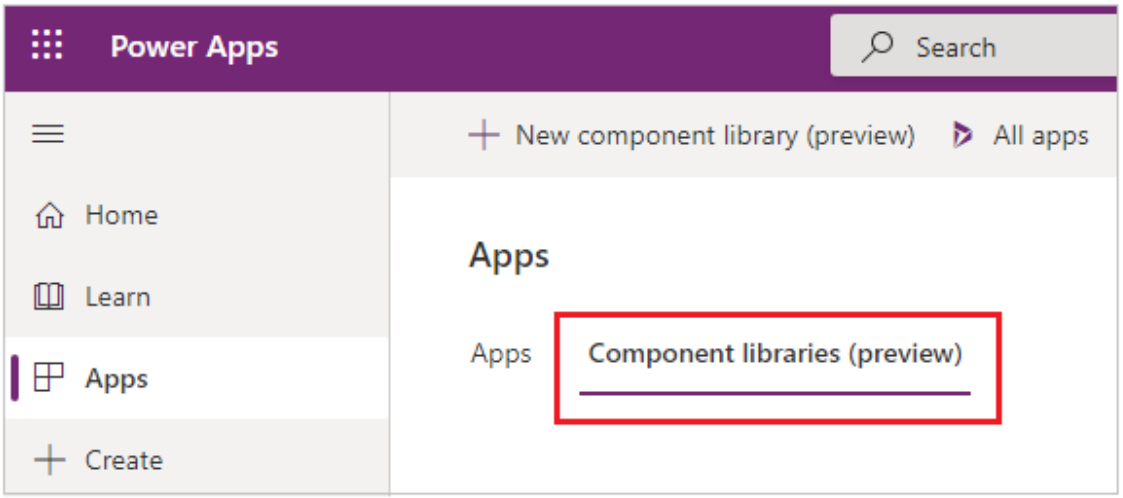
In this article, you'll learn how to create a multi-language app with localized experience. With this method, you can use canvas app components and make translations available in an app using a uniform formula syntax.

> **Important**
>
> The method described in this article use components for canvas apps which is in public preview. For more information, see Create a component for canvas apps

Create a translation component

When working with a multi-language app, the first step is to create a reusable component for translation. In this component, you'll store a table that acts as the dictionary of all translations you'll need. An output property will be used to provide output strings from this dictionary table based on the language of the user running the app that uses this component.

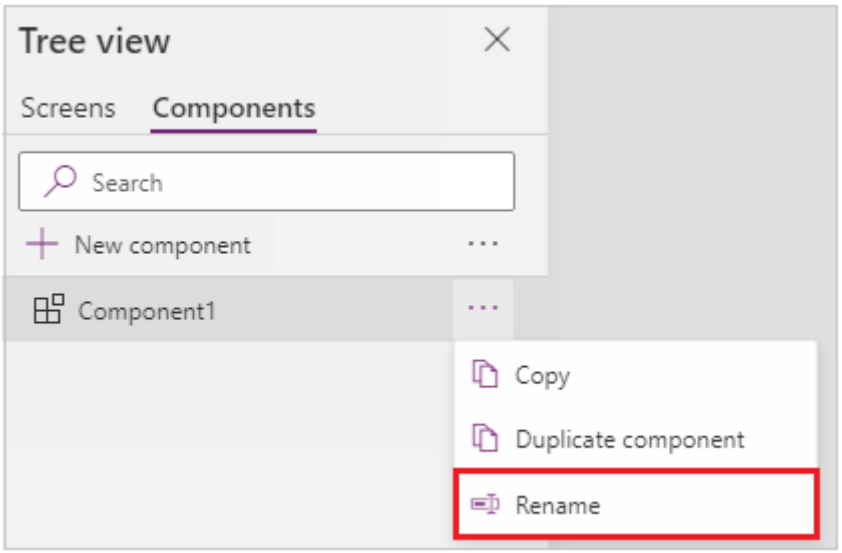
1. Sign in to Power Apps.
2. On the left pane, select **Apps**.
3. Under **Apps**, select **Component libraries (preview)**.



4. Select + **New component library (preview)**.

5. Enter a name, such as "Translation components", and select **Create** to open the component in Power Apps Studio.

6. Rename "Component1" by selecting **...** on the left pane, and then select **Rename** as "Translation component".



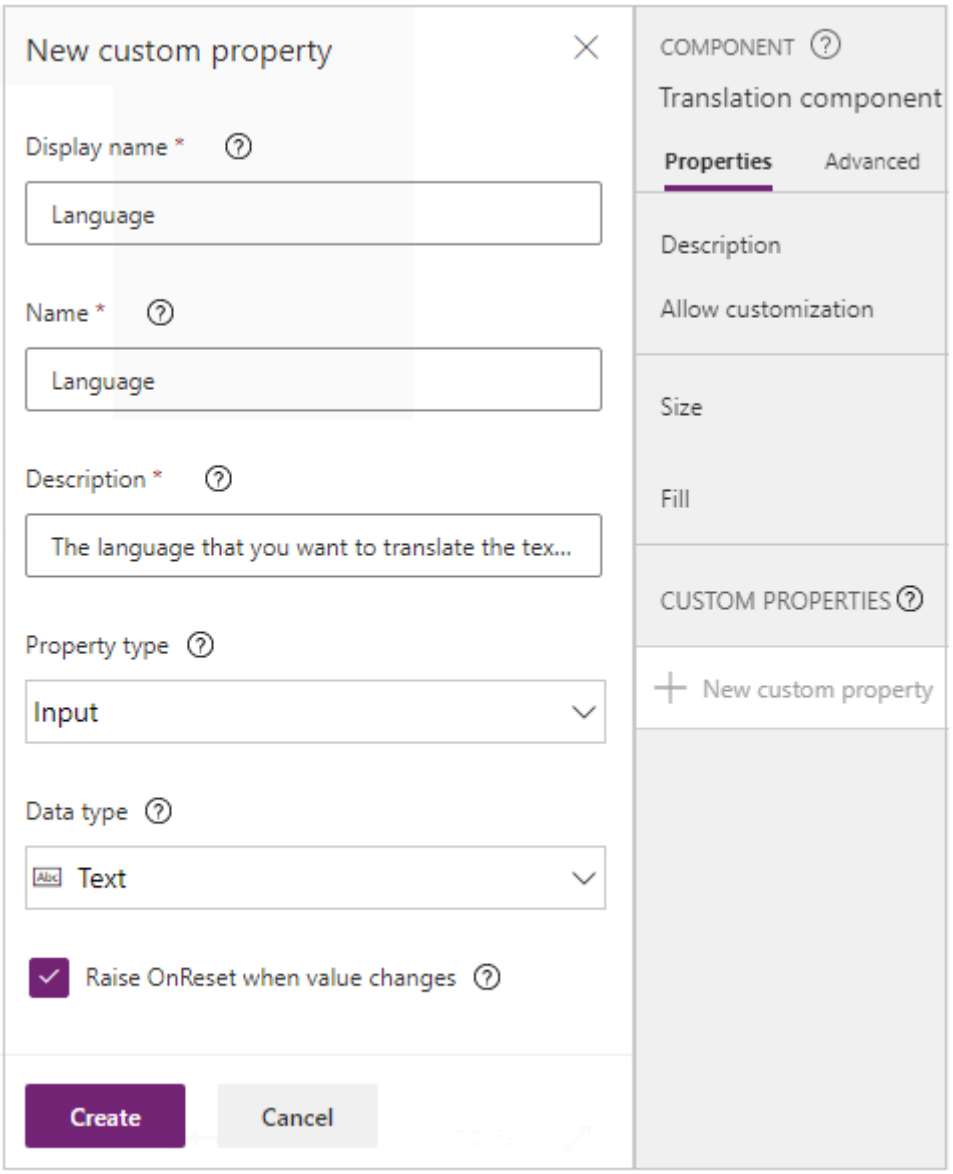
7. From the property pane on the right-side of the screen, select **+ New custom property**.

8. Set the following property values:

Expand table

Property name	Value
Display name	Language
Name	Language
Description	The language that you want to translate the text to.
Property type	Input
Data type	Text

9. Select **Raise OnReset when value changes** checkbox.



10. Select **Create**.

> **Note**
>
> This input property will receive the current locale ID (LCID) of the logged-in user.

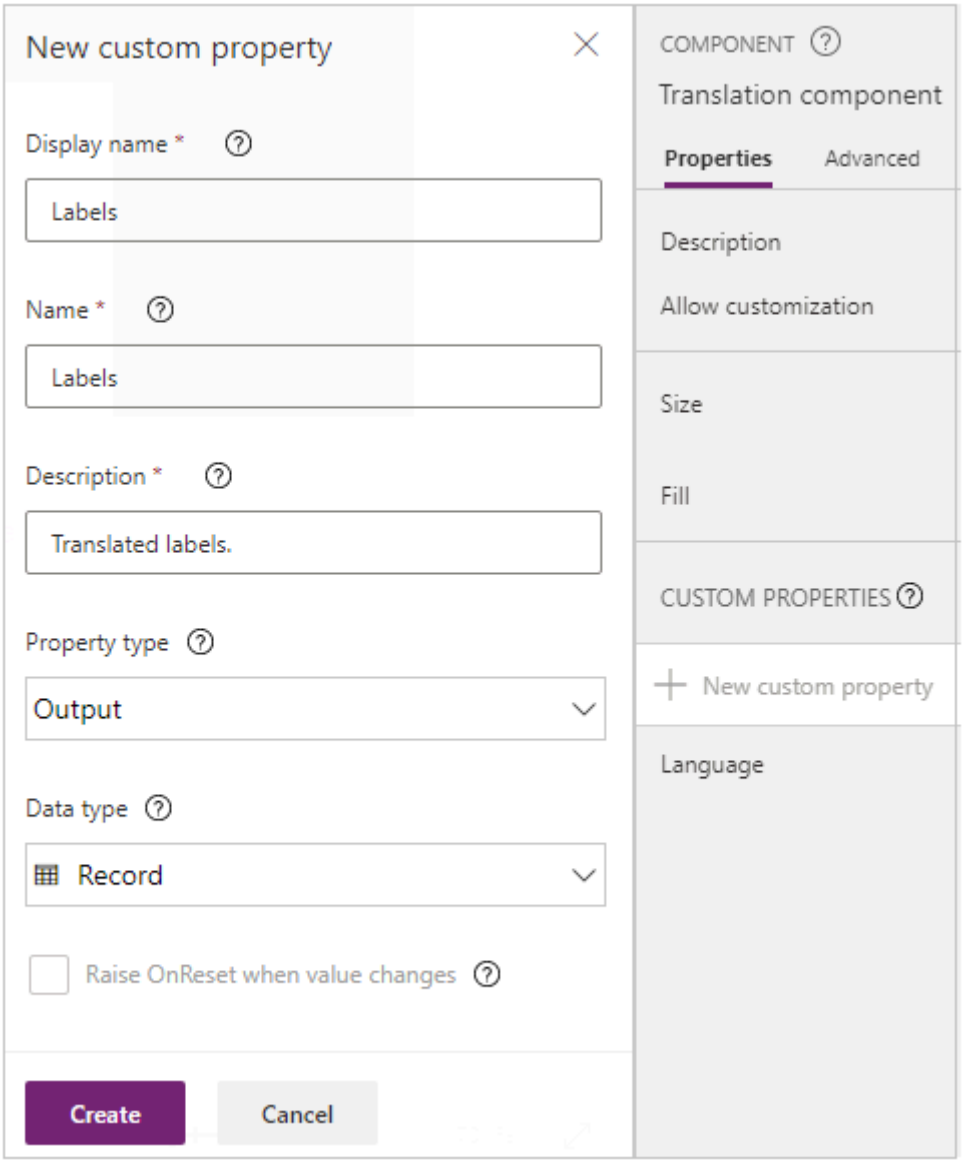
11. From the property pane on the right-side of the screen, select **+ New custom property**.

12. Set the following property values:

Expand table

Property name	Value
Display name	Labels

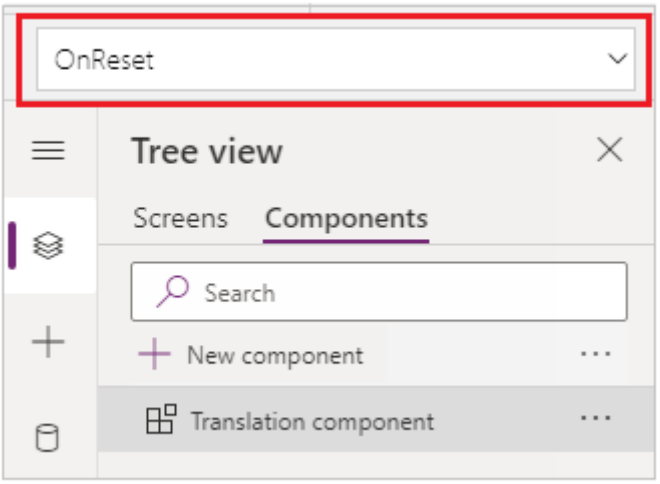
Property name	Value
Name	Labels
Description	Translated labels.
Property type	Output
Data type	Record



13. Select **Create**.

> **Note**
>
> This output property exposes the translated labels based on the input locale ID.

14. On the upper-left side of the screen, select the property list drop-down and choose **OnReset** property for the component.



15. Copy and paste the following formula in the formula bar for the **OnReset** property.

```
Power Fx

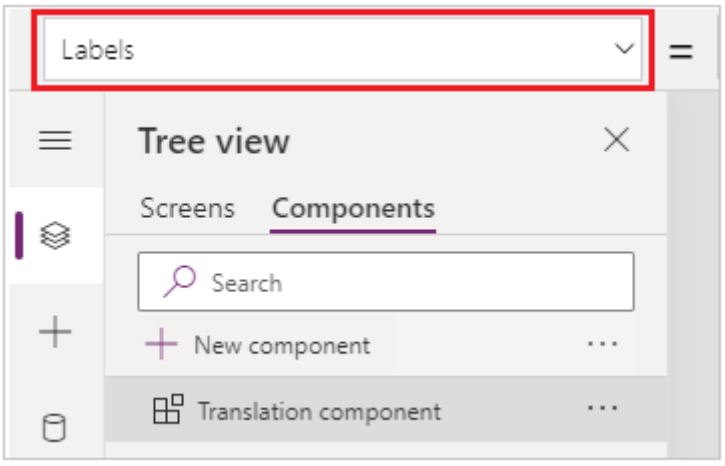
Set(
 varTranslations,
 Table(
        {
            Language: "en-us",
            Labels: {
                Title: "UI Tips for building canvas apps",
                JobTitle: "Power Platform Specialist"
            }
        },
        {
            Language: "pt-br",
            Labels: {
                Title: "Dicas de UI para construir canvas apps",
                JobTitle: "Especialista de Power Platform"
            }
        }
    )
   )
```

The formula uses Set() function to create a table with the labels in different languages as a dictionary. To customize this table as the dictionary for your translations, change the control names such as *Title*, *JobTitle*, *Platform*, *Close*, *Open*, *Cancel*, and so on. You can add, or remove translations for control names depending on your business requirement.

The table should also have an entry for each language that your app supports. Each entry will have a **Labels** property that will contain the translated content of all

possible buttons, inputs, and labels in your app.

16. On the upper-left side of the screen, select the property list drop-down and choose **Labels** property for the component.



17. Copy and paste the following formula in the formula bar for the **Labels** property.

```
Power Fx
```

```
LookUp(
 varTranslations,
 Language = Lower(
     Coalesce(
         Self.Language,
         Language()
     )
 )).Labels
```

The formula finds the right translation entry based on the input **Language** using the Lookup() function. In case where the language isn't set, the formula uses the current user's language as the filter through Coalesce function.

18. Select **File** -> **Save** to save the component library.

19. Select **Publish** to publish the component library.

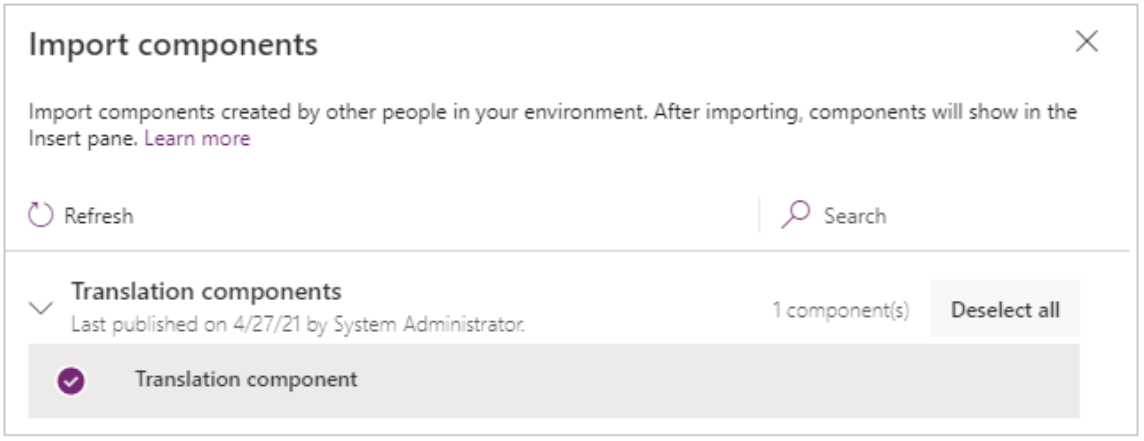
> **Tip**
>
> To learn more about creating, saving, and publishing component library, go to Create an example component library

Your translation component library is created, saved, and published for use.

Use the translation component in your app

Previously, you created the translation component library for reuse. In this section, you'll create an app that uses the translation component library and demonstrate the language translation based on the selected language.

1. Start by creating a blank canvas app with **Phone** layout.
2. On the left-side of the screen, select + (Insert).
3. On the bottom-left side of the screen, select **Get more components**.
4. Select **Translation component**.



> **Note**
>
> The name might be different if you saved the component library created earlier with a different name.

5. Select **Import**.
6. On the left-side of the screen, select + (Insert).
7. Under **Library components**, select **Translation component** to add the component to this app.
8. On the left-side of the screen, select the tree view.
9. Select the translation component.
10. On the upper-left side of the screen, select the property list drop-down and choose **Visible** property for the component.

11. Set the value of the **Visible** property to **false** to make the component invisible on the app.

12. Under **Input** in the list of controls, select **Toggle**.

13. On the upper-left side of the screen, select the property list drop-down and choose **OnChange** property for the component.

14. Update the formula for the **OnCheck** property of the toggle control to the following.

    ```
    Power Fx

        Set(varLanguage,"pt-br")
    ```

    In this formula, the toggle sets a variable called **varLanguage** with the value of "pt-br" using the function Set(), for Portuguese (BR) language code.

15. Update the formula for the **OnUncheck** property of the toggle control to the following.

    ```
    Power Fx

        Set(varLanguage,"en-us")
    ```

    In this formula, the toggle sets a variable called **varLanguage** with the value of "en-us" using the function Set(), for English (US) language code.

16. On the left-side of the screen, select the translation component.

17. On the upper-left side of the screen, select the property list drop-down and choose **Language** property for the component.

18. Set the formula value for **Language** property to `varLanguage`. The variable **varLanguage** is determined by the toggle configured earlier. When the toggle is checked, the language is set to "pt-br". When unchecked, the language is set to "en-us".

19. On the left-side of the screen, select + (Insert).

20. Select **Text label**.

21. Update the label control name to **Title** from the right-side of the screen using the property pane.

22. Select **Text label** again to add one more label.

23. Update the label control name to **JobTitle**.

24. Set the **Title**, and **JobTitle** labels below the toggle control so that both labels are visible.

25. Set the **Text** property for **Title**, and **JobTitle** labels from the upper-left side of the screen to the following.

Expand table

Label	Formula
Title	`'Translation component_1'.Labels.Title`
JobTitle	`'Translation component_1'.Labels.JobTitle`

> **Note**
>
> Replace **'Translation component_1'** in this formula to the name of the component in your app, if different.

Similarly, you can use different labels, and properties, as defined in the component that you created earlier to pass more property values. For example, in addition to *Title*, and *JobTitle*, you can create more properties such as *Description*, or *Instructions* in the component library with the translated text. And then, use such properties on the respective labels, as *'Translation component_1'.Labels.Description*, or *'Translation component_1'.Labels.Instructions*.

26. Select **File** -> **Save**, update the name for your app, and then select **Save** to save your app. More information: Save and publish an app

Test your app with language translation

Now your app is using the translation component. Go to Power Apps and select the app to run.

When the toggle is selected, the language is changed to Portuguese (BR) for the labels. When unchecked, the language is set back to English (US).

With this approach, you can now create your own component having the translations dictionary that fits your business requirement. And then, create more canvas apps that use the component that gives the business users the ability to use different languages.

Create accessible canvas apps

Article • 12/16/2022

An accessible canvas app will allow users with vision, hearing, and other impairments to successfully use the app. In addition to being a requirement for many governments and organizations, following the below guidelines increases usability for all users, regardless of their abilities.

Use the **Accessibility Checker** to help review potential accessibility issues in your app.

Layout and color

Common sense and uncomplicated design helps apps be more accessible to all users. When doing heavy customization of apps take note of the below suggestions. Power Apps themes are designed to meet accessibility standards.

- Ensure all elements are clearly visible and text is of sufficient size. All content must be easily read and understood by the naked eye.
- Ensure input elements are labeled on the screen. **AccessibleLabel** property defines what the screen reader will announce.
- If customizing colors, ensure the contrast ratio of text to background is 4.5:1 or greater. Software tools that assist this process are readily available.
- Ensure layout follows a logical flow when read from top to bottom, left to right.
- Create a responsive app so that low-vision users can zoom in and use it without scrolling back and forth.

Keyboard

When testing your app's accessibility, ensure the app can be used by keyboard only, with or without a screen reader.

The **Tab** key should navigate to interactive elements in a logical order. You can create this with a logical app structure and by setting each control's **TabIndex** property accordingly.

- Label, Image, Icon, Shape controls: Set **TabIndex** to 0 if they are meant to be interactive. Otherwise, set **TabIndex** to -1.
- Do not set **TabIndex** greater than zero.
- Ensure that the **Simplified tab index** app setting is enabled.

Screen readers

The following screen readers have been verified to work with Power Apps:

- **JAWS**: Microsoft Edge
- **Narrator**: Microsoft Edge
- **NVDA**: Google Chrome, Firefox
- **TalkBack**: Google Chrome, Power Apps mobile
- **VoiceOver**: Power Apps mobile, Safari (macOS, iOS, iPadOS)

To ensure a satisfying experience with the screen reader it is recommended to:

- Ensure all input controls have the **AccessibleLabel** property set.
- For images, set **AccessibleLabel** to an appropriate description.
  - If a picture is not used as a button or a link (i.e. icon is there just for the decoration) and should not be read by the screen reader, make sure the **AccessibleLabel** is empty or not set.
  - If a picture or an icon is used as a button, then set **TabIndex** to 0 and **AccessibleLabel** to the link description.

Control type and structure

Using the right controls and grouping them will help screen reader users understand the structure of the app.

- Include at least one heading on each screen of the app. You can create headings by setting the **Role** property of a **Label**.
- Use a **Button** instead of a **Label** for interactive text.
- Group related content in **Containers**.
- Be aware of unsupported design patterns.

Multimedia

Ensure all videos are captioned and a transcript of all audio recordings is available to the user. **Video** control supports closed captions in WebVTT format via the **ClosedCaptionsUrl** property.

With the screen reader enabled, **Timer** does not announce button text, but how much time has passed. Announcements can't be turned off, even if timer is hidden with low opacity.

Working with signatures

If you have a signature field that uses the PenInput control, you need to enable an alternative method of signature input. The recommended way is to show a TextInput control where a user can type their name. Ensure the signing instructions are placed in the **AccessibleLabel** property and the control is placed close to the Pen input - to the right or immediately below.

Organize controls in accessible canvas apps

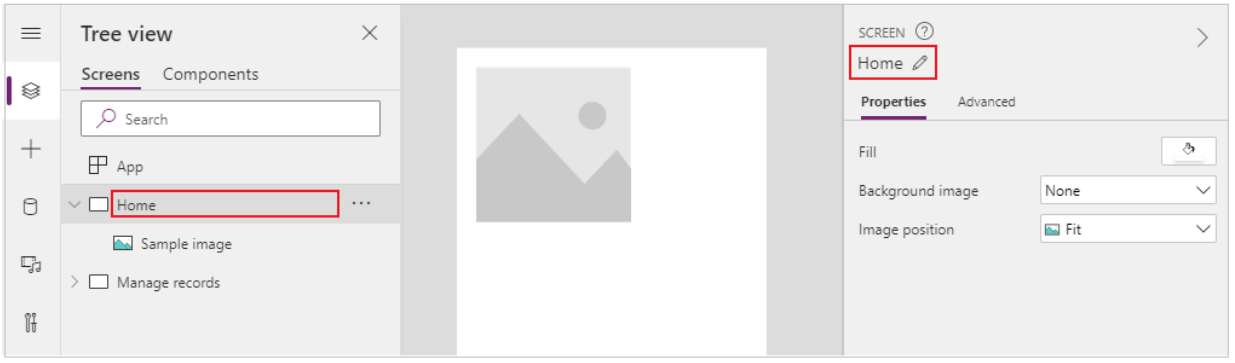
Article • 07/13/2024

Controls in an app should be organized to help screen reader users navigate sequentially. A logical order also reduces confusion for keyboard users and helps them be more productive.

Meaningful screen name

When a screen is loaded, screen readers will say its name. Pick a meaningful name to orientate users.

You can change the screen name in the controls tree or properties panel in Power Apps Studio. Select the screen, and then select to rename the screen.



The first element on a screen is its name. It's visually hidden and accessible only to screen reader users.

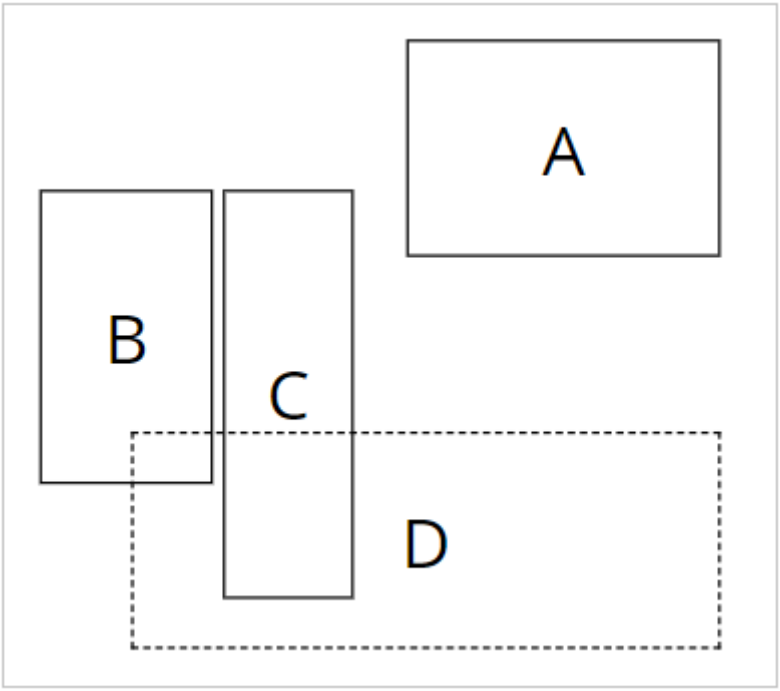
When a new screen loads, Power Apps focuses the screen name. If you use **SetFocus** immediately when the screen loads, the screen name won't be read. Consider creating a visible title and making it a live region to announce the change in context.

Logical control order

Screen reader users can navigate content sequentially. The order is determined by the position of controls, starting from top to bottom, then left to right. The size of the control doesn't matter, only its **X** and **Y** properties matter.

In this example, A appears first in the sequence since it's closest to the top. B and C have the same vertical position, but since B is closer to the left, and hence, it appears before

C. D appears last since it's furthest from the top.

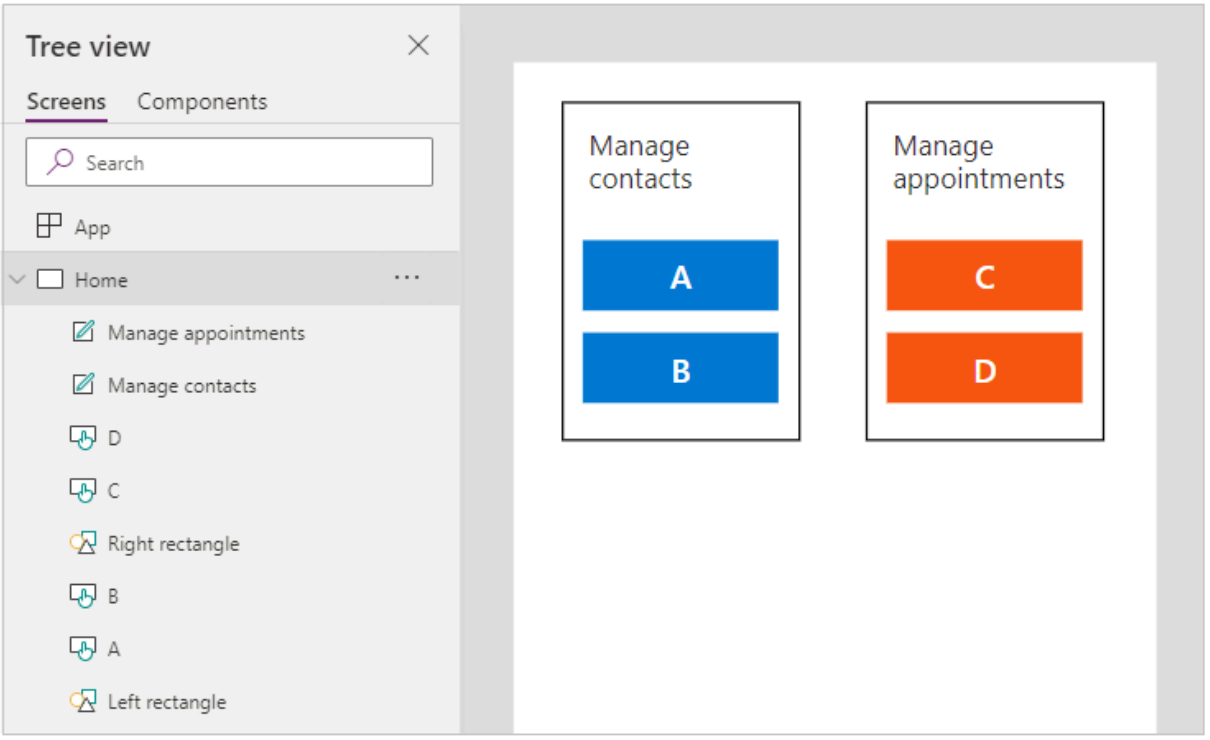


ⓘ Note

- In **Preview** mode when editing an app, the control order is not updated for performance reasons. The order will be correct when the app is published and run.
- Control order is not the same as that shown in the tree view of controls in Power Apps Studio. The tree view sorts controls according to when they were added to the app. It does not affect the order of controls when the app is run.
- When a control's **X** or **Y** value is set to an expression, the control order is not updated when the result of the expression changes. The order is computed and fixed when the app is saved, using the initial state of the app to evaluate expressions.
  - If you're changing its position because other controls are being hidden or shown, you can use auto-layout containers to manage **X** and **Y** for you.
  - You can also position all controls in a logical way regardless of expression values. For example, if control A should always be below control B and B may be hidden sometimes, set A's **Y** to be `If(B.Visible, B.Y + B.Height, B.Y + 1)`. The addition of 1 ensures that A is always below B, even if B is hidden.

Grouped controls

The default order is suitable for isolated content but not for grouped content. Consider two tiles side by side, drawn with **Rectangle** controls. Each tile has a heading. Below the heading are two buttons stacked vertically: A and B for the first tile and C and D for the other.



The default order goes from top to bottom, then left to right. Hence, the order of controls is:

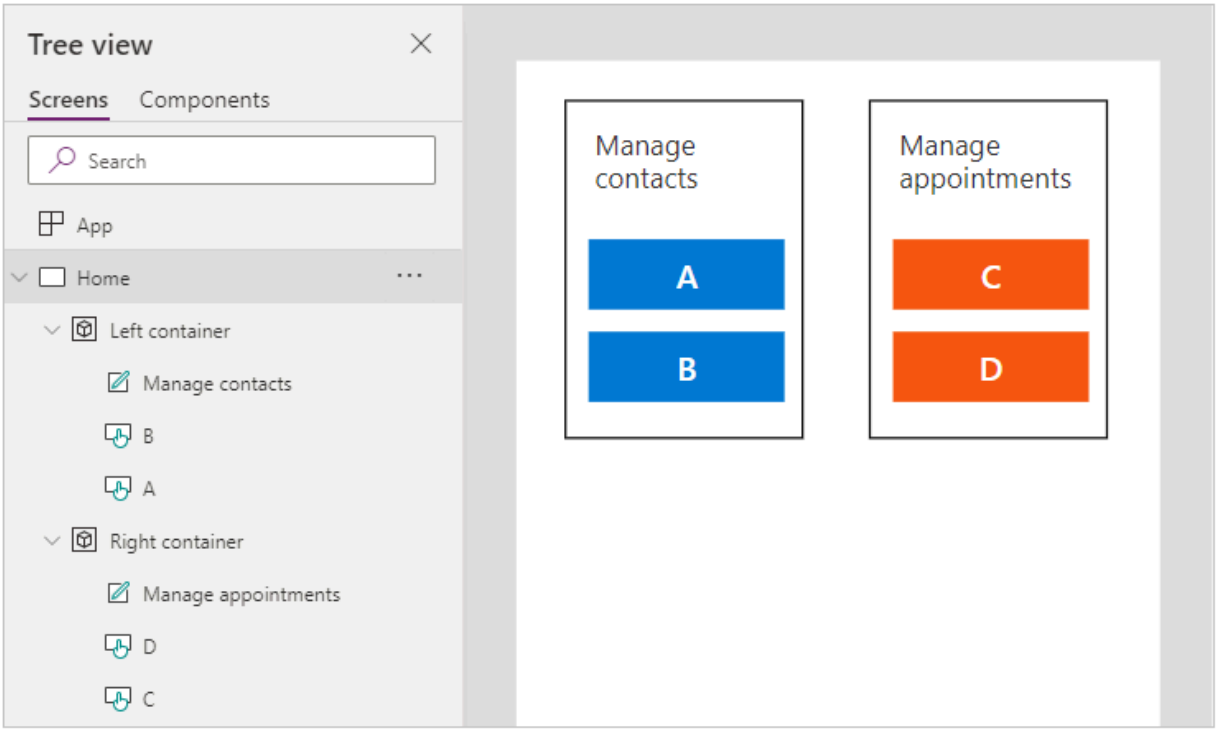
1. Left **Rectangle**
2. Right **Rectangle**
3. Left heading
4. Right heading
5. A
6. C
7. B
8. D

This structure doesn't convey that A and B are together, and similarly, C and D are together.

Use **Containers** to group related content. All controls in a **Container** will appear together in sequence. Within a container, controls are ordered with the same rule: top to bottom, then left to right.

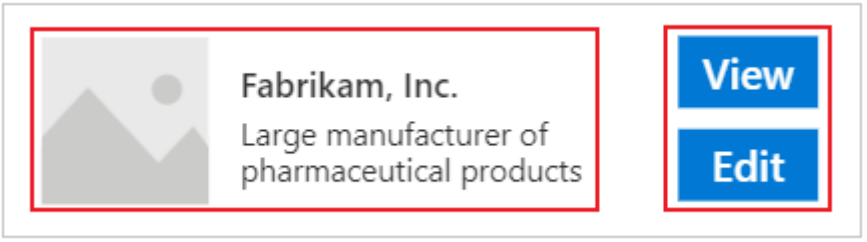
Replacing the **Rectangles** of the previous example with **Containers**, the control order is now logical for screen reader users:

1. Left **Container**
2. Left heading
3. A
4. B
5. Right **Container**
6. Right heading
7. C
8. D



All controls in a **Form Card** and **Gallery** are automatically grouped, so you don't have to use a **Container**. However, if there are subgroups, you should still use **Containers** for them.

In this example, a **Gallery** row has a thumbnail and two pieces of text on the left. On the right are two buttons. Visually and logically, the two sets of controls should be grouped. This ensures that screen reader users will encounter the left group first before the right.



Logical keyboard navigation order

Keyboard navigation is an important aspect of any app. For many, the keyboard is more efficient than using touch or a mouse. The navigation order should:

- Follow the visual flow of controls.
- Follow either an intuitive across and then down "Z" order or a down and then across "reverse-N" order.
- Only have a tab stop at controls that are interactive.

AcceptsFocus specifies whether controls can be reached by keyboard. For classic controls, the equivalent property is **TabIndex**.

Navigation order follows control order: from left-to-right, then top-to-bottom, in a "Z" pattern. You can customize it the same way as with control order. For example, controls in **Containers**, **Form Cards** and **Galleries** are automatically grouped. The Tab key will navigate through all elements inside the container before proceeding to the next control outside of the container.

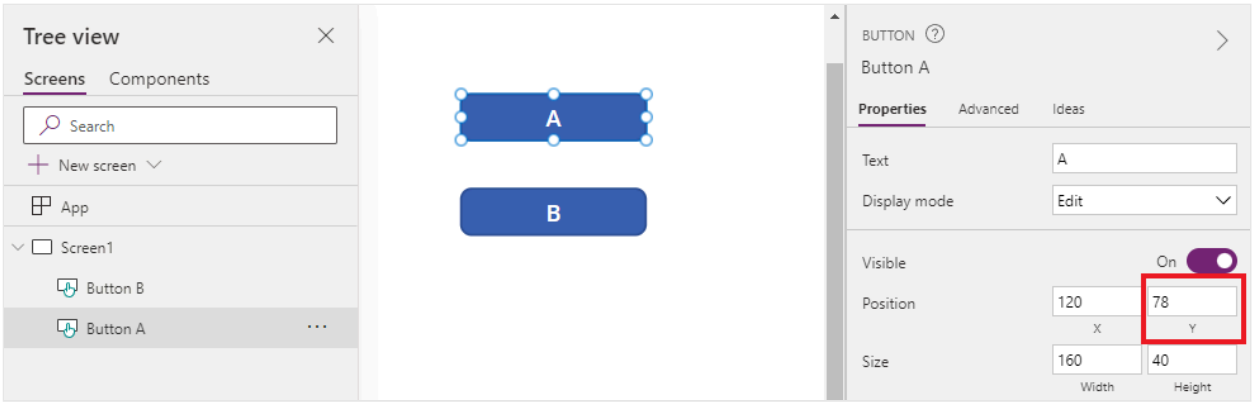
If the navigation order is unexpected, you should first check if the app structure is logical.

> ⓘ **Note**
>
> When controls are dynamically moved on the screen, for example, by having its **X** or **Y** value change according to a Power Fx expression, the navigation order will not be updated.

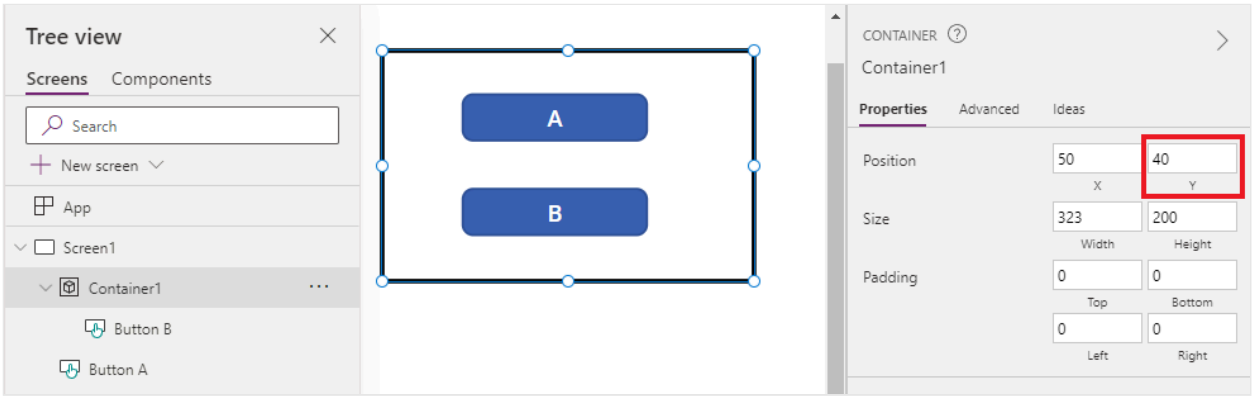
Workaround for custom tab sequence

For rare scenarios where the keyboard navigation order should be different from visual order, you can position container controls carefully to have the same effect.

In the example below, button A is above button B. The natural tab navigation order is A, then B.



To reverse the tab navigation order, put B in a Container control. Set the Y value of the Container to be above A. The app structure now has the Container (and B) before A. Hence, the tab navigation order is B, then A.



With this technique, screen reader users will also encounter B before A when navigating without the **Tab** key.

Custom tab indexes (retired feature)

Custom tab indexes are those that are greater than zero. They are no longer supported. All **TabIndex** values greater than zero will be treated as zero.

Custom tab indexes are almost always a sign of bad design. There are better alternatives like creating an appropriate app structure or using **SetFocus** to change focus.

Some problems with custom tab indexes:

Accessibility

It's a serious accessibility issue to have custom tab indexes. Screen reader users navigate an app using its logical structure. Custom tab indexes ignore that structure. Since screen reader users can also navigate using **Tab** key, they'll be confused when they get a different order from other methods of navigation.

Usability

Users can be confused when some items appear to be skipped. They can be disoriented when focus moves in an unpredictable order. This is even more problematic for users with cognitive disabilities.

Maintenance

App makers have to manually update the **TabIndex** of multiple controls whenever a new one is inserted. It's easy to miss an update or get the order wrong.

Performance

To support custom tab indexes, the Power Apps system has to examine all controls on the page and compute the appropriate order. This computation is an intensive process. Container controls like **Gallery** have complicated rules on how **TabIndex** works for child controls. The system maps the app maker's desired **TabIndex** to a different value to obey these rules. This is why even if TabIndex is set to zero for all controls, the actual HTML `tabindex` will be some positive number.

Integration with other components

Custom tab indexes only work with built-in controls. Controls that aren't integrated into Power Apps' tab index system will have an unexpected navigation order. This can be a problem for code components. Developers of these components have to keep track of interactive elements and set tab index on them. They might use third-party libraries, which may not even provide a way to customize tab indexes. On the other hand, when all tab indexes are either 0 or -1, there's no need to involve Power Apps' tab index system. Any third-party component embedded in the app will automatically get the correct tab sequence.

In the other direction, when canvas apps are embedded in another web page, custom tab indexes don't work. For example, in custom pages. Power Apps can't control the elements outside the canvas app, so the overall tab navigation order will be illogical.

Improved canvas keyboard navigation in canvas apps (experimental)

Article • 11/13/2024

[This article is pre-release documentation and is subject to change.]

Important

- This is an experimental feature, and will be deprecated soon. Instead of using this experimental feature, consider structuring an app appropriately to achieve the desired tab navigation order.
- Experimental features aren't meant for production use and may have restricted functionality. These features are available before an official release so that customers can get early access and provide feedback.

When you're nesting controls such as containers and component instances, the user input value for TabIndex isn't respected sometimes. **Improved canvas keyboard navigation** experimental setting improves the navigation experience in this situation when **Tab** key is pressed on the keyboard helping focus on the desired container or control precisely and predictably.

This feature also adds support for handling accessibility for keyboard tabs inline with rest of the controls in canvas apps. And addresses manual TabIndex assignments for all controls.

Note

This feature is added as "Experimental" to maintain backward compatibility and maintain existing app functionality.

When this feature is turned on, it also enables the following boolean properties for all child controls for the selected container or component instance in canvas apps:

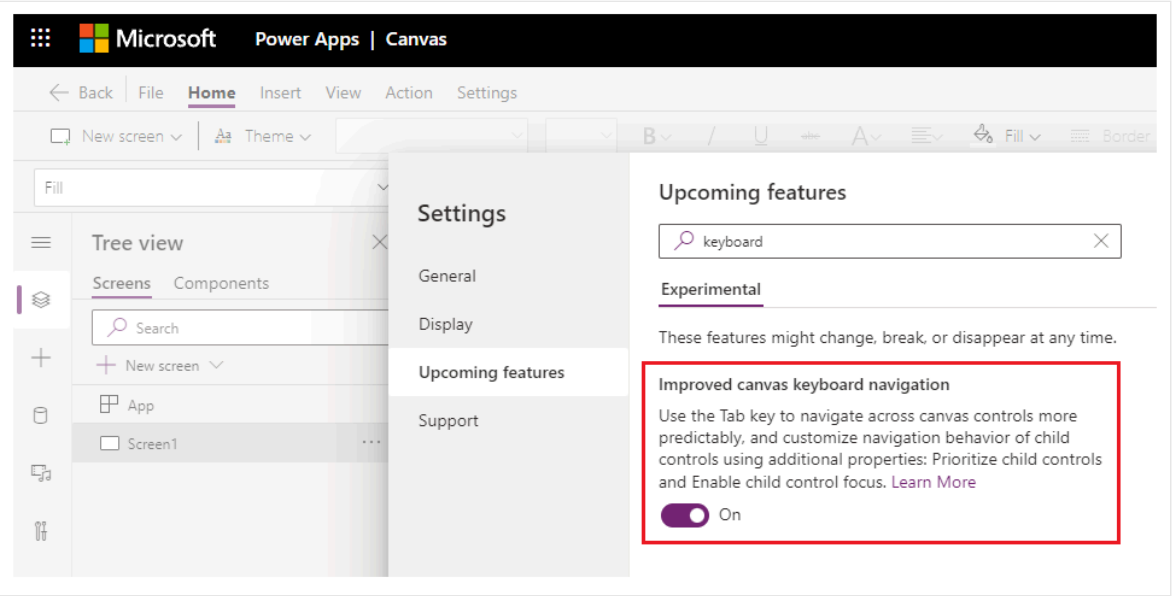
Expand table

Property Name	Description
Prioritize child controls	Determines the order of navigation (**Z-order**) for child controls on canvas when pressing tab key on the keyboard. • **On** (Default): Pressing the tab key on the keyboard will first progress through all child controls before moving the focus outside of the selected container or component instance. This option is recommended for similarly nested HTML elements. • **Off**: Pressing the tab key on the keyboard will progress through all controls only based on Z-order, ignoring parent-child relationship between controls or containers for keyboard navigation. **Note**: This property isn't applicable to responsive or autolayout containers.
Enable child control focus	Determines the value of TabIndex for child controls on canvas when pressing tab key on the keyboard. • **On** (Default): Pressing the tab key behaves as per TabIndex values defined on each control. • **Off**: Pressing the tab key doesn't move focus to any child control within the selected container or component instance. Sets the TabIndex value to **-1** for all child controls.

Configure improved canvas keyboard navigation in your app

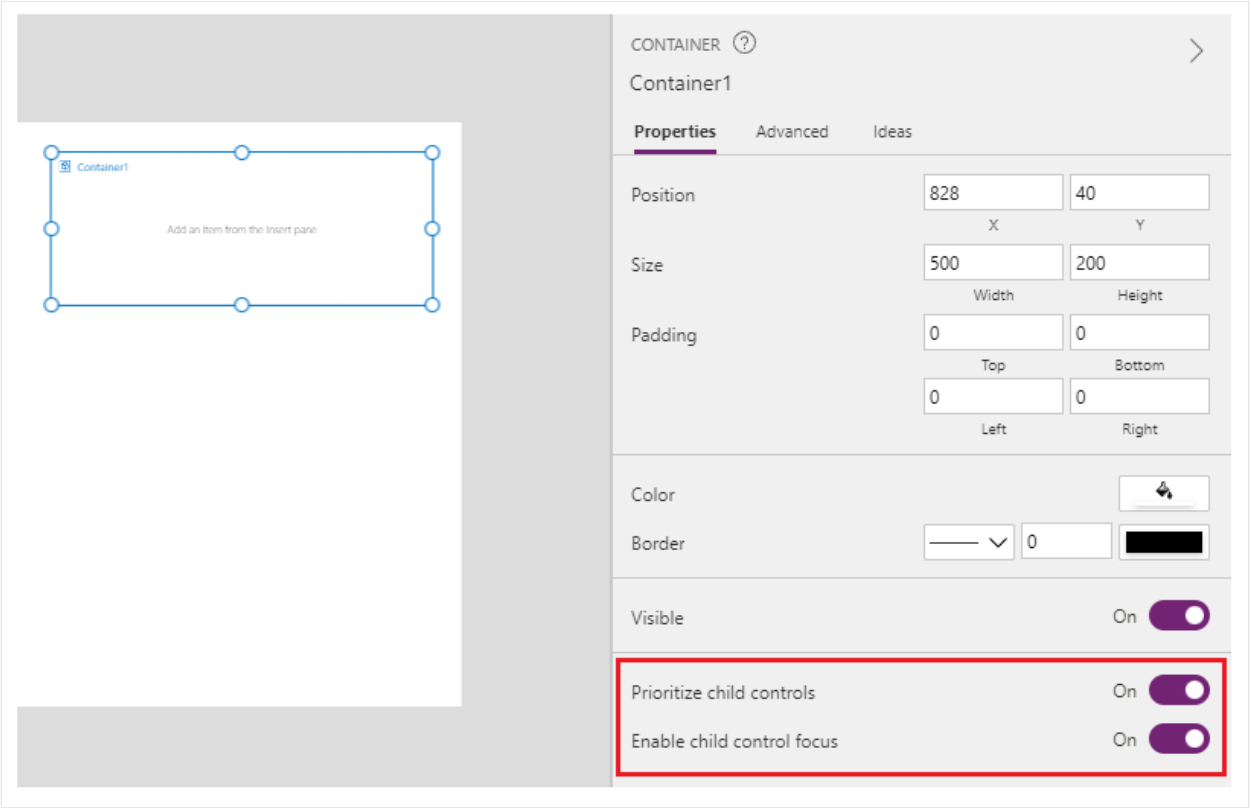
If not already enabled, follow these steps to enable this feature in your app, and set the properties mentioned earlier.

1. Sign in to Power Apps.
2. Select **Apps** from the left-pane.
3. Select your app, and then select **Edit**.
4. In Power Apps Studio, select **Settings** > **Upcoming features** > **Experimental**.
5. Select **Improved canvas keyboard navigation** to turn on the feature.



6. Close settings.

Now that you've enabled the experimental feature, you'll see two new properties for controls and containers—**Prioritize child controls**, and **Enable child control focus**. Change the property values as appropriate.



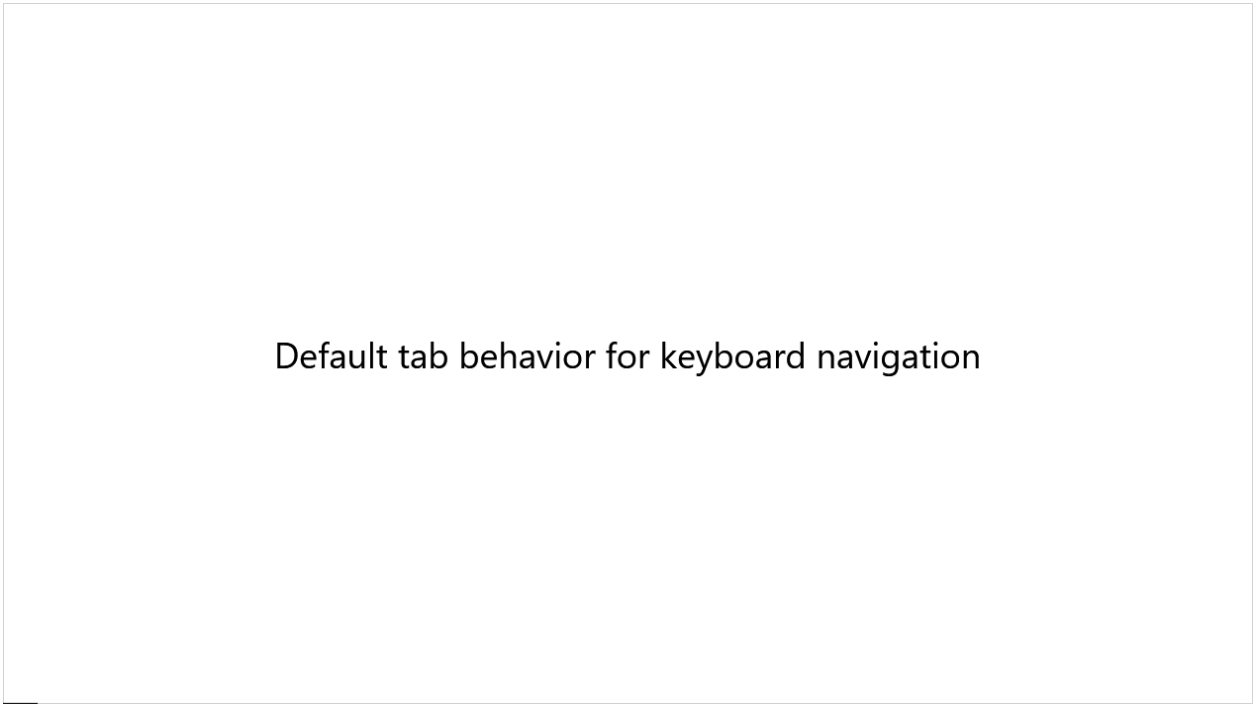
Examples

Now that you understand the new feature with improved canvas keyboard navigation, let's take a look at a few examples to understand the behavior when the tab key is pressed.

Default improved canvas keyboard navigation behavior

The following example shows multiple Text input controls, and several nesting scenarios. The number displayed in the input represents the value of the TabIndex property. There are two nested containers, and component controls overlaid on top of each other.

The default order is determined by the relative position of the controls. When focus enters a container or a component, tabs first traverse the children of the container before moving on to the next available control.



When Prioritize child controls is set to Off

In the following example, each container and component control has the **Prioritize child controls** property set to "Off". All inputs are therefore considered to be on the same level of nesting, so the order is determined purely by their X/Y position relative to the screen.

Advanced configuration with mixed settings

In the following example, the orange outlined containers have **Prioritize child controls** property set to "Off". All others controls have this property set to "On". Also, a custom TabIndex property has been set for some inputs, indicated by the number shown in each input.

Tab order first proceeds through the containers and controls with TabIndex value of greater than 0, and then proceeds through all others with value of 0. This behavior was also the in the earlier implementation.

Accessible colors for canvas apps

Article • 12/16/2022

Colors used in a canvas app should be accessible to color-blind and low-vision users. All Power Apps themes are accessible by default. When modifying colors used in an app, follow these guidelines to ensure that they remain accessible. There are several tools available online which can help you identify color contrast issues.

Minimum contrast for text

- Text and its background must have a contrast ratio of at least 4.5:1
- Large text must have a contrast ratio of at least 3:1
- Disabled text has no contrast requirements

In practical terms, all interactive controls must have adequate color contrast between:

- **Color** and **Fill**
- **PressedColor** and **PressedFill**
- **HoverColor** and **HoverFill**

Minimum contrast for non-text

- Non-text components, such as icons and borders, must have a contrast ratio of at least 3:1 with the colors outside of them.
- Disabled and decorative components have no contrast requirements.

User interface components

All interactive controls must have adequate color contrast between:

- **FocusedBorderColor** and color outside the control

Additional color contrast checks apply for controls where the entire area is interactive or informative. For example, a **Button** or an **Icon** used as a button. This ensures that the boundaries of the control are clear and users know where they can click or tap.

If there is a border for such controls, there should be adequate color contrast between:

- **BorderColor** and color outside the control
- **PressedBorderColor** and color outside the control
- **HoverBorderColor** and color outside the control

If there is no border, there should be adequate color contrast between:

- **Fill** and color outside the control
- **PressedFill** and color outside the control
- **HoverFill** and color outside the control

Graphical objects

If an image conveys important information, consider checking it for contrast issues. This applies to controls where an image can be shown: **Audio**, **Image**, **Microphone**, and **Video**.

For video content, consider checking it for contrast issues. Alternatively or additionally, provide closed captions that describe the video.

Provide other visual cues

Ensure that the app does not convey information with just color. For example, users with red-green color blindness will not be able to distinguish a red error message from a green success message.

Additional cues like an **Icon** or text styles like **Italic** and **Underline** can help convey meaning.

Show or hide content from assistive technologies for canvas apps

Article • 12/16/2022

In most cases, all users should be able to access all content, but you might occasionally want to show content only to sighted users or only to screen-reader users. For example, you might want only screen-reader users to access descriptions of chart trends that are obvious to sighted users. You might also want to hide an icon from screen-reader users if an adjacent label describes it. Another description on the icon would be unnecessarily verbose.

Hide content from all users

- Set **Visible** to false.

Hide content from sighted users and show it to screen-reader users

Use one or more techniques listed below:

- Set **Size** to 0.
- Set **Width** and **Height** to 1.
- Set **X**, **Y**, or both properties such that the control is outside the screen.
- Set **Color** and related properties to transparent.
- Position a rectangle **Shape** above the content, and set **Fill** to the same color as the background color of the screen.

> ⓘ **Note**
>
> Users can still use a keyboard to access an interactive control, such as a **Button**, even if you hide it by using one of the techniques in the previous list. Set **TabIndex** to -1 if you want to prevent users from accessing the control by pressing the Tab key.

Hide content from screen-reader users and show it to sighted users

- For **Image**, **Icon**, and **Shape** controls, set **AccessibleLabel** to the empty string "".

Announce dynamic changes with live regions for canvas apps

Article • 12/16/2022

Dynamic changes pose challenges to the visually-impaired. Users who access an app through a screen reader are focused on one part of the app. If a change happens elsewhere, those users won't be aware of it.

You can solve this problem by adding live regions, which screen readers track. If content changes in a live region, a screen reader will announce that change.

The underlying mechanism for live regions are aria-live regions, so the same guidelines apply.

Example uses of live regions

You can use live regions to notify users when events such as these occur:

- A validation error occurs in a form.
- An action triggered by a button is successful. For example, a user might select a button to add an item to a collection, and a live region could show the message "Item added".
- The user selected a different tab.
- A background timer refreshes a news feed.

Create and configure a live region

You can configure only a **Label** control as a live region. Its **Live** property determines what type of live region it is.

- **Off**: Not a live region. Screen readers don't announce changes.
- **Polite**: Screen readers announce changes after finishing speaking. Use this value for non-critical notifications that don't require immediate attention.
- **Assertive**: Screen readers interrupt themselves to announce changes immediately. Use this for critical notifications that require immediate attention.

If the text content of a live region changes, screen readers will announce the entire text content, not just the changed portion. If the value of the **Text** property is set to the empty string "", the screen reader doesn't announce anything.

To repeat a message, clear text contents by setting the value of the **Text** property to the empty string "" and then set the value to the message again.

Best practices

- Always set **Visible** to true. Some screen readers don't detect live regions that disappear and reappear.
- Avoid changing the value of **Live**. Some screen readers don't detect when a non-live region becomes live and vice-versa.
- Position the live region in a logical position in the app, even if it isn't visible. Ensure that its contents are sensible in context with the elements before and after it. Users can access a live region anytime through regular navigation with a screen reader, not just when changes happen.

Review a canvas app for accessibility in Power Apps

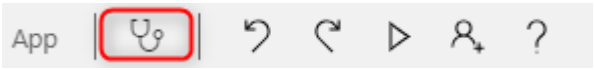
Article • 12/16/2022

Users who have vision, hearing, or other impairments can use your canvas app more easily and successfully if you consider accessibility as you design how the app looks and behaves. If you're not sure how to make your app more accessible, you can run the Accessibility checker in Power Apps Studio. This tool not only finds potential accessibility issues but also explains why each might be a potential problem for users who have a specific disability and offers suggestions on how to resolve each issue. The Accessibility checker detects screen-reader and keyboard issues for you, and you can find information about how to fix color-contrast issues by using accessible colors.

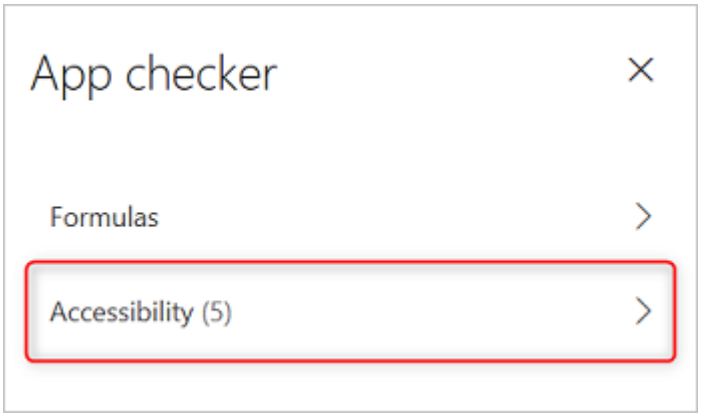
The Accessibility checker helps you identify settings that you might want to change, but you should always consider the suggestions in the context of what your app needs to do. Many suggestions may be worthwhile, but you can ignore any that might do more harm than good.

Find accessibility issues

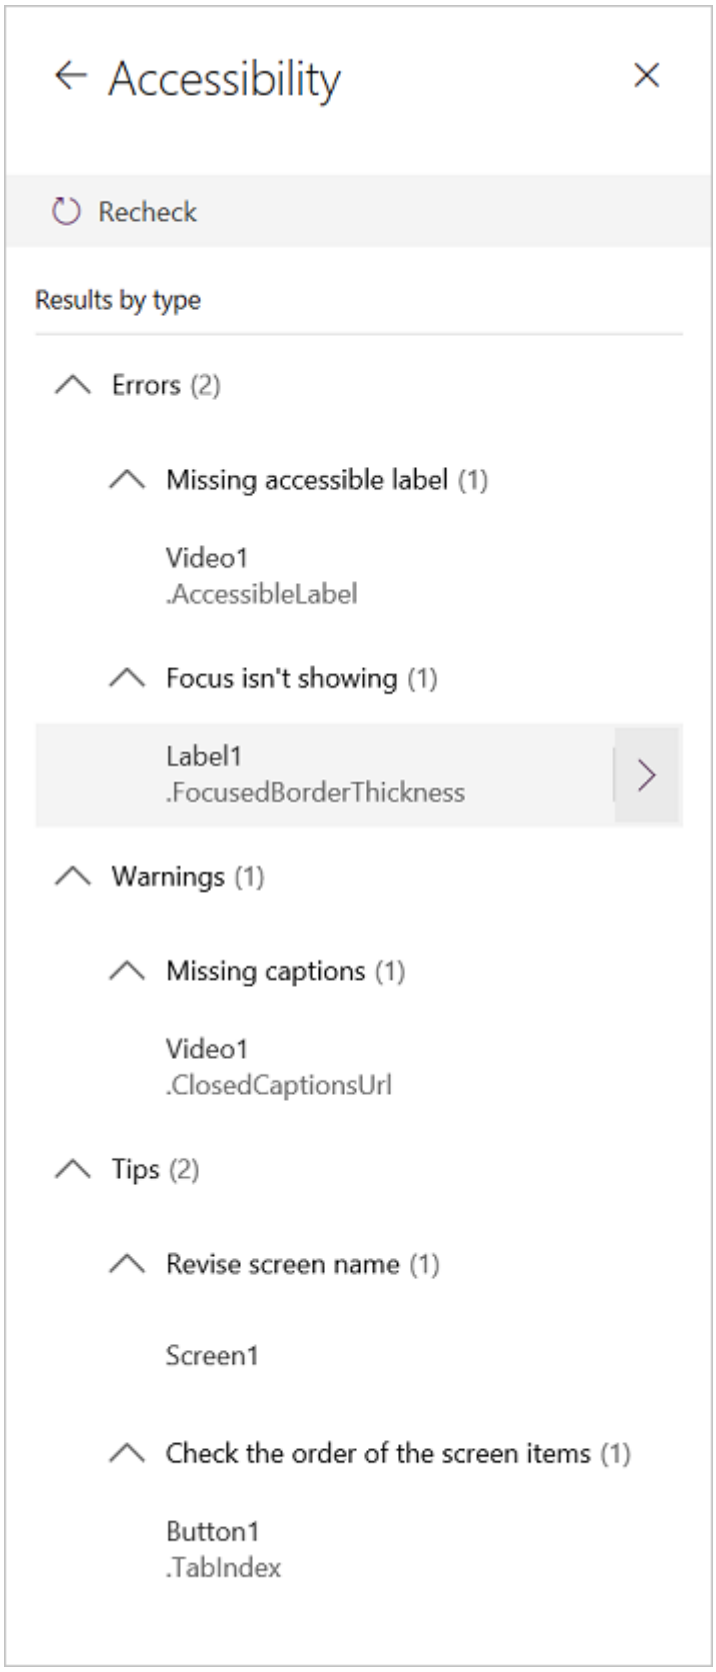
1. In the upper-right corner of Power Apps Studio, select the icon for the App checker.



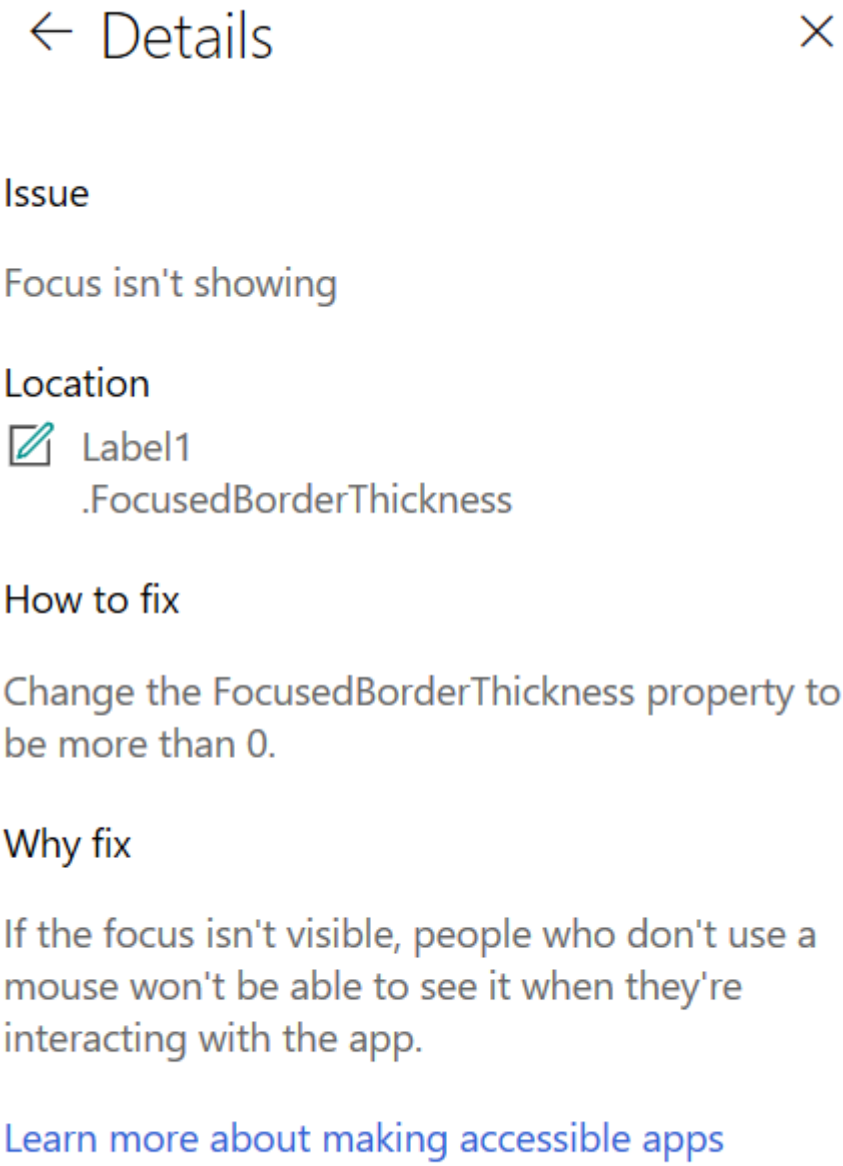
2. In the menu that appears, select **Accessibility**.



A list of issues appears, sorted first by severity and then by screen.



3. Select the arrow next to an item to show details about it.



4. Select the back arrow to return to the list of items.
5. If you decide to address an issue, select it to open the affected property.
6. After you change one or more properties, select **Re-check** to update the list of issues.

   Resolved items disappear from the list, and new items may appear.

Severity of issues

The Accessibility checker classifies each issue as an error, a warning, or a tip based the issue's severity.

- **Errors** identify issues that make the app difficult or impossible to use and understand for users who have a disability.
- **Warnings** identify issues that make the app difficult to use or understand for most but not all users who have a disability.
- **Tips** help you improve the experience of users who have a disability.

Types of issues

Issue Title	Severity	Issue Description	How to fix	Why fix
Missing accessible label	Error	When the accessible-label property of an interactive control contains no text. An interactive control can be inherently interactive, as a button is, or it has interactive properties. For example, you might have set the **OnSelect** property of an image or set its **TabIndex** property to 0 or higher.	Edit the accessible-label property to describe the item.	If the accessible-label property contains no text, people who can't see the screen won't understand what's in images and controls.
Focus isn't showing	Error	When the **FocusBorderThickness** of a control is set to 0. It is good practice to ensure a proper color-contrast ratio between the focus border and the control itself so it's clearly visible.	Change the **FocusedBorderThickness** property to a value that's higher than 0.	If the focus isn't visible, people who don't use a mouse can't see it when they interact with the app.
Missing captions	Warning	When the **ClosedCaptionsURL** property of an **Audio** or **Video** control is empty.	Set the **ClosedCaptionsURL** property to the URL for captions.	Without captions, people who have disabilities might not get any information from a video or audio segment.

Issue Title	Severity	Issue Description	How to fix	Why fix
Missing helpful control settings	Warning	When any of several settings (such as showing labels and markers for charts and showing default controls for **Audio**, **Video**, and **Pen input** controls) are turned off.	Select the warning, and then set the property to **true**.	By changing this property setting, you give the user better information about how the controls in your app function.
HTML won't be accessible	Warning	When a control other than an HTML text control contains HTML. In that case, Power Apps doesn't support accessibility of custom HTML elements.	Use a method other than HTML, or remove the HTML from this element.	Your app won't work correctly or be accessible if you add interactive HTML elements.
Turn off autostart	Warning	When an **Audio** or **Video** control's **Autostart** property is set to **true**.	Set the control's **Autostart** property to **false**.	Video and audio files that play automatically can distract users. Let them choose whether to play a clip.
Revise screen name	Tip	When a screen has a default name, which will be read out by screen readers when users navigate the app.	Give the screen a name that describes what's on the screen or what it's used for.	People who are blind, have low vision, or a reading disability rely on screen names to navigate using the screen reader.
Add State indication text	Tip	When a control that has a state, such as a toggle, but the value labels are turned off.	Set the **ShowValue** property of the control to **true** to show its current state.	Users won't get confirmation of their actions if the state of the control doesn't appear.

Issue Title	Severity	Issue Description	How to fix	Why fix
Check the order of the screen items	Tip	When the **TabIndex** property is greater than 0. App creators can set custom tab orders by setting the **TabIndex** property to a value greater than 0 but it is highly discouraged as it is hard to get right, maintain, and can break screen readers.	Set all **TabIndex** properties to 0 or -1 whenever possible. Instead of using **TabIndex**, use the **Enhanced group** control to change the navigation order from the default. If values of **TabIndex** greater than 0 must be used, make sure that your screen elements match the order in which you'd want to tab through them.	The navigation order should mirror the order in which controls appear on the screen, which is the default. If manual adjustments are made, it is difficult to maintain the correct order especially in the presence of the browser's address bar and other controls outside of the app. This can make a screen reader very difficult to use. When read by the screen reader, the controls should be presented in the same order in which they are seen on the screen, instead of an order that's less intuitive.
Add another input method	Tip	When an app contains a **Pen** control. This tip reminds you to include a separate method of input.	Add a **Text input** control in addition to the **Pen** control for an accessible experience.	Some users can't use a pen and require another way to provide information (for example, by typing a signature).

Accessibility limitations in canvas apps

Article • 03/05/2024

You can design and build accessible canvas apps with built-in controls. Sometimes, the combination of app design, use of various controls, and the configured control properties may result in an app to have an inaccessible user interface.

In this article, you'll learn about these accessibility limitations in canvas apps, and how can you improve the app interface to make it more accessible.

Dialogs and overlays

Dialogs and user interfaces that appear on top of other content are not supported. These overlays require focus management, hiding background content from screen readers, and appropriate control roles.

Consider the following:

- Use separate screens for each “dialog”.
- Use the **Notify** function.
- Create a code component that implements an accessible dialog.

Tabbed interfaces

A tabbed interface is made up of a list of tabs and a panel that shows content associated with the selected tab.

The only built-in control that supports tabbed interfaces is the **Tab list**. Avoid using **Galleries** to create tabs. The list of tabs should be navigable with arrow keys. Appropriate control roles and states are required.

Consider the following:

- Use the built-in **Tab list**.
- Create a code component that implements an accessible tabbed interface.

Custom tables

The only built-in control that supports two-dimensional data is the **Data Table**. Avoid using **Galleries** to present data in rows and columns. Rows and columns have to be annotated so that screen reader users can understand their structure and navigate cells.

Consider the following:

- Use the built-in **Data Table**.
- Present data in one direction only with a **Gallery**.
- Create a code component that implements an accessible table.

Custom combo boxes

It is possible to emulate a combo box by combining a **Text Input** and a **Gallery**. However, combo boxes assembled from built-in controls are not accessible. Combo boxes must handle arrow keys and set appropriate roles and states on its components.

Consider the following:

- Use the built-in **Combo box** or **Drop down**.
- Create a code component that implements an accessible combo box.

Scrollable content

Keyboard users can't scroll **Forms**, **Scrollable screens**, and **Containers** if there are no interactive controls inside them.

For **Galleries** with no interactive content, you can set **TabIndex** on the **Gallery** itself so that keyboard users can focus on it and use arrow keys to scroll it.

For **Labels**, setting **TabIndex** will make them focusable for keyboard scrolling. However, it will also turn them into buttons. Don't making labels scrollable if they're not meant to be buttons. Ensure the **Label** is large enough to fit text. The **AutoHeight** property can be used to automatically adjust the control's size when it is inside a **Form**, **Scrollable screen**, or **Gallery**.

Expandable sections

Expandable sections, also known as disclosures, contain content that is hidden until the user presses a button. There is no built-in support for these elements but there is a workaround.

Mention the expanded state in the **AccessibleLabel** of the button. For example, “Show more details. Collapsed.”.

Update the **AccessibleLabel** when the expanded state changes. Position the expanded content immediately after the button so that screen reader users can logically navigate

to it. Push other content down when the section expands.

Landmarks

You can create headings with **Label** controls. Navigation, banner, and other landmarks are not supported. Power Apps automatically sets the main landmark to the app screen.

For other landmarks, use a heading as a workaround.

Custom roles and states

There is no built-in support for custom roles and states. Hence, it's not recommended to create composite check boxes, sliders, and toggles from built-in controls.

Consider the following:

- Mention the control's role and state in its **AccessibleLabel**. For example, if an **Icon** is used as a check box, its label could be "Enable notifications. Check box. Checked.".
- Create a code component that sets WAI-ARIA roles and states as appropriate.

Custom keyboard handling

It is not possible to react to specific key presses. For example, you can't have custom behavior for arrow keys or the Escape key. Hence, it is not possible to compose list-like controls like radio buttons from built-in controls. Nor can you create overlays that can be dismissed with the Escape key.

Enter or Space key handling is supported with **OnSelect**. However, this property is also triggered by other input methods like mouse clicks. There is no way to distinguish the source of the event.

Focus management

SetFocus function can be used to change focus but it only works in limited scenarios.

It is not possible to detect when controls receive or lose focus.

Hide content from screen reader users only

There is no aria-hidden equivalent to show content to sighted users but hide it for screen reader users. Only a few scenarios are supported.

Send notification from an app

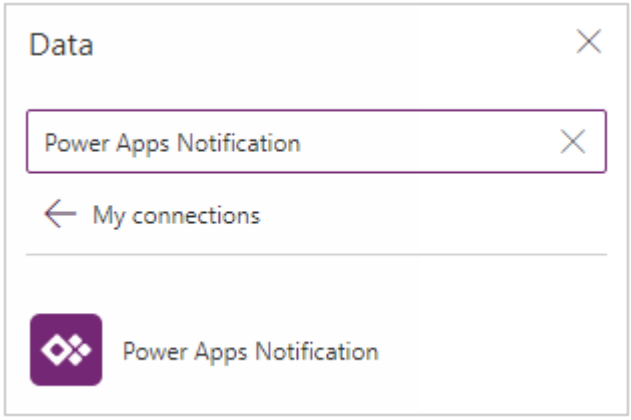
Article • 11/11/2023

You can send a push notification from one app to another or to the same app. In canvas apps, you can send notifications by using the Power Apps Notification connector.

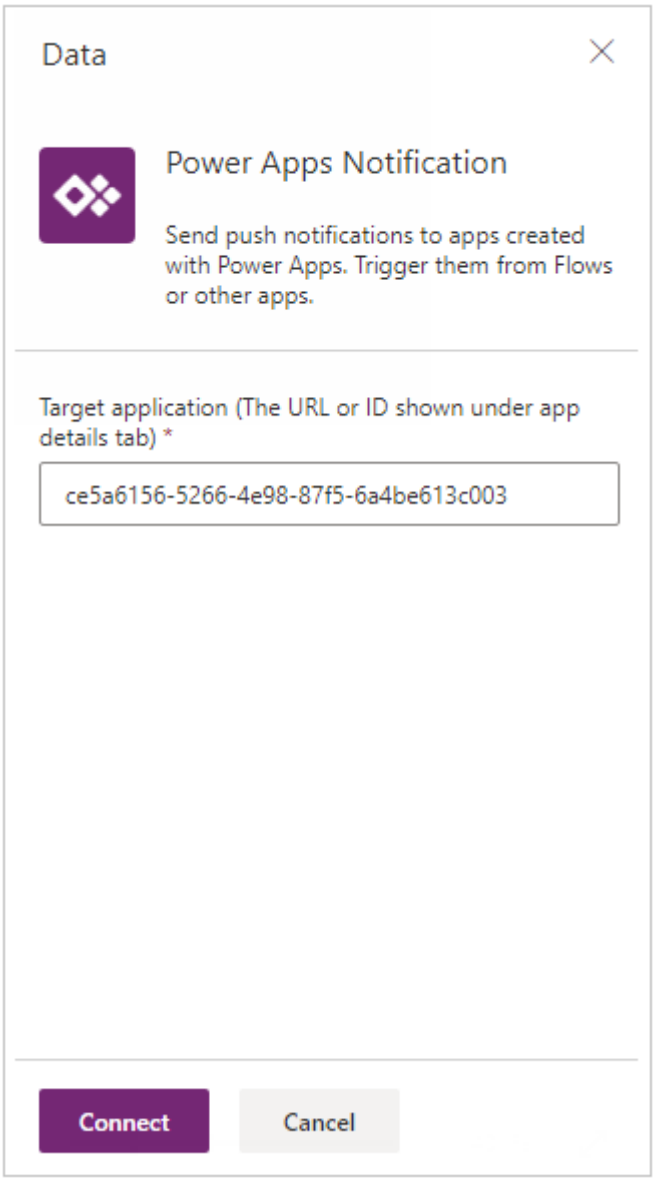
In this article, the sample app used for notifications is built from the default **Case Management** app template.

> **Note**
>
> Before you begin, create push notifications for the Power Apps mobile app. More information: Create push notifications for the Power Apps mobile app.

1. In Power Apps, go to the app to which you want to send push notifications.
2. Copy the app ID. More information: Get an app ID
3. In the left pane, select **Data** - **Connections**.
4. Edit the app. More information: Edit an app
5. Select **View** - **Data sources**.
6. Select **Add data source**.
7. Select **New Connection**.
8. Select **Power Apps Notification**.



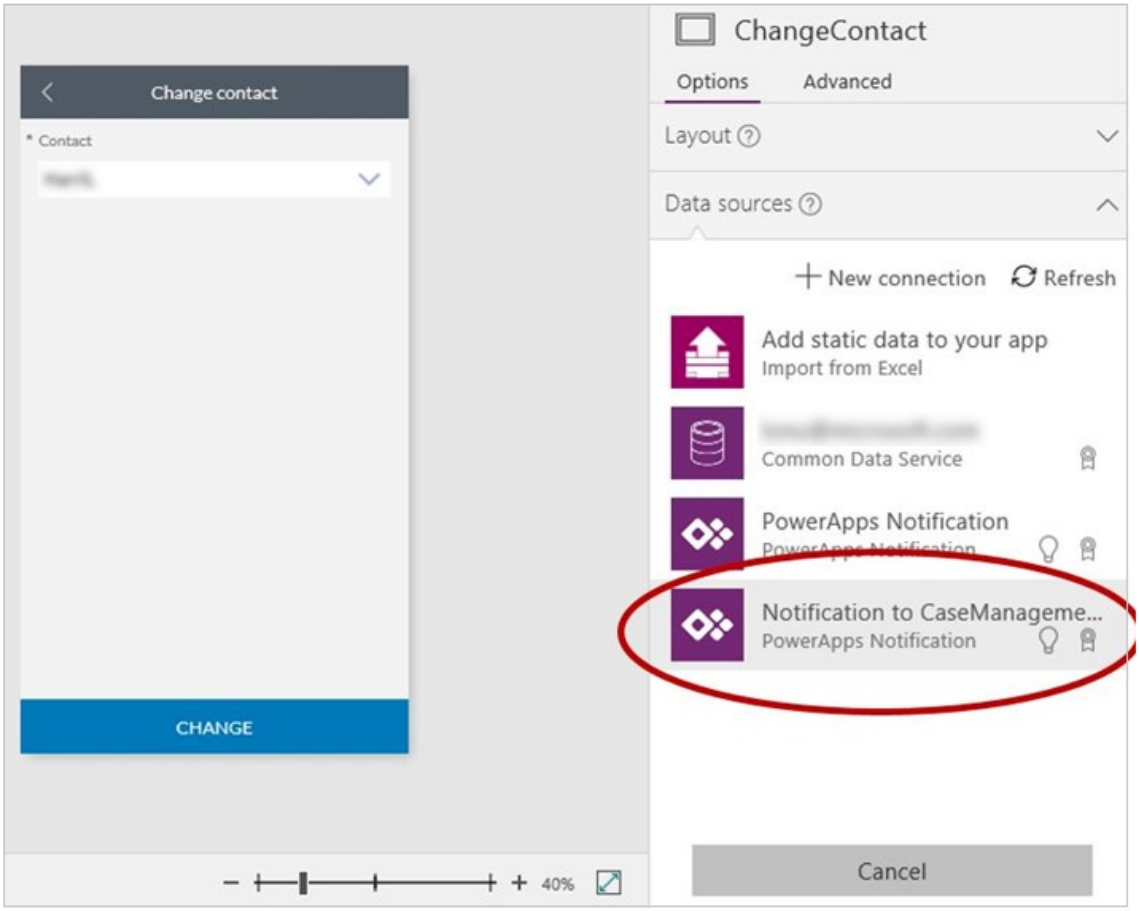
9. Paste the app ID copied from the previous step.



10. Select **Connect**.

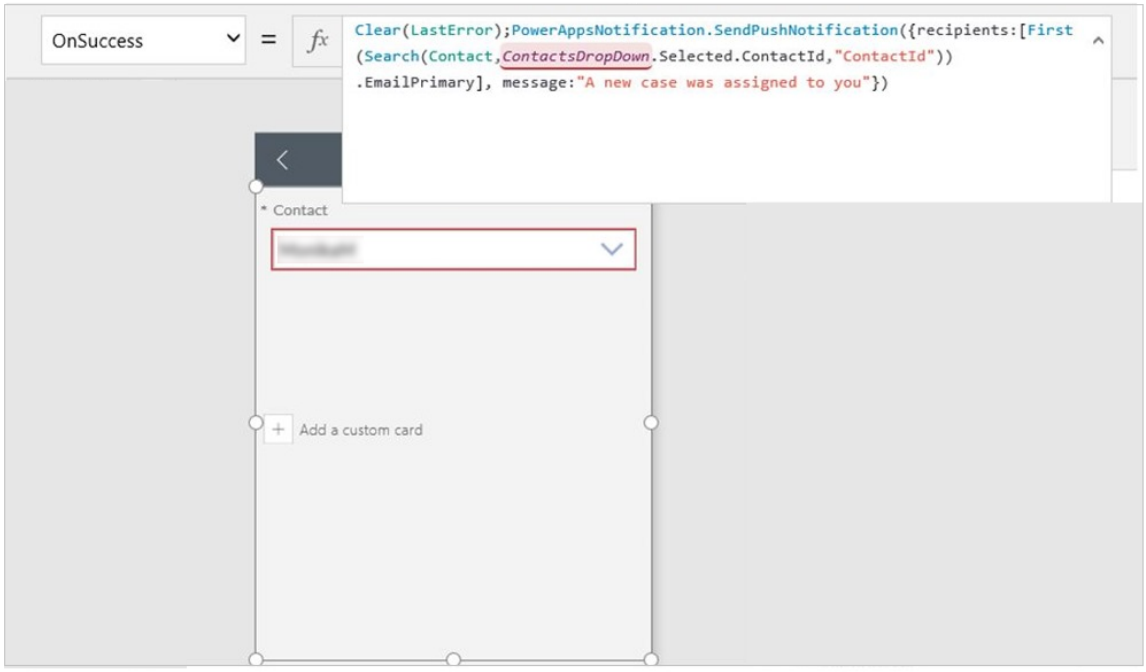
11. Add the push notification connection to the trigger app using the similar steps.

    In our example, we use the same app as the trigger app. The user who reassigns the case also triggers a push notification to the new case owner.



12. From the push notification connection, call the **SendPushNotification** method.

    In our example, we trigger this notification by using the **OnSuccess** property in a form.



Syntax

Expand table

Name	Description
SendPushNotification	Sends a push notification to the app that's specified in the connection settings for the notification.

Parameters

Expand table

Name	Type	Description
recipients	String array, required	A list of: • Email addresses for users or security groups • Object IDs for users or security groups in Microsoft Entra ID
message	String, required	The message body of the push notification.
openApp	Boolean, optional	Whether to open the app when the user taps the push notification.
params	Parameters, optional	Key-value parameters to pass with the notification. These can be further processed in the app to open a specific page and load a specific state.

Sample formulas

Send a basic notification.

Power Apps

```
PowerAppsNotification.SendPushNotification(
    {
        recipients: ["f60ccf6f-7579-4f92-967c-2920473c966b", "72f988bf-86f1-41af-91ab-2d7cd011db47"],
        message: "A new case was assigned to you."
    }
)
```

Send a notification that opens an app and passes along specific parameters.

Power Apps

```
PowerAppsNotification.SendPushNotification(
    {
```

```
        recipients: ["email1@contoso.com", "email2@contoso.com"],
        message: "message in the notification toast",
        params: Table({key:"notificationKey", value:"The value for
notificationKey"}),
        openApp: true
    }
)
```

Disconnect Git version control to edit canvas apps

Article • 05/14/2025

Git version control for editing apps has been removed and is no longer supported.

If your app currently uses this feature, follow these steps to disconnect it:

1. Open your canvas app for editing in Power Apps Studio. On the command bar, select **Settings**.
2. Select **Git version control** and then select **Disconnect**.

If you are using PASopa, download your app from your Git provider and pack the .zip file to an .msapp file. Once your .msapp file is uploaded to Power Apps, follow the steps above to disconnect.

> **Note**
>
> Git version control is replaced with the source control integration feature. More information: Source code integration

Understand new, preview, experimental, and retired features in canvas apps

Article • 04/29/2025

With every release, we make changes and add features to make Power Apps the best tool to fit your needs. We move the product forward.

At the same time, keeping your apps running smoothly is our top priority. Despite our best efforts, any change or improvement might unintentionally introduce a side effect, and your app might not work exactly the way it did before.

To ensure enhancements don't adversely affect current apps, we take features through a progression of stages. These stages give you a chance to try out the feature and provide us with feedback, and for us to gradually roll out the feature while watching for any problems. This article describes this process and how you can control your exposure to features that are under development.

At each stage, the number of people who use the feature increases, helping us to validate that the feature is what you need and that we're not introducing an unintended side effect.

Your feedback is critical throughout this process. Post your feedback in the Power Apps Community Forum.

Feature roll out stages

In short, the stages are:
