Network Driver Design Guide

Article • 09/27/2024

This Network Driver Design Guide describes how to design and create network device drivers for Windows operating systems beginning with Windows Vista.

This guide includes the following sections:

Introduction to Network Drivers Topics

Article • 09/27/2024

This section discusses introductory concepts for kernel-mode network drivers and includes the following topics:

- Roadmap for Developing NDIS Drivers
- Using the Network Driver Design Guide
- Network Architecture for Kernel-Mode Drivers
- Network Driver Programming Considerations
- Driver Stack Management
- NET_BUFFER Architecture
- Introduction to NDIS PDPI

Roadmap for Developing NDIS Drivers

Article • 03/14/2023

To create a Network Driver Interface Specification (NDIS) driver package, follow these steps:

- Step 1: Learn about Windows architecture and drivers.

  You must understand the fundamentals of how drivers work in Windows operating systems. Knowing the fundamentals will help you make appropriate design decisions and let you streamline your development process. For more information about driver fundamentals, see Concepts for all driver developers.

- Step 2: Learn about NDIS.

  For general information about NDIS and NDIS drivers, see the following topics:

  Windows Network Architecture and the OSI Model

  Network Driver Programming Considerations

  Driver Stack Management

  NET_BUFFER Architecture

- Step 3: Determine additional Windows driver design decisions.

  For more information about how to make additional Windows design decisions, see Creating Reliable Kernel-Mode Drivers, Programming Issues for 64-Bit Drivers, and Creating International INF Files.

- Step 4: Learn about the Windows driver build, test, and debug processes and tools.

  Building a driver differs from building a user-mode application. For more information about Windows driver build, debug, and test processes, driver signing, and Windows Hardware Lab Kit (HLK) testing, see Building, Debugging, and Testing Drivers. For more information about building, testing, verifying, and debugging tools, see Driver Development Tools.

- Step 5: Select the type of NDIS driver you will implement.

  For more information about types of NDIS drivers, see Using the Network Driver Design Guide.

  Follow the roadmaps for the type of driver.

Roadmap for Developing NDIS Miniport Drivers

Roadmap for Developing NDIS Protocol Drivers

Roadmap for Developing NDIS Filter Drivers

Roadmap for Developing NDIS Intermediate Drivers

Roadmap to Develop Mobile Broadband Miniport Drivers

Roadmap for Developing Windows Filtering Platform Callout Drivers

- Step 6: Review the Network driver samples in the Windows driver samples repository on GitHub.

- Step 7: Develop (or port), build, test, and debug your NDIS driver.

  See the porting guides if you are porting an existing driver:

  - Porting NDIS 6.x Drivers to NDIS 6.40

  - Porting NDIS 6.x Drivers to NDIS 6.30

  - Porting NDIS 6.x Drivers to NDIS 6.20

  - Porting NDIS 5.x Drivers to NDIS 6.0

    For more information about iterative building, testing, and debugging, see Overview of Build, Debug, and Test Process. This process will help ensure that you build a driver that works.

- Step 8: Create a driver package for your driver.

  For more information about how to install drivers, see Providing a Driver Package. For more information about how to install an NDIS driver, see Components and Files Used for Network Component Installation and Notify Objects for Network Components.

- Step 9: Sign and distribute your driver.

  The final step is to sign and distribute the driver. If your driver meets the quality standards that are defined for the Windows Hardware Lab Kit (HLK), you can distribute it through the Microsoft Windows Update program. For more information about how to distribute a driver, see Get started with the hardware submission process.

These are the basic steps. Additional steps might be necessary based on the needs of your individual driver.

Navigating the Network Driver Design Guide

Article • 12/15/2021

Microsoft Windows-based operating systems support several types of kernel-mode network drivers. The Network section of the Windows Driver Kit (WDK) documentation describes how to write these network drivers. This topic briefly describes the supported types of network drivers and explains which sections of the Network section you should read before writing each type of network driver.

This network driver design guide documents the following Network Driver Interface Specification (NDIS) interfaces:

- NDIS 6.40, which is supported on Windows 8.1, Windows Server 2012 R2, and later versions of Windows. NDIS 6.30 includes support for Network Direct Kernel Provider Interface (NDKPI) 1.12.

  For more information about NDIS 6.30, see Introduction to NDIS 6.40.

- NDIS 6.30, which is supported on Windows 8, Windows Server 2012, and later versions of Windows. NDIS 6.30 includes support for single root/I/O virtualization (SR-IOV), Hyper-V extensible switch, Network Direct Kernel Provider Interface (NDKPI) 1.1, and other services.

  For more information about NDIS 6.30, see Introduction to NDIS 6.30.

- NDIS 6.20, which is supported on Windows 7, Windows Server 2008 R2, and later versions of Windows. NDIS 6.20 includes support for Virtual Machine Queue (VMQ), receive side throttle, and other services.

  For more information about NDIS 6.20, see Introduction to NDIS 6.20.

- NDIS 6.1, which is supported on Windows Vista with Service Pack 1 (SP1), Windows Server 2008, and later versions of Windows. NDIS 6.1 includes support for header-data split, direct OID requests, and other services.

  For more information about NDIS 6.1, see Introduction to NDIS 6.1.

- NDIS 6.0, which is supported on Windows Vista and later versions of Windows. NDIS 6.0 includes support for filter drivers and many additional services that were not provided by earlier NDIS versions. NDIS 6.0 includes major updates to driver initialization and network data management including required support for driver reconfiguration at runtime and the **NET_BUFFER** architecture for handling network packet data. For more information about supporting runtime reconfiguration, see Driver Stack Management. For more information about how to handle network packet data in NDIS 6.0 see NET_BUFFER Architecture.

For more information about NDIS 6.0, see Introduction to NDIS 6.0.

Windows Vista and later operating system versions support the following types of kernel-mode NDIS-based network drivers:

Miniport Drivers

A *miniport driver* manages miniport adapters and provides an interface to the adapters for higher-level drivers. A *miniport adapter* is a conceptual entity that can represent either a physical device or a virtual device. For example, a miniport adapter can represent a network interface card (NIC) or a virtual device that is associated with an intermediate driver.

There are many variations of miniport drivers, such as a *connection-oriented miniport call manager (MCM)*, a *Windows Driver Model (WDM) miniport driver,* and the upper edge of an intermediate driver.

Protocol Drivers

A *protocol driver* provides high-level services in a driver stack. A protocol driver binds to underlying miniport adapters. An *upper-level protocol driver* implements an interface, possibly an application-specific interface, at its upper edge to provide services to users of the network. At its lower edge, a protocol driver provides a protocol interface to pass network data to and receive incoming data from the next-lower driver.

There are many variations of protocol drivers, such as a *connection-oriented call manager (MCM), a connection-oriented client,* and the lower edge of an intermediate driver.

Filter Drivers

A *filter driver* filters information on the interface between protocol drivers and miniport drivers. *Filter modules* are attached in the binding between the protocol driver and the miniport adapter and are generally transparent to the other drivers. Filter drivers can implement *modifying or monitoring filters*. For example, a filter driver can enhance the services that the underlying miniport adapter provides or simply collect statistics.

Intermediate Drivers

An *intermediate driver* interfaces between upper-level protocol drivers and miniport drivers. Intermediate drivers provide a miniport driver interface at their upper-edge to bind to overlying protocol drivers. Intermediate drivers provide a protocol driver interface at their lower edge to bind to underlying miniport adapters. Intermediate drivers are typically used to implement *n* to *m* multiplexer services. For example, an intermediate driver can implement load balance and failover solutions.

Intermediate drivers can also manage hardware when they are configured as a *miniport-intermediate driver*.

For more information about the Windows network architecture and programming considerations, see Network Architecture for Kernel-Mode Drivers and Network Driver Programming Considerations.

For more information about network INF files, which are used to install network components, see Installing Network Components. If your network driver requires a notify object--for example, to control bindings--also see Notify Objects for Network Components.

The following additional driver models are available to use particular hardware technologies and architectures.

Technology	Description

Technology	Description
Scalable Networking	Networking technologies that support the offload of tasks to a network adapter, such as the following: - Header-Data Split, a service that splits the header and the data in received Ethernet frames into separate buffers. - Receive Side Scaling, a network driver technology that improves network performance on multiprocessor systems. - TCP Chimney Offload, an offload of the data-transfer part of the TCP protocol processing to a network adapter that has the appropriate capabilities. - TCP/IP Offload, an offload of tasks or connections to a network adapter that has the appropriate capabilities. - Network Direct Kernel Provider Interface (NDKPI), which enables kernel-mode Windows components, such as SMB server and client, to use remote direct memory access (RDMA) functionality that is provided by independent hardware vendors (IHVs). - Network Virtualization using Generic Routing Encapsulation (NVGRE) Task Offload, which makes it possible to use Generic Routing Encapsulation (GRE)-encapsulated packets with: ○ Large Send Offload (LSO) ○ Virtual Machine Queue (VMQ) ○ Transmit (Tx) checksum offload ○ Receive (Rx) checksum offload
Virtualized Networking	Networking technologies that support Hyper-V virtualization environments, such as the following: - Single Root I/O Virtualization (SR-IOV) - Virtual Machine Queue (VMQ) - Hyper-V Extensible Switch
Wireless Networking	Networking capabilities that include Native 802.11 Wireless LAN.

Technology	Description
Network Module Registrar	A system facility that allows a driver to attach network modules to one another.
Winsock Kernel	A kernel-mode Network Programming Interface (NPI).
IP Helper	A set of utility functions that enable drivers to retrieve and modify information about the network configuration of the local computer.
Windows Filtering Platform Callout Drivers	A kernel-mode interface that enables deep inspection, packet modification, stream modification, and logging of network data.
System Area Networks	A type of network connection that uses Windows Sockets Direct to support a high-performance, connection-oriented network.
Remote NDIS (RNDIS)	A class specification that defines a system-provided, bus-independent message set over a USB bus.

Learning About Miniport Drivers

Article • 12/15/2021

There are several types of miniport drivers. The following list describes which sections of the WDK documentation you should read, depending on the type of miniport driver that you are writing:

Connectionless miniport drivers
If you are writing a miniport driver that controls a network interface card (NIC) for connectionless network media (such as Ethernet), read:

- Introduction to NDIS Miniport Drivers
- NDIS Miniport Drivers

Connection-oriented miniport drivers
If you are writing a miniport driver for connection-oriented network media (such as ISDN), read:

- All of the sections that are listed earlier in this topic under "Connectionless miniport drivers"
- Connection-Oriented NDIS

WAN miniport drivers
If you are writing a miniport driver that controls a wide area network (WAN) NIC, read:

- All of the sections that are listed earlier in this topic under "Connectionless miniport drivers"
- WAN Miniport Drivers

Miniports with a WDM lower interface
If you are writing a miniport driver that interfaces to other kernel drivers and has a Microsoft Windows Driver Model (WDM) lower interface, read:

- All of the sections that are listed earlier in this topic under "Connectionless miniport drivers"
- Miniport Drivers with a WDM Lower Interface

IrDA miniport drivers
If you are writing a miniport driver that controls an IrDA adapter, read:

- All of the sections that are listed earlier in this topic under "Connectionless miniport drivers"

Miniport drivers that support scalable networking

To learn about miniport drivers that support scalable networking, read:

- Scalable Networking

Miniport drivers that support offloading TCP/IP to hardware

To learn about miniport drivers that offload TCP/IP to hardware, read:

- TCP/IP Offload

Learning About Protocol Drivers

Article • 12/15/2021

You can write a protocol driver that has either a connectionless or a connection-oriented lower edge. In addition, your protocol driver can provide Winsock support. The following list describes which sections of the WDK documentation you should read, depending on the type of protocol driver that you are writing:

Protocol drivers that have a connectionless lower edge
If you are writing a protocol driver whose lower edge provides an interface to connectionless miniport drivers, read:

- NDIS Protocol Drivers

Protocol drivers that are connection-oriented clients or that are connection-oriented providers of call manager services
If you are writing a connection-oriented client, which provides an interface to connection-oriented miniport drivers, or if you are writing a connection-oriented call manager, read:

- NDIS Protocol Drivers
- Connection-Oriented NDIS

Protocol drivers that have Winsock support
If you are writing a protocol that provides Winsock support, read:

- NDIS Protocol Drivers
- Transport Helper DLLs for Windows Sockets

Learning About Filter Drivers

Article • 12/15/2021

You can write a filter driver that has a connectionless interface. The following list describes which sections of the WDK documentation you should read, depending on the type of filter driver that you are writing:

Filter drivers
If you are writing a filter driver whose lower edge provides an interface to connectionless miniport drivers, read:

- NDIS Filter Drivers

Learning About Intermediate Drivers

Article • 12/15/2021

You can write an intermediate driver that has either a connectionless or a connection-oriented lower edge. The following list describes which sections of the WDK documentation you should read, depending on the type of intermediate driver that you are writing:

Intermediate drivers that have a connectionless lower edge
If you are writing an intermediate driver whose lower edge provides an interface to connectionless miniport drivers, read:

- NDIS Intermediate Drivers

Intermediate drivers that have a connection-oriented lower edge
If you are writing an intermediate driver whose lower edge provides an interface to connection-oriented miniport drivers, read:

- NDIS Intermediate Drivers
- Connection-Oriented NDIS

Windows network architecture and the OSI model

Article • 12/16/2023

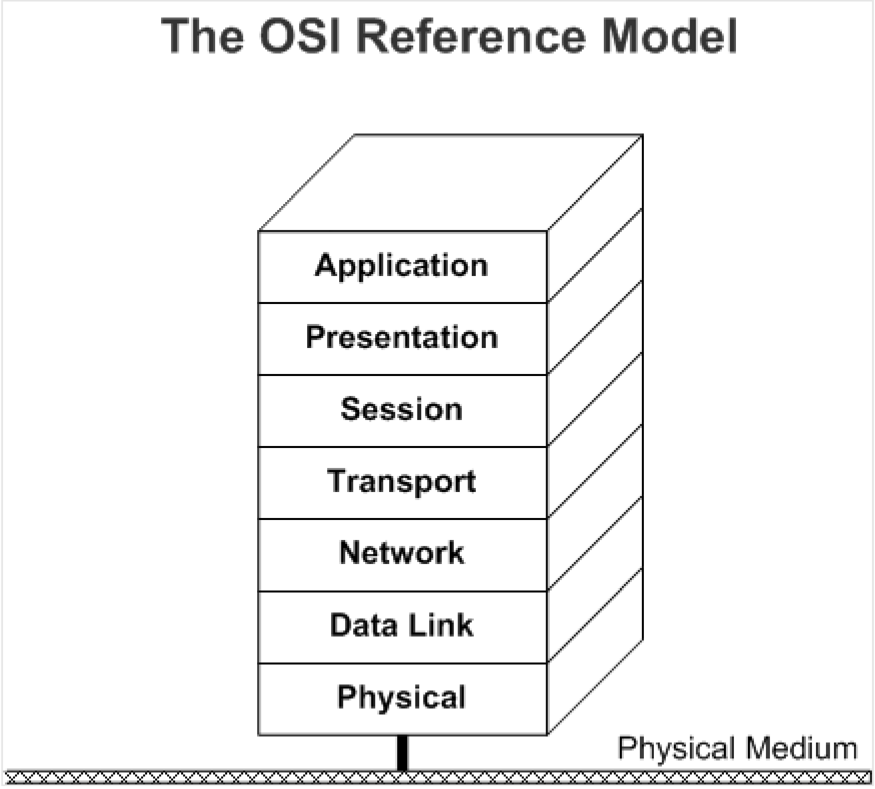
This article explores the Windows network architecture and how Windows network drivers implement the *bottom four* layers of the OSI model.

For general information on all seven layers of the model, see the OSI model.

The Microsoft Windows operating systems use a network architecture that is based on the seven-layer networking model developed by the International Organization for Standardization (ISO) in 1978.

The ISO Open Systems Interconnection (OSI) Reference model describes networking as "a series of protocol layers with a specific set of functions allocated to each layer. Each layer offers specific services to higher layers while shielding these layers from the details of how the services are implemented. A well-defined interface between each pair of adjacent layers defines the services offered by the lower layer to the higher one and how those services are accessed."

The following diagram illustrates the OSI model.



Windows network drivers implement the bottom four layers of the OSI model.

Physical layer

The physical layer is the lowest layer of the OSI model. This layer manages the reception and transmission of the unstructured raw bit stream over a physical medium. It describes the electrical/optical, mechanical, and functional interfaces to the physical medium. The physical layer carries the signals for all of the higher layers.

In Windows, the network interface card (NIC) implements the physical layer, its transceiver, and the medium to which the NIC is attached.

Data link layer

The data link layer sends frames between physical addresses and is responsible for error detection and recovery occurring in the physical layer.

The data link layer is further divided by the Institute of Electrical and Electronics Engineers (IEEE) into two sublayers: media access control (MAC) and logical link control (LLC).

MAC

The MAC sublayer manages access to the physical layer, checks frame errors, and manages address recognition of received frames.

In the Windows network architecture, the MAC sublayer is implemented in the NIC. The NIC is controlled by a software device driver called the miniport driver. Windows supports several variations of miniport drivers including WDM miniport drivers, miniport call managers (MCMs), and miniport intermediate drivers.

LLC

The LLC sublayer provides error-free transfer of data frames from one node to another. The LLC sublayer establishes and terminates logical links, controls frame flow, sequences frames, acknowledges frames, and retransmits unacknowledged frames. The LLC sublayer uses frame acknowledgment and retransmission to provide virtually error free transmission over the link to the layers above.

In Windows, a software driver known as a protocol driver implements the LLC sublayer.

Network layer

The network layer controls the operation of the subnet. This layer determines the physical path that the data should take, based on the following:

- Network conditions
- Priority of service
- Other factors, such as routing, traffic control, frame fragmentation and reassembly, logical-to-physical address mapping, and usage accounting

A protocol driver implements the network layer.

Transport layer

The transport layer ensures that messages are delivered error free, in sequence, and with no loss or duplication. This layer relieves the higher-layer protocols from being concerned about data transfer with their peers.

A minimal transport layer is required in protocol stacks that include a reliable network or LLC sublayer that provides virtual circuit capability. For example, because the NetBEUI transport driver for Windows is an OSI-compliant LLC sublayer, its transport layer functions are minimal. If the protocol stack doesn't include an LLC sublayer, and if the network layer is unreliable or supports datagrams (as with TCP/IP's IP layer or NWLink's IPX layer), the transport layer should include frame sequencing and acknowledgment, as well as retransmission of unacknowledged frames.

In the Windows network architecture, a protocol driver, sometimes referred to as a *transport driver*, implements the transport layer.

Overview of NDIS driver types

Article • 09/27/2024

The Network Driver Interface Specification (NDIS) library abstracts the network hardware from network drivers. NDIS also specifies a standard interface between layered network drivers, thereby abstracting lower-level drivers that manage hardware from upper-level drivers, such as network transports. NDIS also maintains state information and parameters for network drivers, including pointers to functions, handles, and parameter blocks for linkage, and other system values.

NDIS supports the following primary types of network drivers:

- Miniport drivers
- Protocol drivers
- Filter drivers
- Intermediate drivers

Note: These topics detail each type of NDIS driver individually. For more information about the NDIS driver stack and a diagram showing the relationship between all four NDIS driver types, see NDIS Driver Stack.

Miniport drivers

Article • 09/27/2024

An *NDIS miniport driver* has two basic functions:

- Managing a network interface card (NIC), including sending and receiving data through the NIC.
- Interfacing with higher-level drivers, such as filter drivers, intermediate drivers, and protocol drivers.

A miniport driver communicates with its NICs and with higher-level drivers through the NDIS library. The NDIS library exports a full set of functions (**NdisM*Xxx*** and other **Ndis*Xxx*** functions) that encapsulate all of the operating system functions that a miniport driver must call. The miniport driver, in turn, must export a set of entry points (*MiniportXxx* functions) that NDIS calls for its own purposes, or on behalf of higher-level drivers, to access the miniport driver.

> ⓘ **Note**
>
> For more information about the NDIS driver stack and a diagram showing the relationship between all four NDIS driver types, see NDIS Driver Stack.

The following send and receive operations illustrate the interaction of miniport drivers with NDIS and with higher-level drivers:

- When a transport driver has a packet to transmit, it calls an **Ndis*Xxx*** function exported by the NDIS library. NDIS then passes the packet to the miniport driver by calling the appropriate *MiniportXxx* function exported by the miniport driver. The miniport driver then forwards the packet to the NIC for transmission by calling the appropriate **Ndis*Xxx*** functions.
- When a NIC receives a packet addressed to itself, it can post a hardware interrupt that is handled by NDIS or the NIC's miniport driver. NDIS notifies the NIC's miniport driver by calling the appropriate *MiniportXxx* function. The miniport driver sets up the transfer of data from the NIC and then indicates the presence of the received packet to bound higher-level drivers by calling the appropriate **Ndis*Xxx*** function.

Connectionless and Connection-Oriented Miniport Drivers

NDIS supports miniport drivers for both connectionless environments and connection-oriented environments.

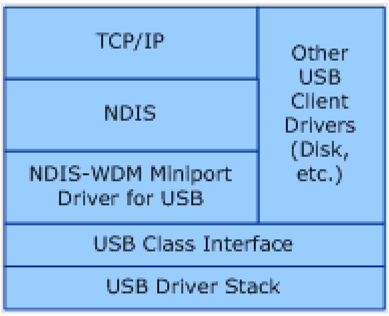
Connectionless miniport drivers control NICs for connectionless network media, such as Ethernet. Connectionless miniport drivers are further divided into deserialized and serialized drivers:

Note All NDIS 6.0 and later drivers are deserialized.

- *Deserialized drivers* serialize the operation of their own *MiniportXxx* functions and that internally queue all incoming send packets. This results in significantly better full-duplex performance, provided that the driver's critical sections (code that only a single thread at a time can run) are kept small.
- *Serialized drivers* rely on NDIS to serialize calls to their *MiniportXxx* functions and to manage their send queues.

Connection-oriented miniport drivers control NICs for connection-oriented network media, such as ISDN. Connection-oriented miniport drivers are always deserialized -- they always serialize the operation of their own *MiniportXxx* functions and queue internally all incoming send packets.

An NDIS miniport driver can have a non-NDIS lower edge (see the following figure).



TCP/IP
NDIS
NDIS-WDM Miniport Driver for USB
Other USB Client Drivers (Disk, etc.)
USB Class Interface
USB Driver Stack

Through its non-NDIS lower edge, a miniport driver uses the class interface for a bus, such as the Universal Serial Bus (USB) to control a device on the bus. The miniport driver communicates with the device by sending I/O request packets (IRPs) either to the bus or directly to remote devices that are attached to the bus. At its upper edge, the miniport driver exposes a standard NDIS miniport driver interface, which enables the miniport driver to communicate with overlying NDIS drivers.

Protocol drivers

Article • 12/15/2021

A network protocol, which is the highest driver in the NDIS hierarchy of drivers, is often used as the lowest-level driver in a transport driver that implements a transport protocol stack, such as a TCP/IP stack. A *transport protocol driver* allocates packets, copies data from the sending application into the packet, and sends the packets to the lower-level driver by calling NDIS functions. A protocol driver also provides a protocol interface to receive incoming packets from the next lower-level driver. A transport protocol driver transfers received data to the appropriate client application.

At its lower edge, a protocol driver interfaces with intermediate network drivers and miniport drivers. The protocol driver calls **Ndis*Xxx*** functions to send packets, read and set information that is maintained by lower-level drivers, and use operating system services. The protocol driver also exports a set of entry points (*ProtocolXxx* functions) that NDIS calls for its own purposes or on behalf of lower-level drivers to indicate up receive packets, indicate the status of lower-level drivers, and to otherwise communicate with the protocol driver.

At its upper edge, a transport protocol driver has a private interface to a higher-level driver in the protocol stack.

> ⓘ **Note**
>
> For more information about the NDIS driver stack and a diagram showing the relationship between all four NDIS driver types, see **NDIS Driver Stack**.

NDIS Protocol Drivers

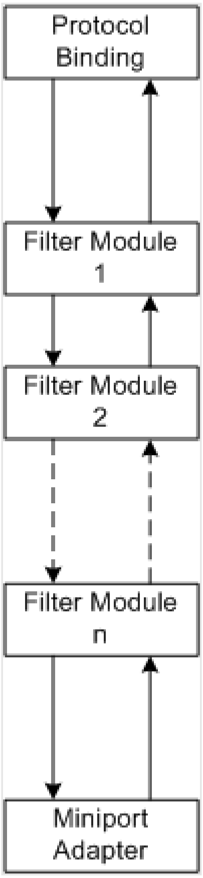
NDIS Protocol Driver Reference

Filter drivers

Article • 09/27/2024

NDIS 6.0 introduced NDIS filter drivers. Filter drivers can monitor and modify the interaction between protocol drivers and miniport drivers. Filter drivers are easier to implement and have less processing overhead than NDIS intermediate drivers.

A *filter module* is an instance of a filter driver. As the following figure illustrates, filter modules are typically layered between miniport adapters and protocol bindings.



A filter driver communicates with NDIS and other NDIS drivers through the NDIS library. The NDIS library exports a full set of functions (**NdisF*Xxx*** and other **Ndis*Xxx*** functions) that encapsulate all of the operating system functions that a filter driver must call. The filter driver, in turn, must export a set of entry points (*FilterXxx* functions) that NDIS calls for its own purposes, or on behalf of other drivers, to access the filter driver.

ⓘ **Note**

For more information about the NDIS driver stack and a diagram showing the relationship between all four NDIS driver types, see NDIS Driver Stack.

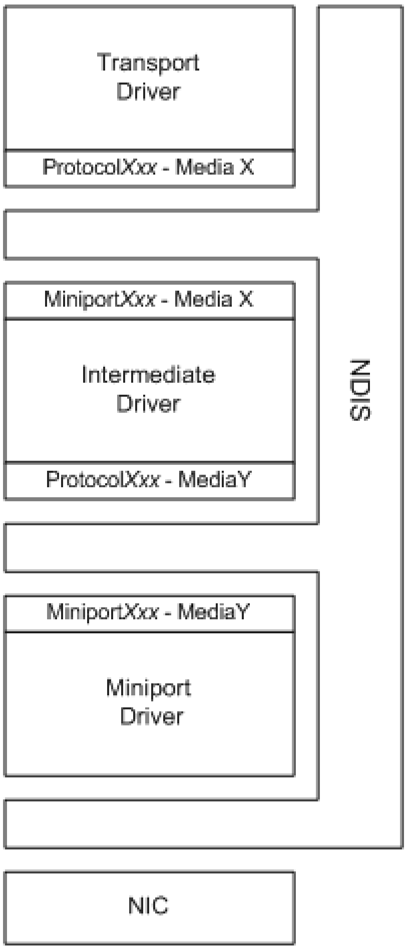
Intermediate drivers

Article • 12/15/2021

As the following figure illustrates, intermediate drivers are typically layered between miniport drivers and transport protocol drivers.



ⓘ **Note**

For more information about the NDIS driver stack and a diagram showing the relationship between all four NDIS driver types, see **NDIS Driver Stack**.

Because of its intermediate position in the driver hierarchy, an intermediate driver must communicate with both overlying protocol drivers and underlying miniport drivers in order to expose:

- Protocol entry points.

  At its lower edge, NDIS calls the *ProtocolXxx* functions to communicate requests from underlying miniport drivers. The intermediate driver looks like a protocol driver to an underlying miniport driver.

- Miniport driver entry points.

  At its upper edge, NDIS calls the *MiniportXxx* functions to communicate the requests of one or more overlying protocol drivers. The intermediate driver looks like a miniport driver to an overlying protocol driver.

An intermediate driver exports a subset of the *MiniportXxx* functions at its upper edge. It also exports one or more virtual adapters, to which overlying protocol drivers can bind. To a protocol driver, a virtual adapter that was exported by an intermediate driver appears to be a physical NIC. When a protocol driver sends packets or requests to a virtual adapter, the intermediate driver propagates these packets and requests to the underlying miniport driver. When the underlying miniport driver indicates received packets, responds to a protocol driver's requests for information, or indicates status, the intermediate driver propagates such packets, responses, and status up to the protocol drivers that are bound to the virtual adapter.

You can use intermediate drivers to:

- Translate between different network media.

- Balance packet transmission across more than one NIC. A load balancing driver exposes one virtual adapter to overlying transport protocols and distributes send packets across more than one NIC.

Network Driver Programming Considerations

Article • 12/15/2021

Microsoft Windows network drivers share similar design goals. Network drivers should be written to be portable and scalable, to provide simple configuration of hardware and software, to use object-based interfaces, and to support asynchronous I/O. This section describes how to apply these general design goals to the network drivers that you write for Microsoft Windows Vista and later operating systems.

This section includes the following topics:

- Performance in Network Drivers
- Performance in Network Adapters
- Portability in Network Drivers
- Multiprocessor Support in Network Drivers
- IRQLs in Network Drivers
- Synchronization and Notification in Network Drivers
- Packet Structures in Network Drivers
- Using Shared Memory in Network Drivers
- Asynchronous I/O and Completion Functions in Network Drivers
- Security Issues for Network Drivers

Performance in Network Drivers

Article • 12/15/2021

Minimizing send and receive path length

Although the send and receive paths differ from driver to driver, there are some general rules for performance optimizations:

- Optimize for the common paths. The Kernprof.exe tool is provided with the developer and IDW builds of Windows that extracts the needed information. The developer should look at the routines that consume the most CPU cycles and attempt to reduce the frequency of these routines being called or the time spent in these routines.

- Reduce time spent in DPC so that the network adapter driver does not use excessive system resources, which would cause overall system performance to suffer.

- Make sure that debugging code is not compiled into the final released version of the driver; this avoids executing excess code.

Partitioning data and code to minimize sharing across processors

Partitioning is needed to minimize shared data and code across processors. Partitioning helps reduce system bus utilization and improves the effectiveness of processor cache. To minimize sharing, driver writers should consider the following:

- Implement the driver as a deserialized miniport as described in Deserialized NDIS Miniport Drivers.

- Use per-processor data structures to reduce global and shared data access. This allows you to keep statistic counters without synchronization, which reduces the code path length and increases performance. For vital statistics, have per-processor counters that are added together at query time. If you must have a global counter, use interlocked operations instead of spin locks to manipulate the counter. See Using Locking Mechanisms Properly below for information about how to avoid using spin locks.

  To facilitate this, KeGetCurrentProcessorNumberEx can be used to determine the current processor. To determine the number of processors when allocating per-processor data structures, KeQueryGroupAffinity can be used.

  The total number of bits set in the affinity mask indicates the number of active processors in the system. Drivers should not assume that all the set bits in the mask will be contiguous because the processors might not be consecutively numbered in the future releases of the operating system. The number of processors in an SMP machine is a zero-based value.

  If your driver maintains per-processor data, you can use the KeQueryGroupAffinity function to reduce cache-line contention.

Avoiding false sharing

False sharing occurs when processors request shared variables that are independent from each other. However, because the variables are on the same cache line, they are shared among the processors. In such situations, the cache line will travel back and forth between processors for every access to any of the variables in it, causing an increase in cache flushes and reloads. This increases the system bus utilization and reduces overall system performance.

To avoid false sharing, align important data structures (such as spin locks, buffer queue headers, singly linked lists) to cache-line boundaries by using NdisGetSharedDataAlignment.

Using locking mechanisms properly

Spin locks can reduce performance if not used properly. Drivers should minimize their use of spin locks by using interlocked operations wherever possible. However, in some cases, a spin lock might be the best choice for some purposes. For example, if a driver acquires a spin lock while handling the reference count for the number of packets that have not been indicated back to the driver, it is not necessary to use an interlocked operation. For more information, see Synchronization and Notification in Network Drivers.

Here are some tips for using locking mechanisms effectively:

- Use NDIS singly-linked list functions such as the following for managing resource pools:

  NdisInitializeSListHead

  NdisInterlockedPushEntrySList

  NdisInterlockedPopEntrySList

  NdisQueryDepthSList

- If you need to use spin locks, use them to only protect data, not code. Don't use one lock to protect all data used in common paths. For example, separate the data used in the send and receive paths into two data structures so that when the send path needs to lock its data, the receive path is not affected.

- If you are using spin locks and the path is already at DPC level, use the **NdisDprAcquireSpinLock** and **NdisDprReleaseSpinLock** functions to avoid extra code when acquiring and releasing the locks.

- To minimize the number of spin lock acquires and releases, use these NDIS RWLock functions:

  NdisAllocateRWLock

  NdisAcquireRWLockRead

  NdisAcquireRWLockWrite

  NdisReleaseRWLock

Using 64-bit DMA

64-Bit DMA If the network adapter supports 64-bit DMA, steps must be taken to avoid extra copies for addresses above the 4 GB range. When the driver calls **NdisMRegisterScatterGatherDma**, the **NDIS_SG_DMA_64_BIT_ADDRESS** flag must be set in the *Flags* parameter.

Ensuring proper buffer alignment

Buffer alignment on a cache-line boundary improves performance when copying data from one buffer to another. Most network adapter receive buffers are properly aligned when they are first allocated, but the user data that must eventually be copied into the application buffer is misaligned due to the header space consumed. In the case of TCP data (the most common scenario), the shift due to the TCP, IP and Ethernet headers results in a shift of 0x36 bytes. To resolve this problem, we recommend that drivers allocate a slightly larger buffer and insert packet data at an offset of 0xA bytes. This will ensure that, after the buffers are shifted by 0x36 bytes for the header, the user data is properly aligned. For more information about cache-line boundaries, see the Remarks section for **NdisMAllocateSharedMemory**.

Using Scatter-Gather DMA

NDIS Scatter/Gather DMA provides the hardware with support to transfer data to and from noncontiguous ranges of physical memory. Scatter-Gather DMA uses a **SCATTER_GATHER_LIST** structure, which includes an array of **SCATTER_GATHER_ELEMENT** structures and the number of elements in the array. This structure is retrieved from the packet descriptor passed to the driver's send function. Each element of the array provides the length and starting physical address of a physically contiguous Scatter-Gather region. The driver uses the length and address information for transferring the data.

Using the Scatter-Gather routines for DMA operations can improve utilization of system resources by not locking these resources down statically, as would occur if map registers were used. For more information, see NDIS Scatter/Gather DMA.

If the network adapter supports TCP Segmentation Offload (Large Send Offload), then the driver will need to pass in the maximum buffer size it can get from TCP/IP into the *MaximumPhysicalMapping* parameter within **NdisMRegisterScatterGatherDma** function. This will guarantee that the driver has enough map registers to build the Scatter-Gather list and eliminate any possible buffer allocations and copying. For more information, see these topics:

- Determining Task Offload Capabilities
- Offloading the Segmentation of Large TCP Packets

Supporting Receive Side Throttle

To minimize disruptions during media playback in multimedia applications, NDIS 6.20 and later drivers must support Receive Side Throttle (RST) in processing receive interrupts. For more information, see:

Receive Side Throttle in NDIS 6.20 "Send and Receive Code Paths" in Summary of Changes Required to Port a Miniport Driver to NDIS 6.20

Performance in Network Adapters

Article • 09/27/2024

There are always tradeoffs in deciding which hardware functions to implement on a network adapter. It's becoming increasingly important to consider adding task offload features that allow for interrupt moderation, dynamic tuning on the hardware, improving the use of the PCI bus, and supporting Jumbo Frames. These offload features are important for the high-end network adapter that is used in configurations requiring top performance.

- Supporting TCP and IP checksum offload
- Supporting large send offload (LSO)
- Supporting IP security (IPSec) offload
- Improving interrupt moderation
- Using the PCI bus efficiently
- Supporting jumbo frames

Supporting TCP and IP checksum offload

For most common network traffic, offloading checksum calculation to the network adapter hardware offers a significant performance advantage by reducing the number of CPU cycles required per byte. Checksum calculation is the most expensive function in the networking stack for two reasons:

- It contributes to long path length.
- It causes cache churning effects (typically on the sender).

Offloading checksum calculation to the sender improves the overall system performance by reducing the load on the host CPU and increasing cache effectiveness.

In the Windows Performance Lab, we have measured TCP throughput improvements of 19% when checksum was offloaded during network-intensive workloads. Analysis of this improvement shows that 11% of the total improvement is due to the path length reduction, and 8% is due to increasing the caches effectiveness.

Offloading checksum on the receiver has the same advantages as offloading checksum on the sender. Increased benefit can be seen on systems that act as both client and server, such as a sockets proxy server. On systems where the CPU isn't necessarily busy, such as a client system, the benefit of offloading checksum may be seen in better network response times, rather than in noticeably improved throughput.

Supporting large send offload (LSO)

Windows offers the ability for the network adapter/driver to advertise a larger Maximum Segment Size (MSS) than the MTU to TCP up to 64K. This allows TCP to allocate a buffer of up to 64K to the driver, which divides the large buffer into packets that fit within the network MTU.

The TCP segmenting work is done by the network adapter/driver hardware instead of the host CPU . This results in a significant performance improvement if the network adapter CPU is able to handle the additional work.

For many of the network adapters tested, there was little improvement seen for pure networking activities when the host CPU was more powerful than the network adapter hardware. However, for typical business workloads, an overall system performance improvement of up to 9% of the throughput has been measured, because the host CPU uses most of its cycles to execute transactions. In these cases, offloading TCP segmentation to the hardware frees the host CPU from the load of segmentation, allowing it extra cycles to perform more transactions.

Supporting IP security (IPSec) offload

Windows offers the ability to offload the encryption work of IPSec to the network adapter hardware. Encryption, especially 3 DES (also known as triple DES), has a very high cycles/byte ratio. Therefore, it's no surprise that offloading IPSec to the network adapter hardware measured a 30% performance boost in secure Internet and VPN tests.

Improving interrupt moderation

A simple network adapter generates a hardware interrupt on the host upon the arrival of a packet or to signal completion of a packet send request. Interrupt latency and resulting cache churning effects add overhead to the overall networking performance. In many scenarios (for example, heavy system usage or heavy network traffic), it's best to reduce the cost of the hardware interrupt by processing several packets for each interrupt.

With heavy network workloads, up to 9% performance improvement in throughput has been measured over network-intensive workloads. However, tuning Interrupt Moderation parameters only for throughput improvements may result in a performance hit on the response time. To maintain optimum settings and accommodate for different workloads, it's best to allow for dynamically adjusted parameters as described in the Auto-tuning later in this article.

Using the PCI bus efficiently

One of the most important factors in the network adapter hardware performance is how efficiently it uses the PCI bus. Further, the network adapter's DMA performance affects the performance of all PCI cards that are on the same PCI bus. The following guidelines must be considered when optimizing PCI usage:

- Streamline DMA transfers by aggregating target pages where appropriate.
- Reduce PCI protocol overhead by performing DMA in large chunks (at least 256 bytes). If possible, time the flow of data so that entire packets are transferred in a single PCI transaction. However, consider how the transfer should take place. For example, don't wait for all of the data to arrive before initiating transfers, because waiting will increase latency and consume additional buffer space.
- It's better to pad the DMA packet transfer with additional bytes, rather than requiring a short extra transfer to "clean up" by transferring the last few bytes of the packet.
- Use the Memory Read, Memory Read Line, and Memory Read Multiple transactions as recommended by the PCI specification.
- The network adapter bus interface hardware should detect limitations in the host memory controller and adjust behavior accordingly. In example, the network adapter bus interface hardware should detect memory-controller pre-fetch limitations on a DMA Memory Reads and wait for a short period before attempting the transaction again. The hardware should detect excessive retries on the part of the network adapter and increase the time before the first retry on future transactions when cut off by the host. There's no point in continuing to submit transactions to the memory controller when you're certain that it's still busy fetching the next sequential set of data.
- Minimize the insertion of wait states, especially during data transfers. It's better to relinquish the bus and let another PCI adapter using the bus get some work done if more than one or two wait states are going to be inserted.
- Use Memory Mapped I/O instead of Programmed I/O. This is also true for drivers.

Supporting jumbo frames

Supporting larger Maximum Transmission Units (MTUs) and thus larger frame sizes, specifically Jumbo Frames, reduces the network stack overhead incurred per byte. A 20% TCP throughput increase has been measured when the MTU was changed from 1514 to

9000. Also, a significant reduction of CPU utilization is obtained due to the fewer number of calls from the network stack to the network driver.

Portability in Network Drivers

Article • 12/15/2021

NDIS drivers should be written so that they are easily portable across all platforms that support Microsoft Windows operating systems. In general, porting from one hardware platform to another should only require recompilation with a system-compatible compiler.

Follow these guidelines when you write NDIS drivers:

- Avoid calling operating system-specific functions. Instead, use the NDIS equivalent functions. NDIS exports a rich set of support functions for writing drivers, and if you call these support functions, you can port the code between Microsoft operating systems that support NDIS.

- Write drivers in C (specifically, the ANSI C Standard). Avoid using any language features that other system-compatible compilers do not support. Do not use any features that the ANSI C standard designates as "implementation defined."

- Avoid dependencies on data types whose size and layout vary across platforms. For example, do not write driver code that calls any C Run-Time Library functions instead of NDIS-provided functions.

- Do not use floating-point operations in kernel mode. If you attempt such operations, a fatal error will occur.

- Use **#ifdef** and **#endif** statements to encapsulate code that is used to support platform-specific features.

Multiprocessor Support in Network Drivers

Article • 12/15/2021

To write a portable driver for all Microsoft Windows versions, you need to write code to safely run on computers with multiple concurrently running processors. A network driver must be multiprocessor-safe and must use the provided NDIS library functions.

In a uniprocessor environment, a single processor runs only one computer instruction at a time, even though it is possible for a network interface card (NIC) or other device to interrupt the current execution stream when packets arrive or as timer interrupts occur. Typically, when manipulating data structures such as packet queues, a driver disables interrupts on the NIC, performs the manipulation, and then reenables interrupts. Many threads in a uniprocessor environment appear to run simultaneously but actually run in interleaved time slices.

In a multiprocessor environment, processors simultaneously run several computer instructions. A driver must synchronize so that when one driver function manipulates common data structures, the same or another driver function on another processor does not attempt to modify shared data at the same time. All driver code is reentrant in a symmetric multiprocessor (SMP) computer. To eliminate this resource protection problem, Windows device drivers use spin locks. For more information, see Synchronization and Notification in Network Drivers.

IRQLs in Network Drivers

Article • 12/15/2021

Every driver function called by NDIS runs at a system-determined IRQL (one of PASSIVE_LEVEL < DISPATCH_LEVEL < DIRQL). For example, a miniport driver's initialization function, halt function, reset function, and shutdown function commonly run at PASSIVE_LEVEL, although the reset and shutdown functions can be invoked at a higher IRQL if the system requires it. Interrupt code runs at DIRQL, so an NDIS intermediate or protocol driver never runs at DIRQL. All other NDIS driver functions run at or below IRQL = DISPATCH_LEVEL.

The IRQL at which a driver function runs affects which NDIS functions it can call. Certain functions can be called only at IRQL = PASSIVE_LEVEL. Others can be called at DISPATCH_LEVEL or lower. You should check every NDIS function for IRQL restrictions.

Any driver function that shares resources with the driver's interrupt service routine (ISR) must be able to raise its IRQL to DIRQL to prevent race conditions. NDIS provides such a mechanism.

Synchronization and Notification in Network Drivers

Article • 12/15/2021

Whenever two threads of execution share resources that can be accessed at the same time, either in a uniprocessor computer or on a symmetric multiprocessor (SMP) computer, they need to be synchronized. For example, on a uniprocessor computer, if one driver function is accessing a shared resource and is interrupted by another function that runs at a higher IRQL, such as an ISR, the shared resource must be protected to prevent race conditions that leave the resource in an indeterminate state. On an SMP computer, two threads could be running simultaneously on different processors and attempting to modify the same data. Such accesses must be synchronized.

NDIS provides spin locks that you can use to synchronize access to shared resources between threads that run at the same IRQL. When two threads that share a resource run at different IRQLs, NDIS provides a mechanism for temporarily raising the IRQL of the lower IRQL code so that access to the shared resource can be serialized.

When a thread depends on the occurrence of an event outside the thread, the thread relies on notification. For example, a driver might need to be notified when some time period has passed so that it can check its device. Or a network interface card (NIC) driver might have to perform a periodic operation such as polling. Timers provide such a mechanism.

Events provide a mechanism that two threads of execution can use to synchronize operations. For example, a miniport driver can test the interrupt on a NIC by writing to the device. The driver must wait for an interrupt to notify the driver that the operation was successful. You can use events to synchronize an operation between the thread waiting for the interrupt to complete and the thread that handles the interrupt.

The following subsections in this topic describe these NDIS mechanisms.

- Spin Locks
- Avoiding Spin Lock Problems
- Timers
- Events

Spin Locks

A *spin lock* provides a synchronization mechanism for protecting resources shared by kernel-mode threads running at IRQL > PASSIVE_LEVEL in either a uniprocessor or a multiprocessor computer. A spin lock handles synchronization among various threads of execution that are running concurrently on an SMP computer. A thread acquires a spin lock before accessing protected resources. The spin lock keeps any thread but the one holding the spin lock from using the resource. On a SMP computer, a thread that is waiting on the spin lock loops attempting to acquire the spin lock until it is released by the thread that holds the lock.

Another characteristic of spin locks is the associated IRQL. Attempted acquisition of a spin lock temporarily raises the IRQL of the requesting thread to the IRQL associated with the spin lock. This prevents all lower IRQL threads on the same processor from preempting the executing thread. Threads, on the same processor, running at a higher IRQL can preempt the executing thread, but these threads cannot acquire the spin lock because it has a lower IRQL. Therefore, after a thread has acquired a spin lock, no other threads can acquire the spin lock until it has been released. A well-written network driver minimizes the amount of time a spin lock is held.

A typical use for a spin lock is to protect a queue. For example, the miniport driver send function, *MiniportSendNetBufferLists*, might queue packets passed to it by a protocol driver. Because other driver functions also use this queue, *MiniportSendNetBufferLists* must protect the queue with a spin lock so that only one thread at a time can manipulate the links or contents. *MiniportSendNetBufferLists* acquires the spin lock, adds the packet to the queue and then releases the spin lock. Using a spin lock ensures that the thread holding the lock is the only thread modifying the queue links while the packet is safely added to the queue. When the miniport driver takes the packets off the queue, such an access is protected by the same spin lock. When running instructions that modify the head of the queue or any of the link fields making up the queue, the driver must protect the queue with a spin lock.

A driver must take care not to overprotect a queue. For example, the driver can perform some operations (for example, filling in a field containing the length) in the network driver-reserved field of a packet before it queues the packet. The driver can do this outside the code region protected by the spin lock, but must do it before queuing the packet. After the packet is on the queue and the running thread releases the spin lock, the driver must assume that other threads can dequeue the packet immediately.

Avoiding Spin Lock Problems

To avoid a possible deadlock, an NDIS driver should release all NDIS spin locks before calling an NDIS function other than an **Ndis*Xxx*Spinlock** function. If an NDIS driver does not comply with this requirement, a deadlock could occur as follows:

1. Thread 1, which holds NDIS spin lock A, calls an **Ndis*Xxx*** function that attempts to acquire NDIS spin lock B by calling the NdisAcquireSpinLock function.

2. Thread 2, which holds NDIS spin lock B, calls an **Ndis*Xxx*** function that attempts to acquire NDIS spin lock A by calling the **NdisAcquireSpinLock** function.

3. Thread 1 and thread 2, which are each waiting for the other to release its spin lock, become deadlocked.

Microsoft Windows operating systems do not restrict a network driver from simultaneously holding more than one spin lock. However, if one section of the driver attempts to acquire spin lock A while holding spin lock B, and another section attempts to acquire spin lock B while holding spin lock A, deadlock results. If it acquires more than one spin lock, a driver should avoid deadlock by enforcing an order of acquisition. That is, if a driver enforces acquiring spin lock A before spin lock B, the situation described above will not occur.

Acquiring a spin lock raises the IRQL to DISPATCH_LEVEL and stores the old IRQL in the spin lock. Releasing the spin lock sets the IRQL to the value stored in the spin lock. Because NDIS sometimes enters drivers at PASSIVE_LEVEL, problems can arise with the following code sequence:

syntax

```
NdisAcquireSpinLock(A);
NdisAcquireSpinLock(B);
NdisReleaseSpinLock(A);
NdisReleaseSpinLock(B);
```

A driver should not access spin locks in this sequence for the following reasons:

- Between releasing spin lock A and releasing spin lock B, the code is running at PASSIVE_LEVEL instead of DISPATCH_LEVEL and is subject to inappropriate interruption.

- After releasing spin lock B, the code is running at DISPATCH_LEVEL which could cause the caller to fault at much later time with an IRQL_NOT_LESS_OR_EQUAL stop error.

Using spin locks impacts performance and, in general, a driver should not use many spin locks. Occasionally, functions that are usually distinct (for example, send and receive functions) have minor overlaps for which two spin locks can be used. Use of more than one spin lock might be a worthwhile tradeoff in order to allow the two functions to operate independently on separate processors.

Timers

Timers are used for polling or timing out operations. A driver creates a timer and associates a function with the timer. The associated function is called when the period specified in the timer expires. Timers can be one-shot or periodic. Once a periodic timer is set, it will continue to fire at the expiration of every period until explicitly cleared. A one-shot timer must be reset each time it fires.

Timers are created and initialized by calling **NdisAllocateTimerObject** and set by calling **NdisSetTimerObject**. If a nonperiodic timer is used, it must reset by calling **NdisSetTimerObject**. A timer is cleared by calling **NdisCancelTimerObject**.

Events

Events are used to synchronize operations between two threads of execution. An event is allocated by a driver and initialized by calling **NdisInitializeEvent**. A thread running at IRQL = PASSIVE_LEVEL calls **NdisWaitEvent** to put itself into a wait state. When a driver thread waits on an event, it specifies a maximum time to wait as well as the event to be waited on. The thread's wait is satisfied when **NdisSetEvent** is called causing the event to be signaled, or when the specified maximum wait-time interval expires, whichever occurs first.

Typically, the event is set by a cooperating thread that calls **NdisSetEvent**. Events are unsignaled when they are created and must be set in order to signal waiting threads. Events remain signaled until **NdisResetEvent** is called.

Packet Structures in Network Drivers

Article • 12/15/2021

In NDIS 6.0 and later versions, a higher layer driver allocates **NET_BUFFER** and **NET_BUFFER LIST** structures to hold network packet information, and sends the structures to the next lower NDIS driver so that the data can be sent on the network. Lower-level drivers allocate NET_BUFFER and NET_BUFFER_LIST structures to hold received data and pass the structures up to interested higher-layer drivers. Sometimes, a higher layer driver allocates structures and passes them to a lower layer driver with a request for the lower layer driver to copy received data into the buffers provided. NDIS provides functions for allocating and manipulating the substructures that make up the NET_BUFFER and NET_BUFFER_LIST structures.

For more information about the structure of network data buffers in NDIS drivers, see NET_BUFFER Architecture.

Using Shared Memory in Network Drivers

Article • 12/15/2021

Miniport drivers for bus-master direct memory access (DMA) devices allocate shared memory for use by the network interface card (NIC) and the miniport driver.

NdisMAllocateSharedMemory can be called by a bus-master miniport driver to allocate memory for permanent sharing between the network adapter and the miniport driver. This function returns a virtual address and a physical address for the shared memory. The addresses are valid until a call to NdisMFreeSharedMemory frees the memory.

Asynchronous I/O and Completion Functions in Network Drivers

Article • 12/15/2021

Latency is inherent in some network operations. Because of this latency, many of the upper-edge functions provided by a miniport driver and the lower-edge functions of a protocol driver are designed to support asynchronous operation. Rather than wasting CPU cycles waiting in a loop for some time-consuming task to finish or a hardware event to signal, network drivers rely on the ability to handle most operations asynchronously.

Asynchronous network I/O is supported by using a *completion* function. The following example illustrates using a completion function for a network *send* operation, but this same mechanism exists for many other operations that are performed by a protocol or miniport driver.

When a protocol driver calls NDIS to send a packet, resulting in a call to the miniport driver's *MiniportSendNetBufferLists* function, the miniport driver can try to complete this request immediately and return an appropriate status value as a result. For synchronous operation, the possible responses are NDIS_STATUS_SUCCESS for successful completion of the send, NDIS_STATUS_RESOURCES, and NDIS_STATUS_FAILURE indicating a failure of some kind.

But a send operation can take some time to complete while the miniport driver (or NDIS) queues the packet and waits for the NIC to indicate the result of the send operation. The miniport driver *MiniportSendNetBufferLists* function can handle this operation asynchronously by returning a status value of NDIS_STATUS_PENDING. When the miniport driver completes the send operation, it calls the completion function, **NdisMSendNetBufferListsComplete**, passing a pointer to the packet descriptor that was sent. This information is passed to the protocol driver, signaling completion.

Most driver operations that can require an extended time to complete support asynchronous operation with a similar completion function. Such functions have names of the form **NdisM*Xxx*Complete**.

Completion functions are also provided to:

- Set and querying configuration.
- Reset hardware.
- Indicate status.

- Indicate received data.
- Transfer received data.

Security Issues for Network Drivers

Article • 12/15/2021

For a general discussion on writing secure drivers, see Creating Reliable Kernel-Mode Drivers.

Beyond following safe coding practices and the general device driver guidance, network drivers should do the following to enhance security:

- All network drivers should validate values that they read from the registry. Specifically, the caller of **NdisReadConfiguration** or **NdisReadNetworkAddress** must not make any assumptions about values read from the registry and must validate each registry value that it reads. If the caller of **NdisReadConfiguration** determines that a value is out of bounds, it should use a default value instead. If the caller of **NdisReadNetworkAddress** determines that a value is out of bounds, it should use the permanent medium access control (MAC) address or a default address instead.

OID-specific issues

- A miniport driver, in its *MiniportOidRequest* or **MiniportCoOidRequest** functions, should validate any object identifier (OID) value that the driver is requested to set. If the driver determines that the value to be set is out of bounds, it should fail the set request. For more information about object identifiers, see Obtaining and Setting Miniport Driver Information and NDIS Support for WMI.

- If an intermediate driver's *MiniportOidRequest* function does not pass a set operation to an underlying miniport driver, the function should validate the OID value. For more information, see Intermediate Driver Query and Set Operations.

Query OID security guidelines

Most Query OIDs can be issued by any usermode application on the system. Follow these specific guidelines for Query OIDs.

1. Always validate the size of the buffer is large enough for the output. Any query OID handler without an output buffer size check has a security bug.

```C++
if (oid->DATA.QUERY_INFORMATION.InformationBufferLength <
sizeof(ULONG)) {
    oid->DATA.QUERY_INFORMATION.BytesNeeded = sizeof(ULONG);
    return NDIS_STATUS_INVALID_LENGTH;
}
```

2. Always write a correct and minimal value to BytesWritten. It is a red flag to assign `oid->BytesWritten = oid->InformationBufferLength` like the following example does.

C++

```
// ALWAYS WRONG
oid->DATA.QUERY_INFORMATION.BytesWritten =
DATA.QUERY_INFORMATION.InformationBufferLength;
```

The OS will copy BytesWritten bytes back to a usermode application. If BytesWritten is larger than the number of bytes the driver actually wrote, then the OS might end up copying back uninitialized kernel memory to usermode, which would be an information disclosure vulnerability. Instead, use code similar to this:

C++

```
oid->DATA.QUERY_INFORMATION.BytesWritten = sizeof(ULONG);
```

3. Never read values back from the buffer. In some cases, the output buffer of an OID is directly mapped into a hostile usermode process. The hostile process can change your output buffer after you've written to it. For example, the code below can be attacked, because an attacker can change NumElements after it is written:

C++

```
output->NumElements = 4;
for (i = 0 ; i < output->NumElements ; i++) {
    output->Element[i] = . . .;
}
```

To avoid reading back from the buffer, keep a local copy. For example, to fix the above example, introduce a new stack variable:

C++

```
ULONG num = 4;
output->NumElements = num;
for (i = 0 ; i < num; i++) {
    output->Element[i] = . . .;
}
```

With this approach, the for loop reads back from the driver's stack variable `num` and not from its output buffer. The driver should also mark the output buffer with the `volatile` keyword, to prevent the compiler from silently undoing this fix.

Set OID security guidelines

Most Set OIDs can be issued by a usermode application running in the Administrators or System security groups. Although these are generally trusted applications, the miniport driver still must not permit memory corruption or injection of kernel code. Follow these specific rules for Set OIDs:

1. Always validate the input is large enough. Any OID set handler without an input buffer size check has a security vulnerability.

   C++

   ```
   if (oid->DATA.SET_INFORMATION.InformationBufferLength < sizeof(ULONG))
   {
       return NDIS_STATUS_INVALID_LENGTH;
   }
   ```

2. Whenever validating an OID with an embedded offset, you must validate that the embedded buffer is within the OID payload. This requires several checks. For example, OID_PM_ADD_WOL_PATTERN may deliver an embedded pattern, that needs to be checked. Correct validation requires checking:

   a. InformationBufferSize >= sizeof(NDIS_PM_PACKET_PATTERN)

   C++

   ```
   PmPattern = (PNDIS_PM_PACKET_PATTERN) InformationBuffer;
   if (InformationBufferLength < sizeof(NDIS_PM_PACKET_PATTERN))
   {
       Status = NDIS_STATUS_BUFFER_TOO_SHORT;
       *BytesNeeded = sizeof(NDIS_PM_PACKET_PATTERN);
       break;
   }
   ```

   b. Pattern->PatternOffset + Pattern->PatternSize does not overflow

   C++

   ```
   ULONG TotalSize = 0;
   if (!NT_SUCCESS(RtlUlongAdd(Pattern->PatternOffset, Pattern->PatternSize, &TotalSize) ||
   ```

```
    TotalSize > InformationBufferLength)
{
    return NDIS_STATUS_INVALID_LENGTH;
}
```

These two checks can be combined using code like the following example:

C++

```
ULONG TotalSize = 0;
if (InformationBufferLength < sizeof(NDIS_PM_PACKET_PATTERN) ||
    !NT_SUCCESS(RtlUlongAdd(Pattern->PatternSize, Pattern-
>PatternOffset, &TotalSize) ||
    TotalSize > InformationBufferLength)
{
    return NDIS_STATUS_INVALID_LENGTH;
}
```

c. InformationBuffer + Pattern->PatternOffset + Pattern->PatternLength does not overflow

C++

```
ULONG TotalSize = 0;
if (!NT_SUCCESS(RtlUlongAdd(Pattern->PatternOffset, Pattern-
>PatternLength, &TotalSize) ||
    (!NT_SUCCESS(RtlUlongAdd(TotalSize, InformationBuffer,
&TotalSize) ||
    TotalSize > InformationBufferLength)
{
    return NDIS_STATUS_INVALID_LENGTH;
}
```

d. Pattern->PatternOffset + Pattern->PatternLength <= InformationBufferSize

C++

```
ULONG TotalSize = 0;
if(!NT_SUCCESS(RtlUlongAdd(Pattern->PatternOffset, Pattern-
>PatternLength, &TotalSize) ||
    TotalSize > InformationBufferLength))
{
    return NDIS_STATUS_INVALID_LENGTH;
}
```

Method OID security guidelines

Method OIDs can be issued by a usermode application running in the Administrators or System security groups. They are a combination of a Set and a Query, so both preceding lists of guidance also apply to Method OIDs.

Other network driver security issues

- Many NDIS miniport drivers expose a control device by using NdisRegisterDeviceEx. Those that do this must audit their IOCTL handlers, with all the same security rules as a WDM driver. For more information, see Security Issues for I/O Control Codes.

- Well-designed NDIS miniport drivers should not rely on being called in a particular process context, nor interact very closely with usermode (with IOCTLs & OIDs being the exception). It would be a red flag to see a miniport that opened usermode handles, performed usermode waits, or allocated memory against usermode quota. That code should be investigated.

- Most NDIS miniport drivers should not be involved in parsing packet payloads. In some cases, though, it may be necessary. If so, this code should be audited very carefully, as the driver is parsing data from an untrusted source.

- As is standard when allocating kernel-mode memory, NDIS drivers should use appropriate NX Pool Opt-In Mechanisms. In WDK 8 and newer, the `NdisAllocate*` family of functions are properly opted in.

Driver Stack Management

Article • 12/15/2021

NDIS 6.0 introduced the ability to pause and restart a driver stack. To support the stack management features that NDIS 6.0 provides, you must rewrite legacy drivers.

NDIS 6.0 also introduced NDIS filter drivers. Filter drivers can monitor and modify the interaction between protocol drivers and miniport drivers. Filter drivers are easier to implement and have less processing overhead than NDIS 5.*x* intermediate drivers. For these reasons, you should use filter drivers instead of filter intermediate drivers.

A driver stack contains the following logical elements:

Miniport Adapter
A *miniport adapter* is an adapter instance of an NDIS miniport driver or intermediate driver. The virtual miniport of an intermediate driver is a miniport adapter. NDIS configures the other elements of a driver stack over a miniport adapter after a device becomes available.

Protocol Binding
A *protocol binding* is a binding instance of a protocol driver. A protocol binding binds an NDIS protocol driver to a miniport adapter. Multiple protocol drivers can bind to a miniport adapter.

Filter Module
A *filter module* is an instance of a filter driver. NDIS can pause a driver stack to insert, remove, or reconfigure a filter module. Filter modules can monitor and modify the behavior of a miniport adapter.

The following topics provide more information about the driver stack, driver states, and driver stack operations:

- NDIS Driver Stack
- Adapter States of a Miniport Driver
- Binding States of a Protocol Driver
- Module States of a Filter Driver
- NDIS Stack Operations

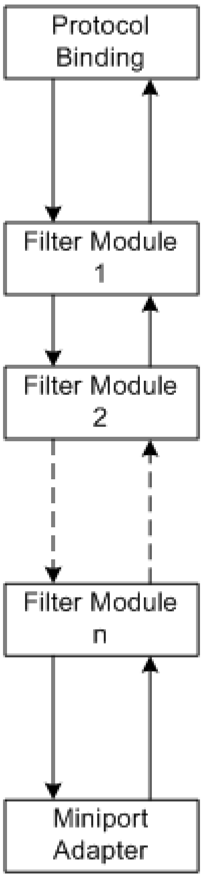
NDIS Driver Stack

Article • 03/14/2023

Basic Stack Configuration

The following figure shows a basic configuration of the logical elements in an NDIS 6.0 driver stack. The figure illustrates a driver stack with an unspecified number of filter modules. The arrows represent information flow between the elements of the stack.



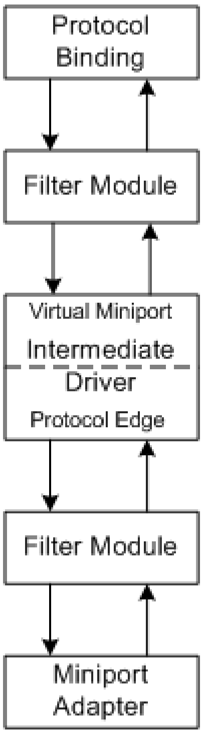
As the preceding figure shows, you can stack any number of filter modules over a miniport adapter. These modules can be instances of different filter drivers and/or multiple instances of the same filter driver. If a miniport driver manages more than one miniport adapter, a separate driver stack can exist over each miniport adapter.

Protocol drivers bind to miniport adapters. Therefore, underlying filter modules in a driver stack are transparent to protocol drivers. To obtain information about underlying filter modules, protocol drivers can enumerate the filter modules in a driver stack.

If more than one protocol driver binds to an miniport adapter, the filter modules are the same for both protocol drivers. Based upon the binding, NDIS routes requests to the correct protocol driver.

NDIS 6.0 Stack with Intermediate Driver

The following figure shows an NDIS 6.0 driver stack with an intermediate driver.



If you include an NDIS intermediate driver in the driver stack, the stack is essentially two stacks: one above the other.

The intermediate driver's virtual miniport provides the miniport adapter for the upper stack, whereas the intermediate driver's protocol edge provides the protocol binding for the lower stack.

A virtual miniport has the same states as any other miniport adapter. For more information about miniport adapter states, see Adapter States of a Miniport Driver.

The protocol edge of the intermediate driver should implement the same binding states as a protocol driver. For more information about binding states, see Binding States of a Protocol Driver.

Adapter States of a Miniport Driver

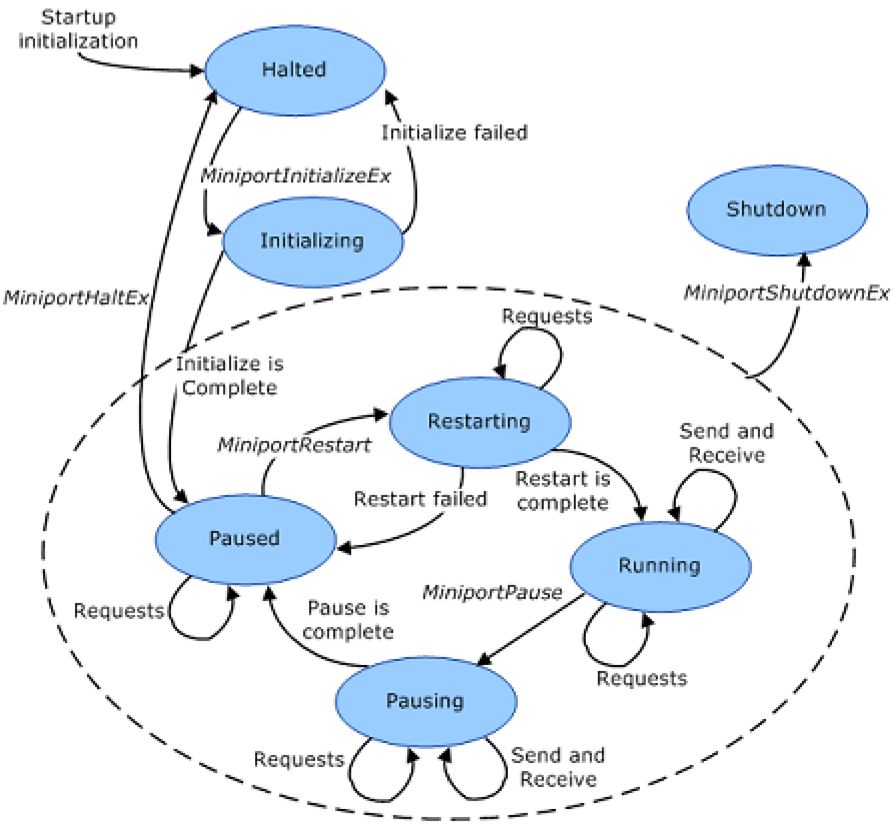
Article • 12/15/2021

For each miniport adapter that it manages, an NDIS miniport driver must support the following set of operational states:

- Halted
- Shutdown
- Initializing
- Paused
- Restarting
- Running
- Pausing

The following figure shows the interrelationships between these states.



Note The reset operation does not affect miniport adapter operational states. Also, the state of the adapter might change while a reset operation is in progress. For example, NDIS might call a driver's pause handler when there is a reset operation in progress. In this case, the driver can complete either the reset or the pause operation in any order while following the normal requirements for each operation. For a reset operation, the driver can fail transmit request packets or it can keep them queued and complete them later. However, you should note that an overlying driver cannot complete a pause operation while its transmit packets are pending.

The following defines the adapter states:

Halted
Halted is the initial state of all miniport adapters. When a miniport adapter is in the Halted state, and NDIS calls the driver's *MiniportInitializeEx* function to initialize the miniport adapter, the miniport adapter enters the Initializing state. If *MiniportInitializeEx* fails, the miniport adapter returns to the Halted state. When the miniport adapter is in the Paused state and NDIS calls the *MiniportHaltEx* function, the miniport adapter returns to the Halted state.

Shutdown
A miniport adapter in the *Shutdown* state cannot be used until the system is shut down and restarted. When the miniport adapter is in the Paused, Restarting, Running, or Pausing state and NDIS calls the miniport driver's *MiniportShutdownEx* function, the miniport adapter enters the Shutdown state.

Initializing
In the *Initializing* state, a miniport driver completes any operations that are required to initialize a miniport adapter. When a miniport adapter is in the Halted state and the NDIS calls the miniport driver's *MiniportInitializeEx* function, the miniport adapter enters the Initializing state. If *MiniportInitializeEx* succeeds, the miniport adapter enters the Paused state. If *MiniportInitializeEx* fails, the miniport adapter returns to the Halted state.

Paused
When a miniport adapter is in the *Paused* state, a miniport driver does not indicate received network data or accept send requests. When a miniport adapter is in the Pausing state and the pause operation is complete, the miniport adapter enters the Paused state. When a miniport adapter is in the Initializing state and *MiniportInitializeEx* is successful, the miniport adapter enters the Paused state. When NDIS calls the miniport driver's **MiniportRestart** function, the miniport adapter transitions from the Paused state to the Restarting state. When NDIS calls the miniport driver's *MiniportHaltEx* function, the miniport adapter transitions from the Paused state to the Halted state.

Restarting
In the *Restarting* state, a miniport driver completes any operations that are required to restart send and receive operations for a miniport adapter. When a miniport adapter is in the Paused state and NDIS calls the driver's *MiniportRestart* function, the miniport

adapter enters the Restarting state. If the restart fails, the miniport adapter returns to the Paused state. If the restart is successful, the miniport adapter enters the Running state.

Running
In the *Running* state, a miniport driver performs normal send and receive processing for a miniport adapter. When the miniport adapter is in the Restarting state and the driver is ready to perform send and receive operations, the miniport adapter enters the Running state.

Pausing
In the *Pausing* state, a miniport driver completes any operations that are required to stop send and receive operations for a miniport adapter. The driver must wait for NDIS to return all outstanding receive indications. When a miniport adapter is in the Running state and NDIS calls the driver's *MiniportPause* function, the miniport adapter enters the Pausing state. A miniport driver cannot fail a pause operation. When the pause operation is complete, the miniport adapter enters the Paused state.

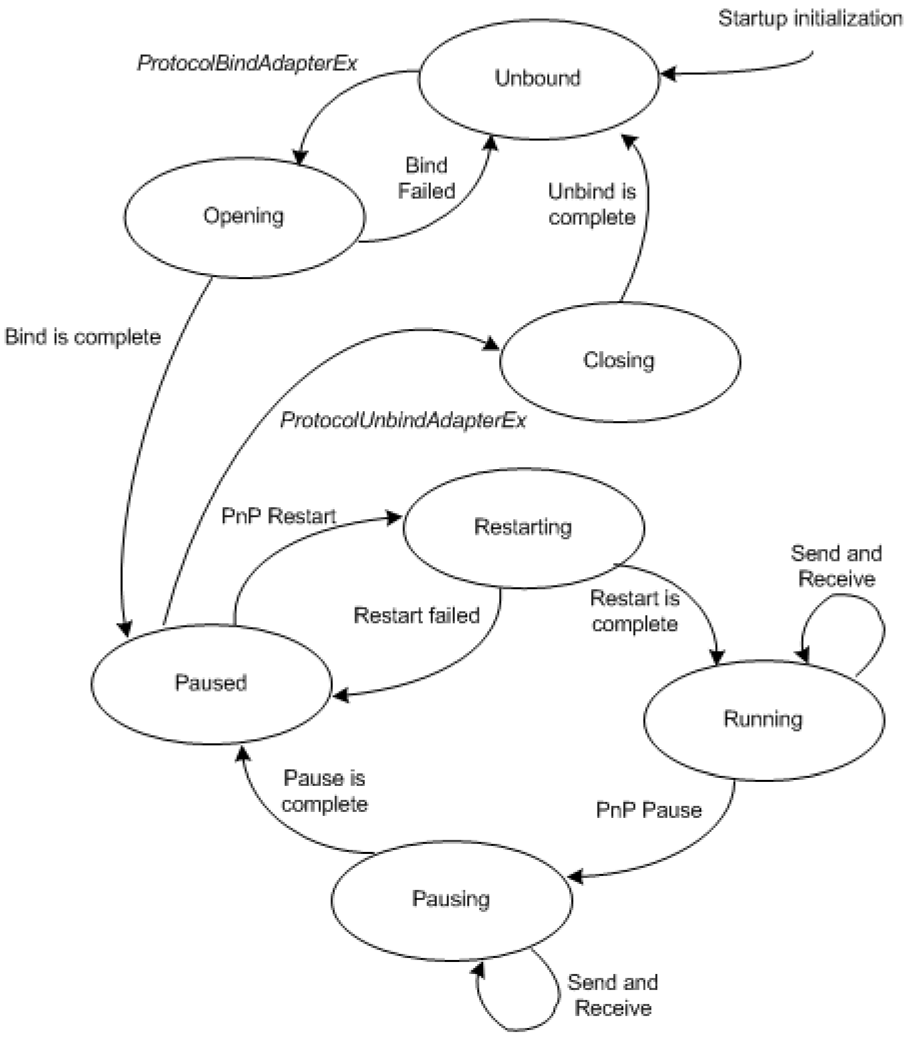
Binding States of a Protocol Driver

Article • 12/15/2021

An NDIS protocol driver must support the following operational states for each binding that the driver manages:

- Unbound
- Opening
- Running
- Closing
- Pausing
- Paused
- Restarting

The following figures shows the relationship between these states.



The following defines the protocol driver binding states:

Unbound
The *Unbound* state is the initial state of a binding. In this state, the protocol driver waits for NDIS to call the *ProtocolBindAdapterEx* function. After NDIS calls *ProtocolBindAdapterEx*, the binding enters the Opening state. After an unbind operation is complete, a binding returns to the Unbound state from the Closing state.

Opening
In the *Opening* state, a protocol driver allocates resources for the binding and attempts to open the miniport adapter. After NDIS calls the driver's *ProtocolBindAdapterEx* function, the binding enters the Opening state. If the protocol driver fails to bind to the miniport adapter, the binding returns to the Unbound state. If the driver successfully binds to the miniport adapter, the binding enters the Paused state.

Running
In the *Running* state, a protocol driver performs normal send and receive processing for a binding. When the binding is in the Restarting state and the driver is ready to perform send and receive operations, the binding enters the Running state.

Closing
In the *Closing* state, the protocol driver closes the binding to the miniport adapter and then releases the resources for the binding. After NDIS calls the protocol driver's *ProtocolUnbindAdapterEx* function, the binding enters the Closing state. After the protocol driver completes the unbind operations, the binding enters the Unbound state.

Pausing
In the *Pausing* state, a protocol driver completes any operations that are required to stop send and receive operations for a binding. When a binding is in the Running state and NDIS sends the protocol driver a PnP pause notification, the binding enters the Pausing state. The protocol driver must wait for all its outstanding send request to complete. A protocol driver cannot fail a pause operation. After the pause operation is complete, the binding enters the Paused state.

Paused
In the *Paused* state, the protocol driver does not perform send or receive operations for a binding. When a binding is in the Pausing state and a pause operation is complete, the binding enters the Paused state. When a binding is in the Opening state and a open operation completes successfully, the binding enters the Paused state. If NDIS sends the protocol driver a PnP restart notification for the binding, the binding enters the Restarting state. If NDIS calls the driver's *ProtocolUnbindAdapterEx* function, the binding enters the Closing state.

Restarting
In the *Restarting* state, a protocol driver completes any operations that are required to restart send and receive operations for a binding. When a binding is in the Paused state and NDIS sends the protocol driver a PnP restart notification, the binding enters the Restarting state. If the restart fails, the binding returns to the Paused state. If the restart is successful, the binding enters the Running state.

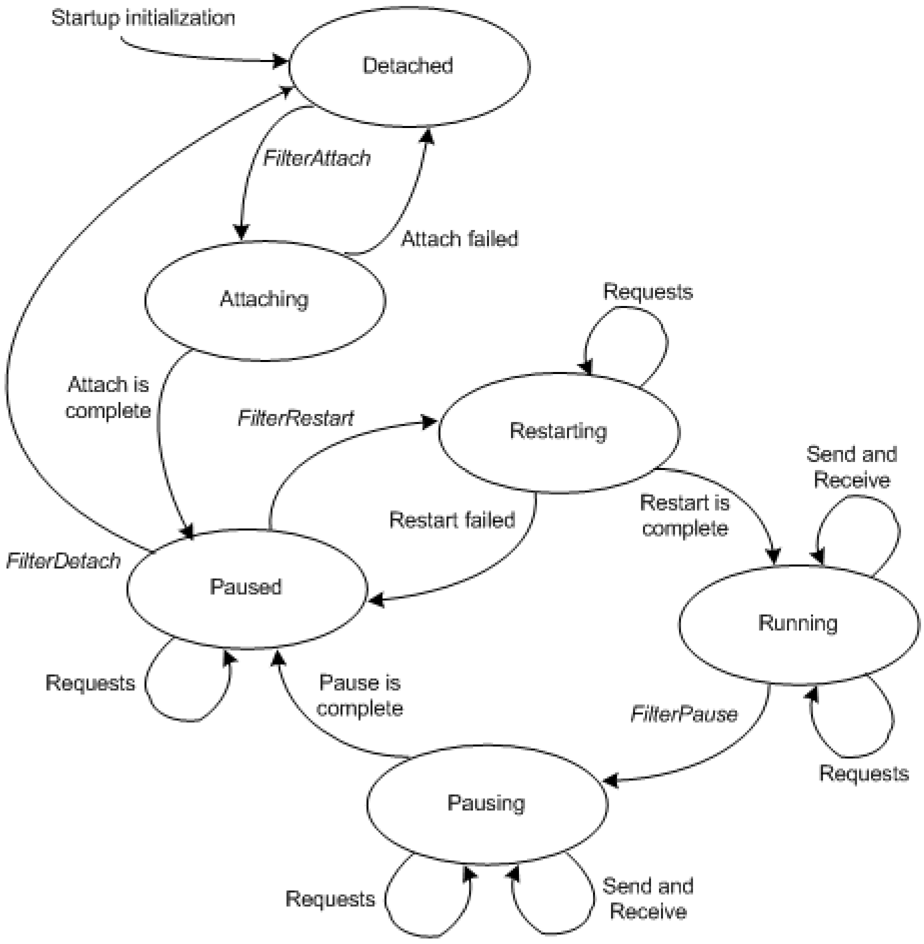
Module States of a Filter Driver

Article • 12/15/2021

An NDIS filter driver must support the following operational states for each filter module (instance of a filter driver) that the driver manages:

- Detached
- Attaching
- Paused
- Restarting
- Running
- Pausing

The following figure shows the relationships between these states.



The following defines the filter module states:

Detached

The *Detached* state is the initial state of a filter module. When a filter module is in this state, NDIS can call the filter driver's *FilterAttach* function to attach the filter module to the driver stack. When NDIS calls a filter driver's *FilterAttach* function, the filter module enters the Attaching state. If the attach operation fails, the filter module returns to the Detached state. When the module is in the Paused state and NDIS calls the *FilterDetach* function, the module returns to the Detached state.

Attaching
When a filter module is in the *Attaching* state, a filter driver prepares to attach the module to the driver stack. After the filter module preparation is complete, the filter module enters the Paused state. If a failure occurs (for example, because the required resources are not available), the filter module returns to the Detached state.

Paused
When a filter module is in the *Paused* state, the filter module does not perform send or receive operations. When a filter module is in the *Attaching* state and *FilterAttach* is successful, the filter module enters the *Paused* state. When a filter module is in the *Pausing* state and the pause operation completes, the filter module enters the *Paused* state. When a filter module is in the *Paused* state and NDIS calls the filter driver's **FilterRestart** function, the filter module enters the *Restarting* state. When a filter module is in the *Paused* state and NDIS calls the driver's *FilterDetach* handler, the filter module enters the *Detached* state.

Restarting
In the *Restarting* state, a filter driver completes any operations that are required to restart send and receive operations for a filter module. When a filter module is in the Paused state and NDIS calls the driver's *FilterRestart* function, a filter module enters the Restarting state. If the restart fails, the filter module returns to the Paused state. If the restart is successful, the filter module enters the Running state.

Running
In the *Running* state, a filter driver performs normal send and receive processing for a filter module. When the filter module is in the Restarting state and the driver is ready to perform send and receive operations, the filter module enters the Running state.

Pausing
In the *Pausing* state, a filter driver completes any operations that are required to stop send and receive operations for a filter module. The filter driver must wait for all its outstanding send requests to complete and for NDIS to return all its outstanding receive indications. When a filter module is in the Running state and NDIS calls the driver's *FilterPause* function, the filter module enters the Pausing state. A filter driver cannot fail a pause operation. After the pause operation is complete, the filter module enters the Paused state.

NDIS Filter Drivers

Starting a Driver Stack

Article • 12/15/2021

After the system detects a networking device, the system starts an NDIS driver stack for the device. The device can be a virtual device or a physical device. In either case, a driver stack start operation proceeds as follows:

1. The system loads and initializes the drivers if they are not already loaded.

   It does not load the drivers in any particular order.

2. The system calls each driver's **DriverEntry** function.

   After **DriverEntry** returns:

   - The miniport adapter for the device is in the Halted state.
   - The filter modules are in the Detached state.
   - The protocol binding is in the Unbound state.

3. The system requests NDIS to start the miniport adapter.

   To initialize the miniport adapter, NDIS calls the miniport driver's *MiniportInitializeEx* function. If *MiniportInitializeEx* is successful, the miniport adapter enters the Paused state.

4. NDIS attaches the filter modules, beginning with the module that is closest to the miniport driver and progressing to the top of the driver stack.

   To request the driver to attach a filter module to the driver stack, NDIS calls a filter driver's *FilterAttach* function. If each attach operation is successful, the filter module enters the Paused state.

5. After all the underlying drivers are in the Paused state, NDIS calls the protocol driver's *ProtocolBindAdapterEx* function.

   Then the protocol driver binding enters the Opening state. The protocol driver calls the **NdisOpenAdapterEx** function to open the binding with the miniport adapter.

6. NDIS allocates the necessary resources for the binding and calls the protocol driver's *ProtocolOpenAdapterCompleteEx* function.

   The binding enters the Paused state.

7. To complete the bind operation, the protocol driver calls the **NdisCompleteBindAdapterEx** function.

8. NDIS restarts the driver stack. For more information about restarting the driver stack, see Restarting a Driver Stack.

Stopping a Driver Stack

Article • 12/15/2021

If a device is removed, NDIS stops a driver stack. A driver stack stop operation proceeds as follows:

1. NDIS pauses the driver stack. For more information about pausing the driver stack, see Pausing a Driver Stack.

2. NDIS calls the protocol driver's *ProtocolUnbindAdapterEx* function.

   The binding enters the Closing state. After outstanding OID and send requests are complete and all receive data is returned, the binding enters the Unbound state.

3. NDIS detaches all the filter modules, beginning from the top of the stack and progressing down to the miniport driver.

   After NDIS calls a filter driver's *FilterDetach* function and the filter driver releases all the resources for a filter module, the filter module is in the Detached state.

4. NDIS halts the miniport adapter.

   After NDIS calls the miniport driver's *MiniportHaltEx* function, the miniport driver releases all the resources for the miniport adapter and the miniport adapter is in the Halted state.

5. If all of a filter driver's modules are detached, the system can unload the filter driver.

6. If all the miniport adapters that a miniport driver manages are halted, the system can unload the miniport driver.

Pausing a Driver Stack

Article • 12/15/2021

NDIS pauses a driver stack to complete operations such as inserting a filter module or adding a binding. In general, a driver stack pause operation proceeds as follows:

1. NDIS sends a PnP pause event to the protocol driver.

   The binding enters the Pausing state. After all outstanding send requests are complete, the protocol driver completes the PnP event. The binding is in the Paused state.

2. NDIS pauses all the filter modules, beginning at the top of the stack and progressing down to the miniport driver.

   After NDIS calls the filter driver's *FilterPause* function, the filter module enters the Pausing state. After NDIS returns all outstanding receive indications, and all outstanding send operations are complete, the filter module enters the Paused state.

3. NDIS pauses the miniport adapter.

   After NDIS calls the miniport driver's *MiniportPause* function, the miniport adapter enters the Pausing state. After NDIS returns all outstanding receive indications, the miniport adapter enters the Paused state.

Note NDIS drivers cannot fail a pause request. You should log any errors that occur.

Restarting a Driver Stack

Article • 12/15/2021

NDIS restarts a driver stack after operations such as inserting a filter module or adding a binding. A driver stack restart operation proceeds as follows:

1. NDIS restarts the miniport adapter.

   After NDIS calls the miniport driver's **MiniportRestart** function, the miniport adapter enters the Restarting state. The miniport driver prepares to resume send and receive operations. If the preparation fails, the miniport adapter returns to the Paused state. After the driver is ready to resume send and receive operations, the miniport adapter enters the Running state.

2. NDIS restarts the filter modules, beginning at the bottom of the driver stack and progressing up to the protocol driver.

   After NDIS calls a filter driver's **FilterRestart** function, the filter module enters the Restarting state. The filter driver prepares to resume send and receive operations. If the preparation fails, the module returns to the Paused state. After the driver is ready to resume send and receive operations, the filter module enters the Running state.

3. NDIS sends a PnP restart event to the protocol driver.

   The binding enters the Restarting state. The protocol driver prepares to resume send and receive operations. If the preparation fails, the binding returns to the Paused state. After the protocol driver is ready to resume send and receive operations, the binding enters the Running state.

Modifying a Running Driver Stack

Article • 12/15/2021

NDIS modifies a driver stack for operations such as inserting, removing, or reconfiguring a filter module. NDIS can activate or deactivate the bypass mode in a filter module. For more information about bypass mode in filter drivers, see Data Bypass Mode.

Note If filter driver entry points change (that is, because of bypass mode), NDIS pauses and restarts the driver stack. Pause and restart could cause some network packets to be dropped on the transmit path, or receive path. Network protocols that provide a reliable transport mechanism might retry the network I/O operation in the case of a lost packet, but other protocols that do not guarantee reliability do not retry the operation.

NDIS modifies a running driver stack as follows:

1. NDIS pauses the driver stack.

   For more information, see Pausing a Driver Stack.

2. NDIS modifies the stack.

   For example, to add a filter module, NDIS determines where to insert the new filter module into the stack and creates, inserts, and attaches the filter module.

3. When a filter module is inserted or deleted, the characteristics of the driver stack might change. In this case, NDIS sends a Plug and Play event notification to all of the protocol bindings and filter modules in the driver stack to notify the drivers of this change.

4. NDIS restarts the driver stack.

   For more information, see Restarting a Driver Stack.

NET_BUFFER Architecture

Article • 12/15/2021

This section provides high level information about **NET_BUFFER** structures and related data structures and functions. NET_BUFFER structures provide an efficient means to package and manage network data.

The following topics are included in this section:

Network Data Structures

Retreat and Advance Operations

Dispatch IRQL Tracking

Send and Receive Operations

Ethernet Send and Receive Operations

Derived NET_BUFFER_LIST Structures

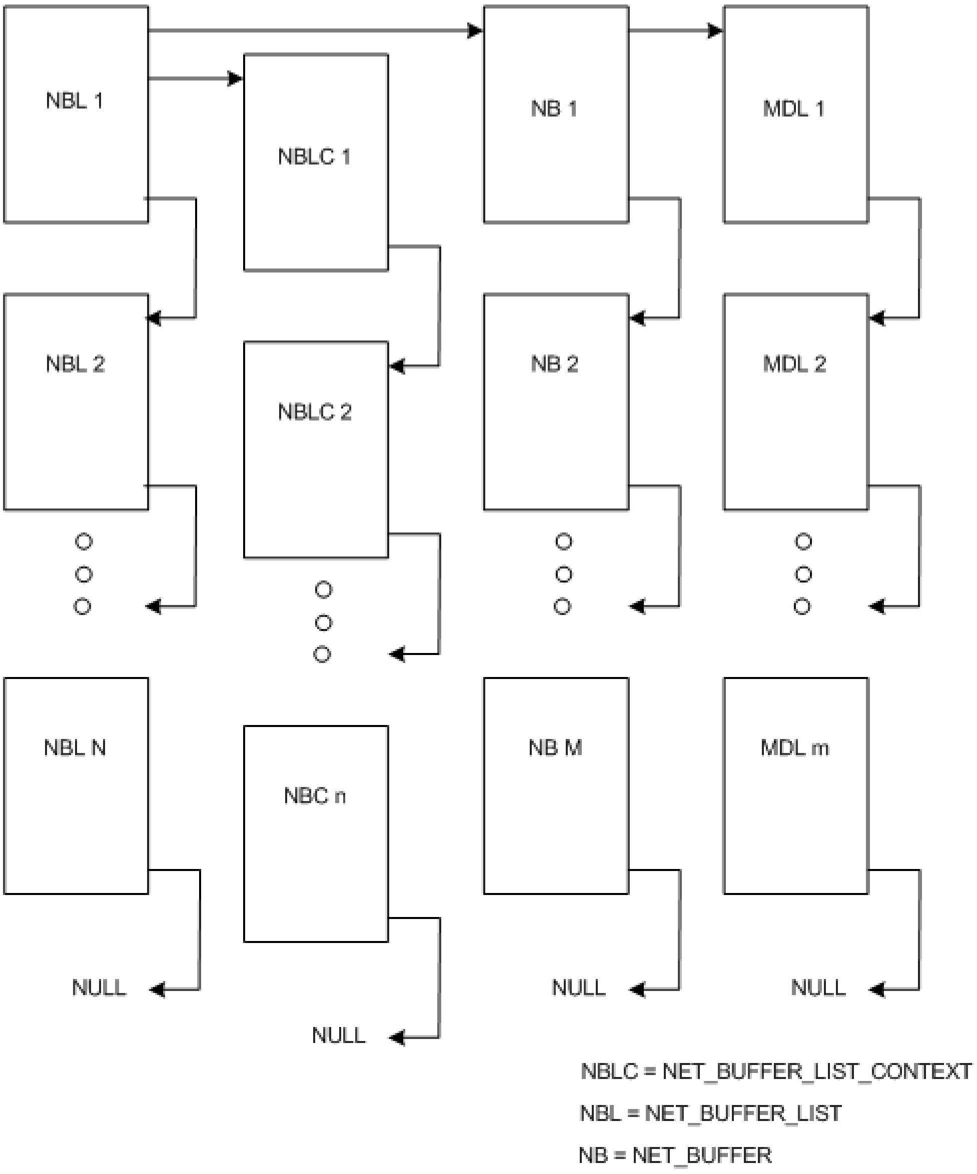
Network Data Structures

Article • 12/15/2021

Network data consists of packets of data that are sent or received over the network. NDIS provides data structures to describe and organize such data. The primary network data structures for NDIS 6.0 and later are:

- NET_BUFFER
- NET_BUFFER LIST
- NET_BUFFER_LIST_CONTEXT

The following figure illustrates the relationships between these structures.



In NDIS 6.0 and later, the NET_BUFFER is the basic building block for packaging network data. Each NET_BUFFER structure has an MDL chain. The MDLs map the addresses of data buffers to the data space that the NET_BUFFER structures specify. This data mapping is identical to the MDL chains that NDIS 5.*x* and earlier drivers use in the **NDIS_PACKET** structure. NDIS provides functions to manipulate the MDL chain.

Multiple NET_BUFFER structures can be attached to a NET_BUFFER_LIST structure. The NET_BUFFER structures are organized as a NULL-terminated singly linked list. Only the driver that originates a NET_BUFFER_LIST structure, or NDIS, should modify the linked list directly to insert and delete NET_BUFFER structures.

NET_BUFFER LIST structures contain information that describes all the **NET_BUFFER** structures that are attached to a list. If a driver requires additional space for context information, the driver can store such information in the NET_BUFFER_LIST_CONTEXT structures. NDIS provides functions to allocate, free and access the data in the NET_BUFFER_LIST_CONTEXT structures.

Multiple NET_BUFFER_LIST structures can be attached to form a list of NET_BUFFER_LIST structures. The NET_BUFFER_LIST structures are organized as a NULL-terminated singly linked list. Drivers can modify the linked list directly to insert and delete NET_BUFFER_LIST structures.

NET_BUFFER Structure

NET_BUFFER LIST

NET_BUFFER_LIST Structure

NET_BUFFER_LIST_CONTEXT

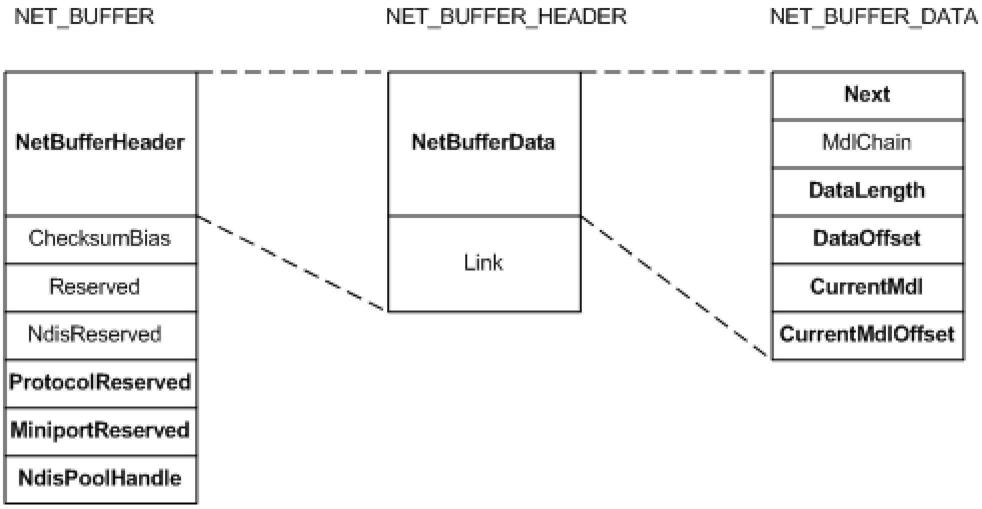
NET_BUFFER_LIST_CONTEXT Structure

NET_BUFFER Structure

Article • 12/15/2021

NDIS 6.0 and later NET_BUFFER structures are analogous to the NDIS_PACKET structures used by NDIS 5.*x* and earlier drivers. Each NET_BUFFER structure packages a packet of network data.

The following figure shows the fields in a NET_BUFFER structure.



The NET_BUFFER structure includes a NET_BUFFER_HEADER structure in the **NetBufferHeader** member. The NET_BUFFER_HEADER structure includes a NET_BUFFER_DATA structure in the **NetBufferData** member. You should use NDIS macros to access NET_BUFFER structure members. For a complete list of these macros, see the NET_BUFFER structure reference page.

Some of the NET_BUFFER structure members are only used by NDIS. The members that drivers typically use are:

ProtocolReserved
Reserved for use by protocol drivers.

MiniportReserved
Reserved for use by miniport drivers.

NdisPoolHandle
Specifies a pool handle that identifies the NET_BUFFER pool from which the NET_BUFFER structure was allocated.

Next
Specifies a pointer to the next NET_BUFFER structure in a linked list of NET_BUFFER structures. If this is the last NET_BUFFER structure in the list, this member is **NULL**.

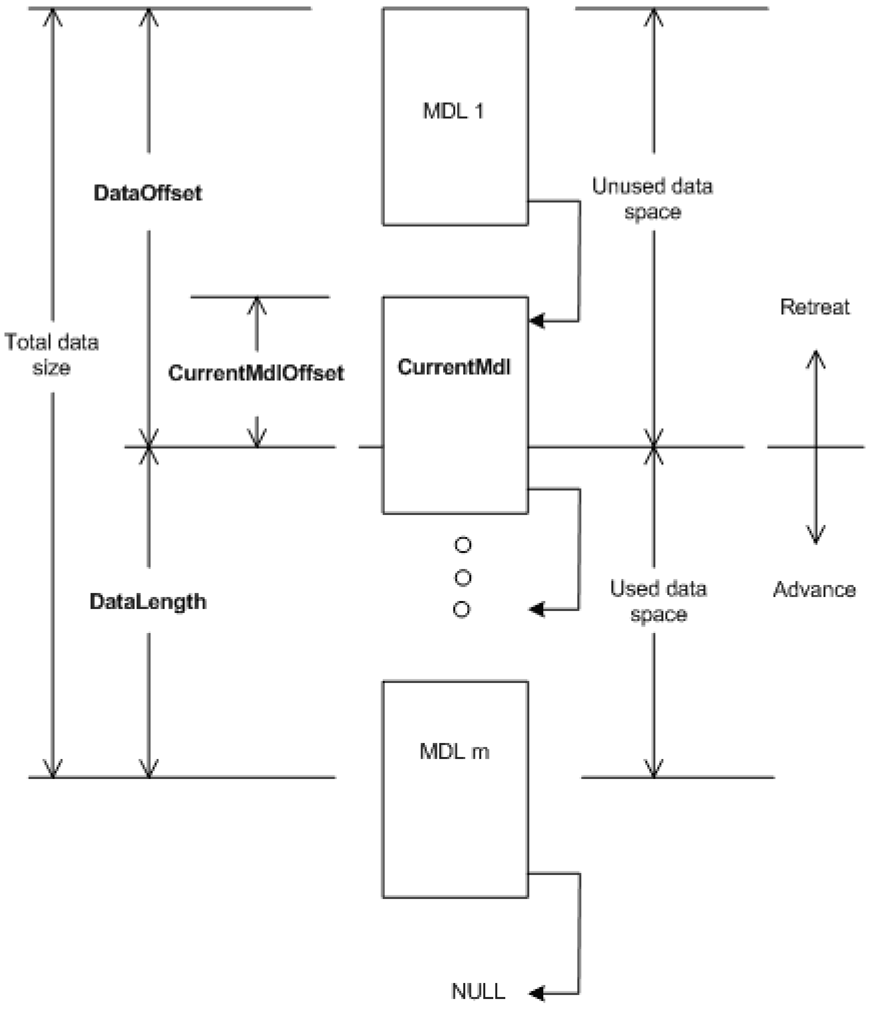
DataLength
Specifies the length in bytes of the network data in the MDL chain.

DataOffset
Specifies the offset, in bytes, from the start of memory in the MDL chain to the start of the network data in the MDL chain.

CurrentMdl
Specifies a pointer to the first MDL that the current driver is using. This pointer provides an optimization that improves performance by skipping over any MDLs that the current driver is not using.

CurrentMdlOffset
Specifies the offset, in bytes, to the beginning of the used data space in the MDL that is specified by the **CurrentMdl** member of the NET_BUFFER structure.

The following figure shows the relationship between the **CurrentMdl**, **CurrentMdlOffset**, **DataOffset**, and **DataLength** members and the data space.



NDIS provides functions to manage the data space in the MDL chain. How drivers use the data space changes dynamically with the current driver. Sometimes there is data space that is currently unused by the current driver. Although the *unused data space* is currently unused, it can contain valid data. For example, on the receive path, the *unused data space* can contain header information that was used by a lower level driver.

Drivers perform retreat and advance operations to increase and decrease the *used data space*. For more information about retreat and advance operations, see Retreat and Advance Operations.

The following terms and definitions describe elements of the **NET_BUFFER** data space:

Used data space
Used data space contains data that the current driver is using at the current time. Drivers increase *used data space* with retreat operations and reduce *used data space* with advance operations.

Unused data space
The current driver is not using this data space at the current time.

Total data size
The total data size is the sum of the size of the *used data space* and *unused data space*. To calculate the total size, add the **DataOffset** to the **DataLength** .

Retreat
Retreat operations increase the size of the *used data space*.

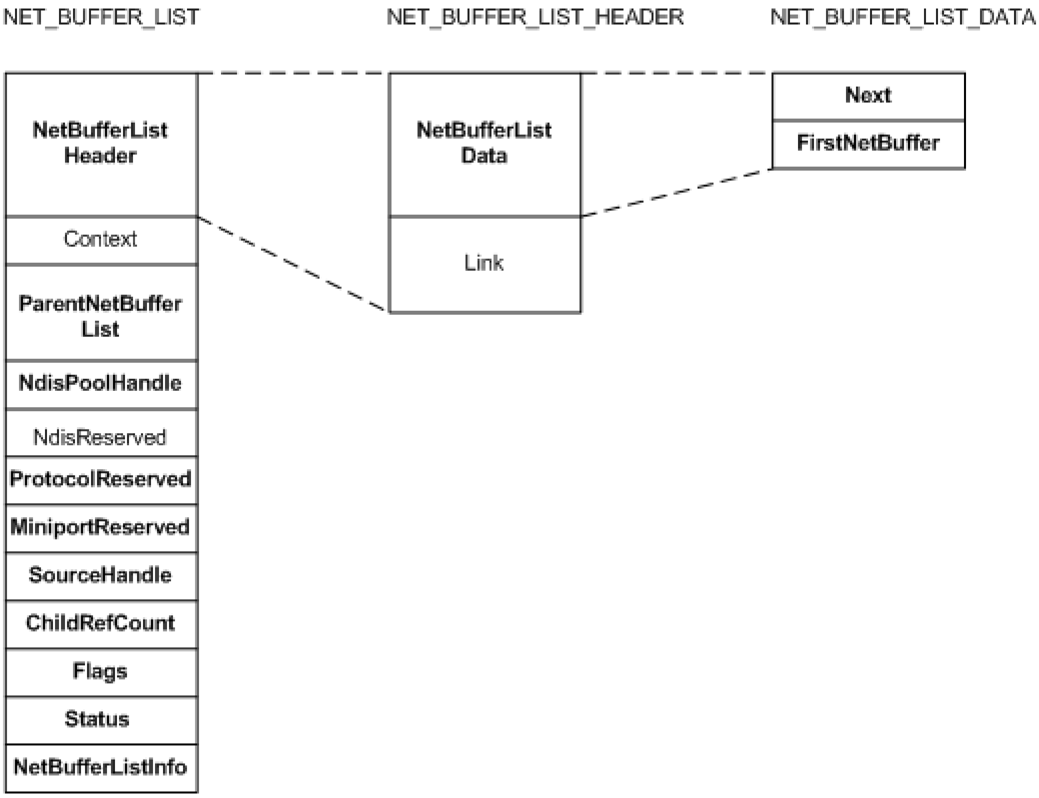
Advance
Advance operations decrease the size of the *used data space*.

NET_BUFFER_LIST Structure

Article • 12/15/2021

A NET_BUFFER_LIST structure packages a linked list of NET_BUFFER structures.

The following figure shows the fields in a NET_BUFFER_LIST structure.



The NET_BUFFER_LIST structure includes a NET_BUFFER_LIST_HEADER structure in the **NetBufferListHeader** member. The NET_BUFFER_LIST_HEADER structure includes a NET_BUFFER_LIST_DATA structure in the **NetBufferListData** member. You should use NDIS macros to access NET_BUFFER_LIST structure members. For more information about these macros, see the NET_BUFFER_LIST structure reference page.

Some of the members are only used by NDIS. The members that drivers are most likely to use are defined in the following list:

ParentNetBufferList

If a NET_BUFFER_LIST structure is a child that was derived from a parent(cloned, fragmented, or reassembled), **ParentNetBufferList** specifies a pointer to the parent NET_BUFFER_LIST structure. Otherwise, this parameter is **NULL**.

NdisPoolHandle

Specifies a pool handle that identifies the NET_BUFFER_LIST pool from which the NET_BUFFER_LIST structure was allocated.

ProtocolReserved
Reserved for use by protocol drivers.

MiniportReserved
Reserved for use by miniport drivers.

SourceHandle
A handle that NDIS provided to the driver in a binding or attaching operation by using one of the following driver-supplied routines:

Miniport Driver
MiniportInitializeEx

Protocol Driver
ProtocolBindAdapterEx

Filter Driver
FilterAttach

NDIS uses **SourceHandle** to return the NET_BUFFER_LIST structure to the driver that sent the NET_BUFFER_LIST structure. NDIS drivers should not read this handle.

ChildRefCount
If a **NET_BUFFER_LIST** structure is a parent (has children derived by clone, fragment, or reassemble operations), **ChildRefCount** specifies the number of existing children. Otherwise, this parameter is zero.

Flags
Reserved for future specification of attributes for the NET_BUFFER_LIST structure. There are currently no flags available to drivers.

Status
Specifies the final completion status of a network data operation for this NET_BUFFER_LIST structure. Miniport drivers write this value before completing a send operation.

NetBufferListInfo
Specifies **NET_BUFFER_LIST** structure information that is common to all **NET_BUFFER** structures in the list. This information is often referred to as "out-of-band (OOB) data."

Next
Specifies a pointer to the next NET_BUFFER_LIST structure in a linked list of NET_BUFFER_LIST structures. If a NET_BUFFER_LIST structure is the last structure in the list, this member is **NULL**.

FirstNetBuffer
Specifies a pointer to the first NET_BUFFER structure in a linked list of NET_BUFFER structures that is associated with this NET_BUFFER_LIST structure.

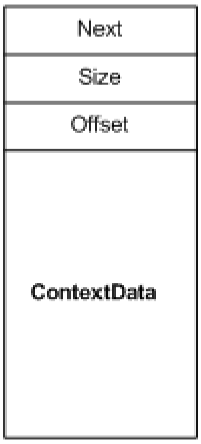
Note **Context** is a pointer to a **NET_BUFFER_LIST_CONTEXT** structure. NDIS provides macros and functions to manipulate the data at **Context** . For more information about the NET_BUFFER_LIST_CONTEXT structure, see NET_BUFFER_LIST_CONTEXT Structure.

NET_BUFFER_LIST_CONTEXT Structure

Article • 06/15/2022

NDIS drivers use NET_BUFFER_LIST_CONTEXT structures to store additional data that is associated with a NET_BUFFER_LIST structure. The **Context** member of the NET_BUFFER_LIST structure is a pointer to a NET_BUFFER_LIST_CONTEXT structure. The information stored in the NET_BUFFER_LIST_CONTEXT structures is opaque to NDIS and other drivers in the stack.

The following figure shows the fields in a NET_BUFFER_LIST_CONTEXT structure.



The NET_BUFFER_LIST_CONTEXT structure includes **ContextData** member that contains the context data. This data can be any context information that a driver requires for the NET_BUFFER_LIST structure.

Drivers should use the following NDIS macros and functions to access and manipulate members in a NET_BUFFER_LIST_CONTEXT structure:

NdisAllocateNetBufferListContext

NdisFreeNetBufferListContext

NET_BUFFER_LIST_CONTEXT_DATA_START

NET_BUFFER_LIST_CONTEXT_DATA_SIZE

Retreat and Advance Operations

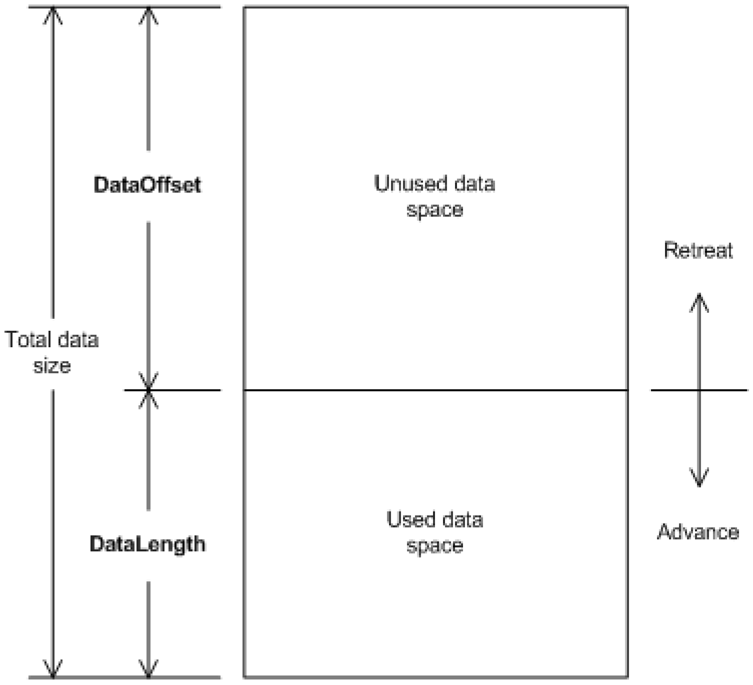
Article • 12/15/2021

NDIS provides retreat and advance functions to manipulate **NET_BUFFER** structures. Retreat operations make more *used data space* available to the current driver. Advance operations release *used data space*.

Retreat operations are required during send operations or when a driver returns received data to an underlying driver. For example, during a send operation, a driver can call the **NdisRetreatNetBufferDataStart** function to make room for header data.

Advance operations are required when a send operation is complete or when a driver receives data from an underlying driver. For example, during a receive operation, a driver can call the **NdisAdvanceNetBufferDataStart** function to skip over the header data that was used by a lower level driver. In this case, the header data remains in the buffer in the *unused data space*.

The following figure shows the relationship between the network data and these operations.



The following topics provide more information about advance and retreat operations:

Retreat Operations

Advance Operations

Retreat Operations

Article • 12/15/2021

Retreat operations can increase the size of the used data space in a NET_BUFFER structure or in all of the NET_BUFFER structures in a NET_BUFFER_LIST structure.

NDIS provides the following retreat functions:

NdisRetreatNetBufferDataStart

NdisRetreatNetBufferListDataStart

Retreat operations can sometimes allocate MDLs that are associated with a NET_BUFFER structure. To provide the mechanism for allocating MDLs, a driver can provide an optional entry point for a NetAllocateMdl function. If the entry point is **NULL**, NDIS uses a default method to allocate MDLs. MDLs must be freed within a NetFreeMdl function that provides the reciprocal of the mechanism that was used to allocate the MDL.

To obtain the new **DataLength**, NDIS adds the driver-specified *DataOffsetDelta* to the current **DataLength** . If the size of the *unused data space* is greater than the *DataOffsetDelta*, a retreat operation reduces the **DataOffset** . In this case, the new **DataOffset** is the current **DataOffset** minus the *DataOffsetDelta* .

If the *DataOffsetDelta* is greater than **DataOffset**, a retreat operation allocates new data space. In this case, NDIS adjusts the **DataOffset** accordingly.

For send operations, NDIS allocates memory if there isn't enough *unused data space* to satisfy a retreat request. If no memory allocation is required, NDIS simply adjusts the **DataOffset** and **DataLength** . For better performance, drivers should allocate enough total data size before sending to accommodate the retreat operations of all the underlying drivers.

For the receive return case, NDIS simply adjusts the **DataOffset** and **DataLength** accordingly. The retreat operation reverses the advance operation that took place during receive processing. After the retreat operation, the *used data space* contains the header data that underlying drivers used during receive processing.

Advance Operations

Article • 12/15/2021

Advance operations decrease the size of the used data space in a NET_BUFFER structure or in all of the NET_BUFFER structures in a NET_BUFFER_LIST structure.

Drivers use the following advance functions:

NdisAdvanceNetBufferDataStart

NdisAdvanceNetBufferListDataStart

Advance operations can sometimes free MDLs that are associated with a NET_BUFFER structure. To provide the mechanism for freeing MDLs, a driver can provide an optional entry point for a NetFreeMdl functions. If the entry point is **NULL**, NDIS uses a default method to allocate MDLs. MDLs must only be freed within a *NetFreeMdl* using that reciprocal of the mechanism that was used to allocate the MDL in the NetAllocateMdl function.

To obtain the new **DataLength**, NDIS subtracts the driver-specified *DataOffsetDelta* from the current **DataLength** . If a previous retreat operation allocated new data space, the advance operation can free such previously allocated memory. If an advance operation does not free memory, NDIS simply adds the *DataOffsetDelta* to the current **DataOffset** to obtain the new **DataOffset** . If the advance operation freed memory, NDIS adjusts the **DataOffset** accordingly.

For the send complete case, advance operations can free memory that was allocated in previous retreat operations. For better performance, drivers should allocate enough total data size before sending to accommodate the retreat operations of all the underlying drivers.

For the receive indication case, advance operations simply adjust the **DataOffset** and **DataLength** accordingly. After the advance operation, the headers of lower layers remain in the *unused data space*.

Obtaining Pool Handles

Article • 12/15/2021

The following NDIS pool allocation functions require a handle to allocate resources:

- NdisAllocateNetBufferPool
- NdisAllocateNetBufferListPool

NDIS 6.0 drivers obtain a handle as follows:

Protocol drivers
Protocol drivers call the NdisRegisterProtocolDriver function to obtain a handle.

Miniport drivers
NDIS calls the *MiniportInitializeEx* function to pass the handle to the miniport driver.

Intermediate drivers
Intermediate drivers call the NdisRegisterProtocolDriver function to obtain a handle for pools used in send operations and NDIS calls *MiniportInitializeEx* to pass the handle to the intermediate driver for pools used in receive operations.

Filter drivers
NDIS calls the *FilterAttach* function to pass the handle to the filter driver.

Other drivers
If a driver cannot obtain a handle through one of the preceding methods, the driver can call the NdisAllocateGenericObject function to get a handle.

Dispatch IRQL Tracking

Article • 12/15/2021

To improve system performance, some NDIS functions (for example, the *MiniportSendNetBufferLists* function) include a dispatch level flag that indicates the current IRQL. The proper use of the dispatch level flag can help to avoid unnecessary attempts to set the IRQL.

There are other flags that control other attributes, but the names for the dispatch level flags are:

NDIS_SEND_FLAGS_DISPATCH_LEVEL

NDIS_SEND_COMPLETE_FLAGS_DISPATCH_LEVEL

NDIS_RECEIVE_FLAGS_DISPATCH_LEVEL

NDIS_RETURN_FLAGS_DISPATCH_LEVEL

NDIS_RWL_AT_DISPATCH_LEVEL

The caller must determine the dispatch level flag setting from the known current IRQL, not by testing the IRQL. For example, you know the IRQL because it is a fixed characteristic of the driver design, or the driver saved the current IRQL.

If the known current IRQL is DISPATCH_LEVEL, the caller should set this flag. If the current IRQL is unknown, or the caller is not running at DISPATCH_LEVEL, the caller should clear this flag. If the caller is NDIS, the called function should test this flag to avoid changing the IRQL.

Drivers should not test for the IRQL to determine the value for the dispatch level flag. Testing would defeat the purpose of the flag. If necessary, the called function can simply do the testing itself. How a driver determines that it should or should not set the flag is left to the design of the particular driver.

Send and Receive Operations

Article • 12/15/2021

In a single function call, NDIS 6.0 drivers can send multiple **NET_BUFFER_LIST** structures with multiple **NET_BUFFER** structures on each NET_BUFFER_LIST structure. Also, NDIS drivers can indicate completed send operations for multiple NET_BUFFER_LIST structures with multiple NET_BUFFER structures on a NET_BUFFER_LIST structure.

In the receive path, miniport drivers can use a list of NET_BUFFER_LIST structures to indicate receives. Each NET_BUFFER_LIST indicated by a miniport driver contains one NET_BUFFER structure. However, Native 802.11 drivers can have more than one NET_BUFFER structure. Because a different protocol binding can process each NET_BUFFER_LIST structure, NDIS can return each NET_BUFFER_LIST structure to the miniport driver independently.

To support NDIS 5.*x* and earlier drivers, NDIS provides a translation layer between the **NDIS_PACKET**-based and NET_BUFFER-based interfaces. NDIS performs the necessary conversion between **NET_BUFFER** structures and NDIS_PACKET structures. To avoid performance degradation due to translation, NDIS drivers must be updated to use NET_BUFFER structures and should support multiple **NET_BUFFER_LIST** structures in all data paths.

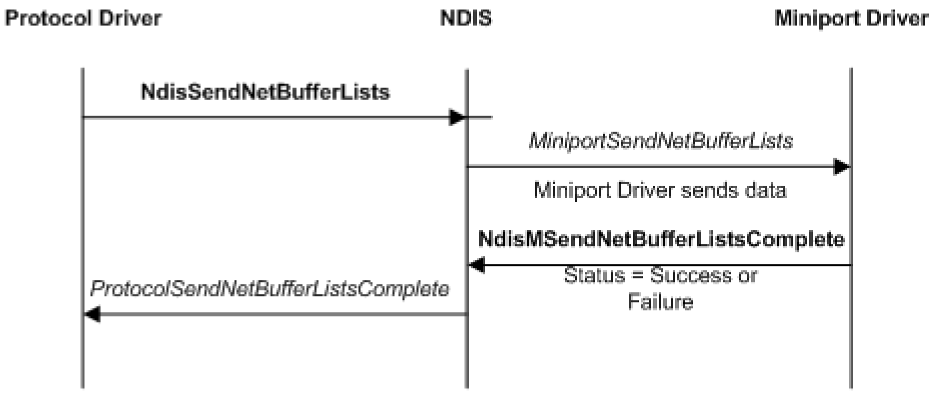
Looping Back NDIS Packets

Sending Network Data

Article • 12/15/2021

The following figure illustrates a basic send operation, which involves a protocol driver, NDIS, and a miniport driver.



Protocol Driver
NDIS
Miniport Driver
NdisSendNetBufferLists
MiniportSendNetBufferLists
Miniport Driver sends data
NdisMSendNetBufferListsComplete
Status = Success or Failure
ProtocolSendNetBufferListsComplete

Protocol drivers call the **NdisSendNetBufferLists** function to send **NET_BUFFER_LIST** structures on a binding. NDIS calls the miniport driver's *MiniportSendNetBufferLists* function to forward the NET_BUFFER_LIST structures to an underlying miniport driver.

All NET_BUFFER-based send operations are asynchronous. The miniport driver calls the **NdisMSendNetBufferListsComplete** function with an appropriate status code when it is done. The sending of each NET_BUFFER_LIST structure can be completed individually. NDIS calls the protocol driver's **ProtocolSendNetBufferListsComplete** function each time the miniport driver calls **NdisMSendNetBufferListsComplete**.

Protocol drivers can reclaim the ownership of the NET_BUFFER_LIST structures and all associated structures and data as soon as the NDIS calls the protocol driver's *ProtocolSendNetBufferListsComplete* function.

The miniport driver or NDIS can return the **NET_BUFFER_LIST** structures in any order. Protocol drivers are guaranteed that the list of **NET_BUFFER** structures attached to each NET_BUFFER_LIST structure has not been modified.

Any NDIS driver can separate the NET_BUFFER structures in a NET_BUFFER_LIST structure. Any NDIS driver can also separate the MDLs in a NET_BUFFER structure. However, the driver must always return the NET_BUFFER_LIST structures with the NET_BUFFER structures and MDLs in the original form. For example, an intermediate driver might separate a NET_BUFFER_LIST into two new NET_BUFFER_LIST structures and pass on part of the original data to the next driver. However, when the intermediate driver completes the processing of the original NET_BUFFER_LIST it must return the complete NET_BUFFER_LIST with the original NET_BUFFER structures and MDLs.

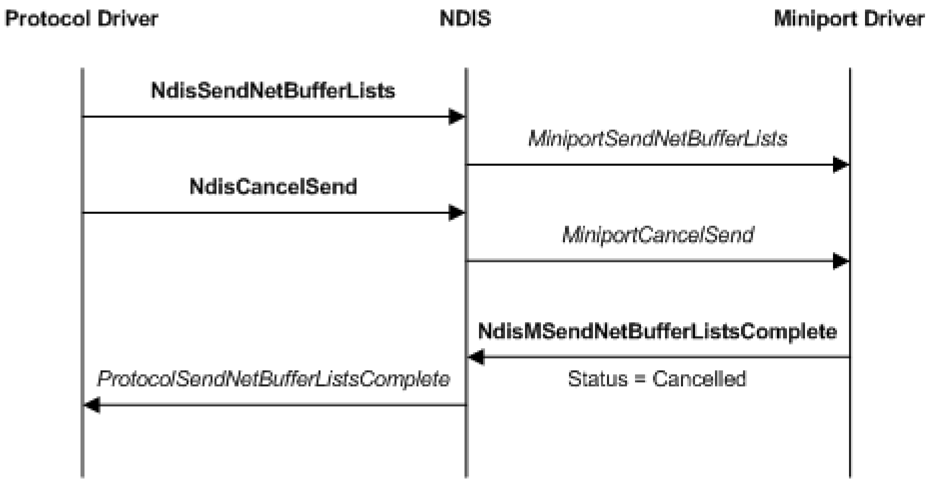
Protocol drivers set the **SourceHandle** member in the NET_BUFFER_LIST structure to the *NdisBindingHandle* that NDIS provided in a call to the **NdisOpenAdapterEx** function. NDIS uses the **SourceHandle** member to return the NET_BUFFER_LIST structures to the protocol driver that sent the NET_BUFFER_LIST structures.

Intermediate drivers also set the **SourceHandle** member in the NET_BUFFER_LIST structure to the *NdisBindingHandle* value that NDIS provided in a call to **NdisOpenAdapterEx**. If an intermediate driver forwards a send request, the driver must save the **SourceHandle** value that the overlying driver provided before it writes to the **SourceHandle** member. When NDIS returns a forwarded NET_BUFFER_LIST structure to the intermediate driver, the intermediate driver must restore the **SourceHandle** that it saved.

Canceling a Send Operation

Article • 12/15/2021

The following figure illustrates canceling a send operation.



A driver calls the NDIS_SET_NET_BUFFER_LIST_CANCEL_ID macro for each NET_BUFFER_LIST structure that it passes to lower-level drivers for transmission. The NDIS_SET_NET_BUFFER_LIST_CANCEL_ID function marks the specified packet with a cancellation identifier.

Before assigning cancellation IDs to packets, a driver should call NdisGeneratePartialCancelId to obtain the high-order byte of each cancellation ID that it assigns. This ensures that the driver does not duplicate cancellation IDs assigned by other drivers in the system. Drivers typically call **NdisGeneratePartialCancelId** once from the **DriverEntry** routine; however, drivers can obtain more than one partial cancellation identifier by calling **NdisGeneratePartialCancelId** more than once.

To cancel the pending transmission of data in a marked NET_BUFFER_LIST structure, a driver passes the cancellation ID to the NdisCancelSendNetBufferLists function. Drivers can obtain a NET_BUFFER_LIST structure's cancellation ID by calling the NDIS_GET_NET_BUFFER_LIST_CANCEL_ID macro.

If a driver marks all NET_BUFFER_LIST structures with the same cancellation identifier, it can cancel all pending transmissions with a single call to **NdisCancelSendNetBufferLists**. If a driver marks all NET_BUFFER_LIST structures within a subgroup of NET_BUFFER_LIST structures with a unique identifier, it can cancel all pending transmissions within that subgroup with a single call to **NdisCancelSendNetBufferLists**.

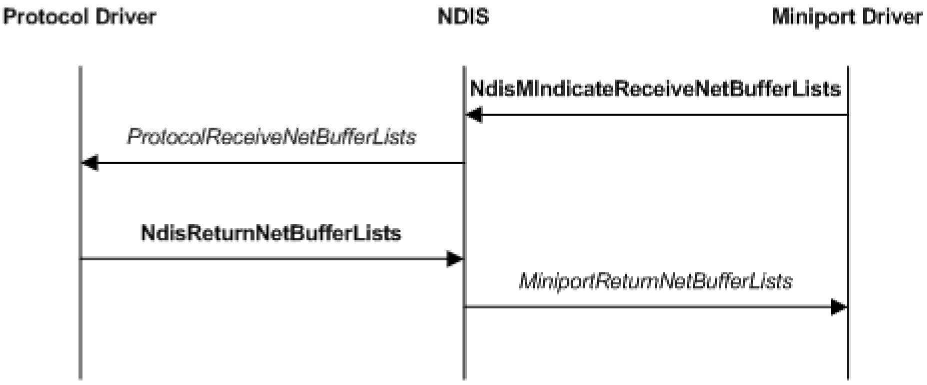
NDIS calls the *MiniportCancelSend* function of the appropriate lower-level driver on the binding. After aborting the pending transmission, the underlying miniport driver calls the NdisMSendNetBufferListsComplete function, to return the NET_BUFFER_LIST structures and a completion status of NDIS_STATUS_SEND_ABORTED. NDIS, in turn, calls the appropriate driver's **ProtocolSendNetBufferListsComplete** function.

In its *ProtocolSendNetBufferListsComplete* function, a protocol driver can call NDIS_SET_NET_BUFFER_LIST_CANCEL_ID with *CancelId* set to **NULL**. This prevents the NET_BUFFER_LIST from inadvertently being used again with a stale cancellation ID.

Receiving Network Data

Article • 12/15/2021

The following figure illustrates a basic receive operation, which involves a miniport driver, NDIS, and a protocol driver.



Protocol Driver
NDIS
Miniport Driver
NdisMIndicateReceiveNetBufferLists
ProtocolReceiveNetBufferLists
NdisReturnNetBufferLists
MiniportReturnNetBufferLists

Miniport drivers call the NdisMIndicateReceiveNetBufferLists function to indicate NET_BUFFER structures to higher level drivers. Every NET_BUFFER structure should usually be attached to a separate NET_BUFFER_LIST structure. This allows protocol drivers to create a subset of the original list of NET_BUFFER_LIST structures and forward them to different clients. Some drivers, for example native IEEE 802.11 miniport drivers, might attach more than one NET_BUFFER structure to a NET_BUFFER_LIST structure.

After linking all the NET_BUFFER_LIST structures, a miniport driver passes a pointer to the first NET_BUFFER_LIST structure in the list to the **NdisMIndicateReceiveNetBufferLists** function. NDIS examines the NET_BUFFER_LIST structures and it calls the ProtocolReceiveNetBufferLists function of each protocol driver that is associated with the NET_BUFFER_LIST structures. NDIS passes a subset of the list that includes only the NET_BUFFER_LIST structures that are associated with the correct binding to each protocol driver. NDIS matches the **NetBufferListFrameType** value that is specified in the NET_BUFFER_LIST structure to the frame type that each protocol driver registers.

If the NDIS_RECEIVE_FLAGS_RESOURCES flag in the *ReceiveFlags* parameter that is passed to a protocol driver's *ProtocolReceiveNetBufferLists* function is set, NDIS regains the ownership of the NET_BUFFER_LIST structures immediately after the *ProtocolReceiveNetBufferLists* call returns.

Note If the NDIS_RECEIVE_FLAGS_RESOURCES flag is set, the protocol driver must retain the original set of NET_BUFFER_LIST structures in the linked list. For example, when this flag is set the driver might process the structures and indicate them up the stack one at a time but before the function returns it must restore the original linked list.

If the NDIS_RECEIVE_FLAGS_RESOURCES flag in the *ReceiveFlags* parameter that is passed to a protocol driver's *ProtocolReceiveNetBufferLists* function is not set, the protocol driver can retain ownership of the NET_BUFFER_LIST structures. In this case, the protocol driver must return the NET_BUFFER_LIST structures by calling the **NdisReturnNetBufferLists** function.

If a miniport driver is running low on receive resources, it can set the NDIS_RECEIVE_FLAGS_RESOURCES flag in the *ReceiveFlags* parameter in the call to **NdisMIndicateReceiveNetBufferLists**. In that case, the driver can reclaim the ownership of all the indicated **NET_BUFFER_LIST** structures and embedded **NET_BUFFER** structures as soon as **NdisMIndicateReceiveNetBufferLists** returns. Indicating NET_BUFFER structures with the NDIS_RECEIVE_FLAGS_RESOURCES flag set forces the protocol drivers to copy the data and therefore should be avoided. A miniport driver should detect when it is about to run out of receive resources and take any steps that are necessary to avoid this situation.

NDIS calls a miniport driver's *MiniportReturnNetBufferLists* function after the protocol driver calls **NdisReturnNetBufferLists**.

Note If a miniport driver indicates a NET_BUFFER_LIST structure with the NDIS_RECEIVE_FLAGS_RESOURCES flag set, that does not mean that NDIS will indicate the NET_BUFFER_LIST structure to the protocol driver with the same status. For example, NDIS could copy a NET_BUFFER_LIST structure with the NDIS_RECEIVE_FLAGS_RESOURCES flag set and indicate the copy to the protocol driver with the flag cleared.

NDIS can return **NET_BUFFER_LIST** structures to the miniport driver in any arbitrary order and in any combination. That is, the linked list of NET_BUFFER_LIST structures returned back to a miniport driver by a call to its *MiniportReturnNetBufferLists* function, can have NET_BUFFER_LIST structures from different previous calls to **NdisMIndicateReceiveNetBufferLists**.

Miniport drivers should set the **SourceHandle** member in the NET_BUFFER_LIST structures to the *MiniportAdapterHandle* that NDIS provided to the miniport driver in the *MiniportInitializeEx* function. Filter drivers must set the **SourceHandle** member of each NET_BUFFER_LIST structure that the filter driver originated to the filter's **NdisFilterHandle** that NDIS provided to the filter driver in the *FilterAttach* function. Filter drivers must not modify the **SourceHandle** member in any NET_BUFFER_LIST structures that were not originated by the filter driver.

Intermediate drivers also set the **SourceHandle** member in the NET_BUFFER_LIST structure to the *MiniportAdapterHandle* value that NDIS provided to the intermediate driver in the *MiniportInitializeEx* function. If an intermediate driver forwards a receive indication, the driver must save the **SourceHandle** value that the underlying driver provided before it writes to the **SourceHandle** member. When NDIS returns a forwarded NET_BUFFER_LIST structure to the intermediate driver, the intermediate driver must restore the **SourceHandle** that it saved.

Looping Back NDIS Packets

Article • 03/14/2023

If the NDIS_NBL_FLAGS_IS_LOOPBACK_PACKET flag in the **NblFlags** member of the NET_BUFFER_LIST structure is set, the packet is a loopback packet. Protocol drivers and filter drivers can check this flag to determine if a packet is a loopback packet.

NDIS loops packets back if all of the following three conditions are satisfied:

1. The underlying miniport adapter media type is **NdisMedium802_3** or **NdisMedium802_5**.

2. Any one of the following three conditions is satisfied:

   a. A protocol binding set the NDIS_PACKET_TYPE_PROMISCUOUS setting with the OID_GEN_CURRENT_PACKET_FILTER OID to specify its packet filter (and, for Windows 8 and later, did not set NDIS_PACKET_TYPE_NO_LOCAL in the same OID) and either of the following is true:

      - There is more than one binding to the miniport adapter.
      - There is a filter module attached to the miniport adapter and the filter module registered a receive handler.

   b. A protocol binding set the NDIS_PACKET_TYPE_ALL_LOCAL setting with the OID_GEN_CURRENT_PACKET_FILTER OID to specify its packet filter and either of the following is true.

      - There is more than one binding to the miniport adapter.
      - There is a filter module attached to the miniport adapter and the filter module registered a receive handler.

   c. The caller sets the NDIS_SEND_FLAGS_CHECK_FOR_LOOPBACK flag in the *SendFlags* parameter of the **NdisSendNetBufferLists** function.

3. The packet is acceptable as determined by the packet filter set with the OID_GEN_CURRENT_PACKET_FILTER OID for the miniport adapter. The following are some examples:

   - If the packet is a direct packet, the destination address in the packet must match the MAC address of the miniport adapter.
   - If the packet is a multicast packet, the packet filter must have NDIS_PACKET_TYPE_ALL_MULTICAST set or the destination address matches

one of the multicast address in the miniport adapter's multicast address list and the packet filter has NDIS_PACKET_TYPE_MULTICAST set.
- If the packet is a broadcast packet, the miniport adapter's packet filter must have NDIS_PACKET_TYPE_BROADCAST set.
- The miniport adapter's packet filter has NDIS_PACKET_TYPE_PROMISCUOUS or NDIS_PACKET_TYPE_ALL_LOCAL set.

A protocol binding receives loopback packets if either of the following is true:

1. The protocol binding is the original sender of the packet and NDIS_SEND_FLAGS_CHECK_FOR_LOOPBACK is set.

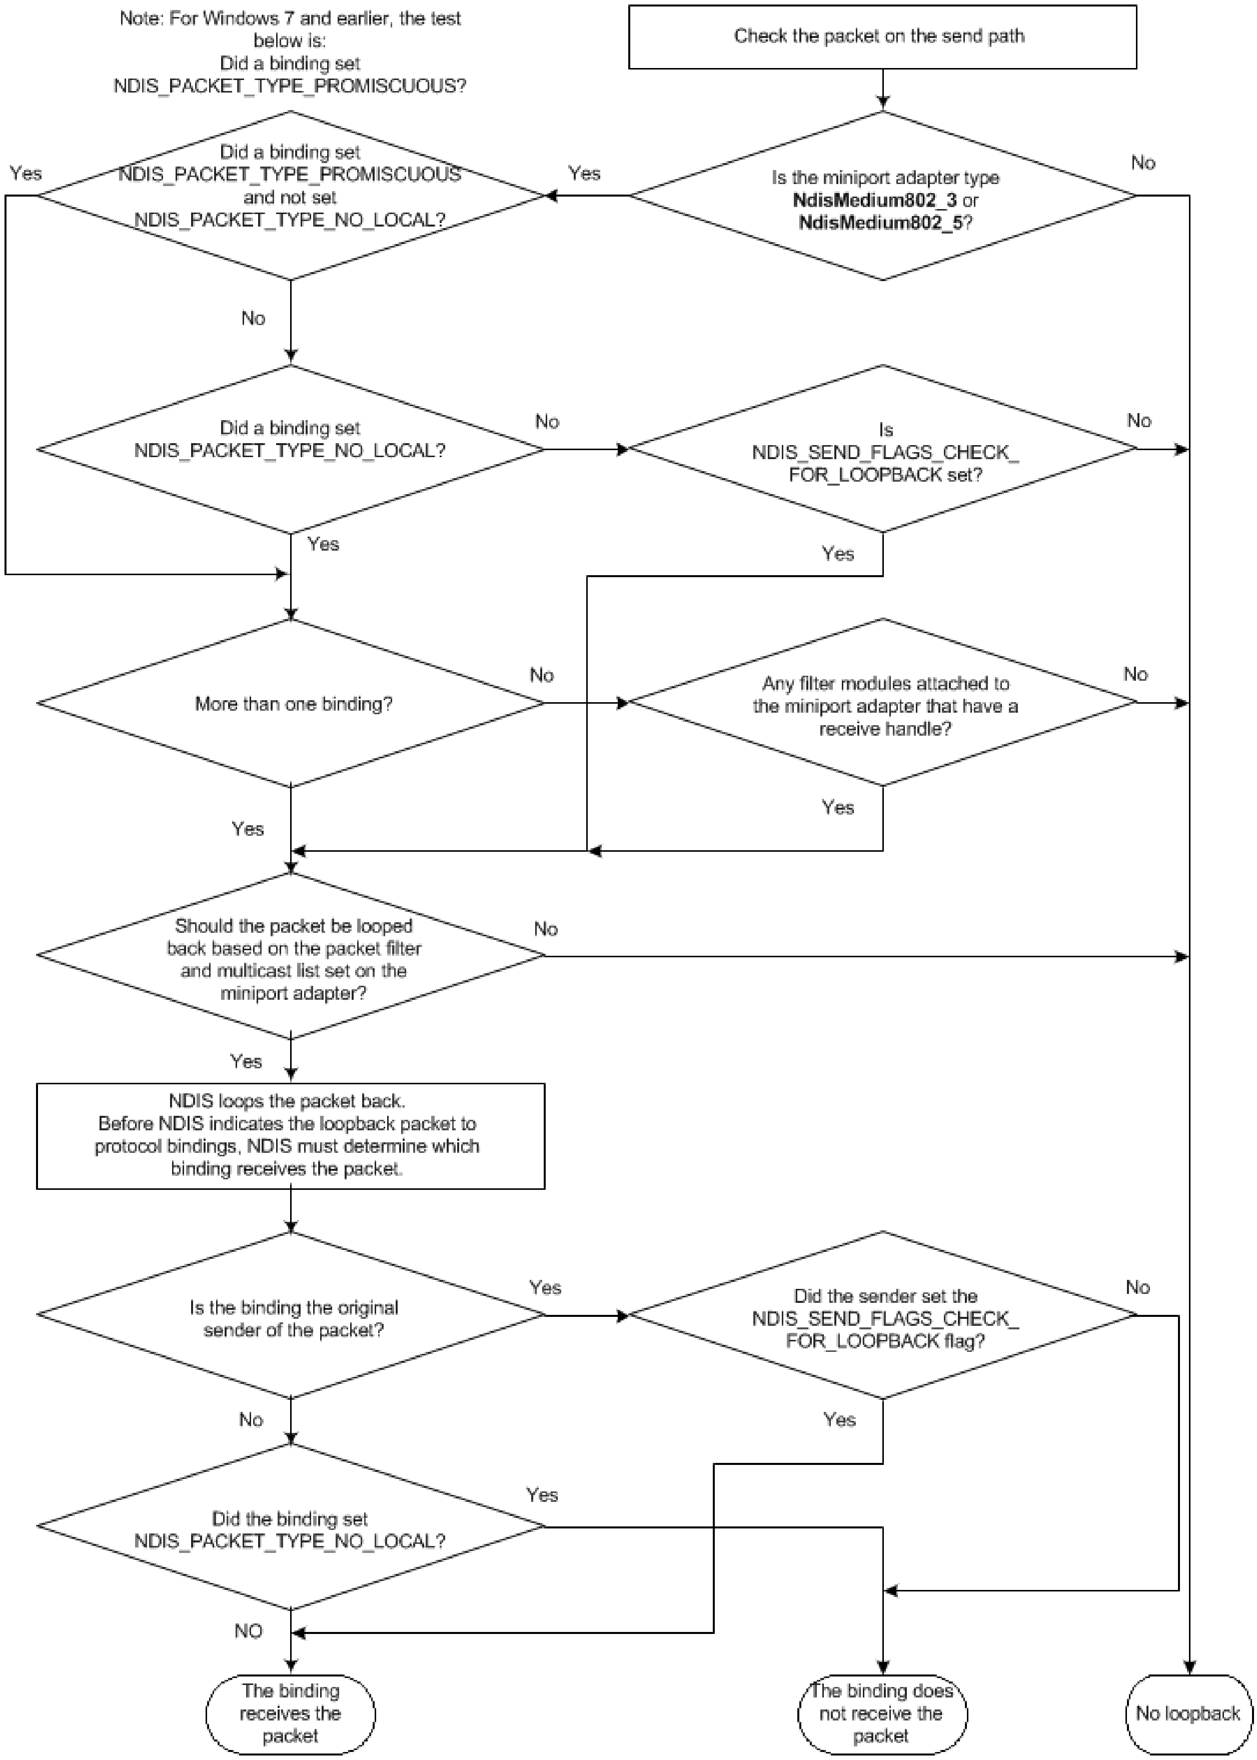
2. The protocol binding does not set NDIS_PACKET_TYPE_NO_LOCAL in the packet filter.

A protocol binding will not receive loopback packets if either of the following is true:

1. The protocol binding sets NDIS_PACKET_TYPE_NO_LOCAL in the packet filter and it is not the original sender for the packet.

2. The protocol binding is the original sender but NDIS_SEND_FLAGS_CHECK_FOR_LOOPBACK is not set in the *SendFlags* parameter in a call to the **NdisSendNetBufferLists** function.

The following figure shows the loopback algorithm logic flow.



Note: For Windows 7 and earlier, the test below is: Did a binding set NDIS_PACKET_TYPE_PROMISCUOUS?
Check the packet on the send path
Is the miniport adapter type **NdisMedium802_3** or **NdisMedium802_5**?
Yes
No
Did a binding set NDIS_PACKET_TYPE_PROMISCUOUS and not set NDIS_PACKET_TYPE_NO_LOCAL?
Yes
No
Did a binding set NDIS_PACKET_TYPE_NO_LOCAL?
No
Yes
Is NDIS_SEND_FLAGS_CHECK_ FOR_LOOPBACK set?
No
Yes
More than one binding?
No
Yes
Any filter modules attached to the miniport adapter that have a receive handle?
No
Yes
Should the packet be looped back based on the packet filter and multicast list set on the miniport adapter?
No
Yes
NDIS loops the packet back. Before NDIS indicates the loopback packet to protocol bindings, NDIS must determine which binding receives the packet.
Is the binding the original sender of the packet?
Yes
No
Did the sender set the NDIS_SEND_FLAGS_CHECK_ FOR_LOOPBACK flag?
No
Yes
Did the binding set NDIS_PACKET_TYPE_NO_LOCAL?
Yes
NO
The binding receives the packet
The binding does not receive the packet
No loopback

Ethernet Send and Receive Operations

Article • 12/15/2021

This section defines send and receive requirements for Ethernet drivers. For general information about send and receive operations, see Send and Receive Operations.

This section includes the following topics:

Sending Ethernet Frames

Indicating Received Ethernet Frames

Sending Ethernet Frames

Article • 12/15/2021

The Windows TCP/IP transport supports a set of requirements for sending Ethernet frames. Any driver (for example, a MUX intermediate driver or filter driver) that originates send requests or modifies the send requests of overlying drivers must support the requirements that the TCP/IP transport implements.

Note If any driver in a driver stack does not follow these requirements, underlying miniport drivers, MUX intermediate drivers, and filter drivers might behave unpredictably.

For Ethernet send requests, drivers must support these requirements:

- If a driver originates a send request, the driver should allocate a NET_BUFFER_LIST structure for the Ethernet frames. The **NetBufferListInfo** member in each NET_BUFFER_LIST structure must include the out-of-band (OOB) data that is required for the particular use. The OOB data applies to all of the NET_BUFFER structures that are associated with a NET_BUFFER_LIST structure.

- If a driver originates a send request, the driver should allocate one or more NET_BUFFER structures for the Ethernet frames and link these structures to the NET_BUFFER_LIST structure. Each NET_BUFFER structure that is linked to a NET_BUFFER_LIST structure describes a single Ethernet frame. The driver may chain multiple NET_BUFFER_LIST structures in a send request.

- All NET_BUFFER structures that are associated with a NET_BUFFER_LIST structure must have the same Ethernet frame type and IP protocol version (IPv4 or IPv6).

- All NET_BUFFER structures that are associated with a NET_BUFFER_LIST structure must have the same source and destination MAC addresses.

- If a driver is sending TCP or UDP frames, all of the NET_BUFFER structures that are associated with a NET_BUFFER_LIST structure must be associated with same TCP or UDP connection. **Note** Subject to the following requirements, transmitted Ethernet frames can be split. That is, multiple memory descriptor lists (MDLs) can be associated with a NET_BUFFER structure in a send request.

- Do not split the MAC header of the transmit Ethernet frame across multiple MDLs. Treat the Virtual LAN (VLAN) (or Priority) flag, if present, as part of the MAC header. Therefore, this flag must be in the same MDL as the rest of the MAC header.

- If a driver changes the links in the MDL chain in a NET_BUFFER structure or the NET_BUFFER chain in a NET_BUFFER_LIST structure, the driver must restore the links to the original configuration before it returns ownership of the NET_BUFFER_LIST to an overlying driver. However, drivers are not required to restore the links between NET_BUFFER_LIST structures.

Indicating Received Ethernet Frames

Article • 12/15/2021

The Windows TCP/IP protocol driver imposes a set of requirements for receiving Ethernet frames. Any driver that originates receive indications of Ethernet frames or modifies receive indications of underlying drivers must support the general requirements that TCP/IP imposes. These drivers include Ethernet miniport drivers, MUX intermediate drivers, and filter drivers.

Note If a driver does not follow these requirements, overlying drivers (such as the TCP/IP transport, MUX intermediate drivers, and filter drivers) might behave unpredictably.

Drivers that originate Ethernet receive indications must support the following requirements:

- The driver must allocate a **NET_BUFFER_LIST** structure for the received Ethernet frame. Each **NET_BUFFER_LIST** structure must include the out-of-band (OOB) data that is defined in the **NetBufferListInfo** member of the **NET_BUFFER_LIST** required for the particular use.

- The driver must allocate a **NET_BUFFER** structure for the frame and link it to a **NET_BUFFER_LIST** structure. The Ethernet miniport must assign exactly one **NET_BUFFER** structure to a **NET_BUFFER_LIST** structure when indicating received data. This restriction applies only to the Ethernet receive path. It is not applicable to the other media types, such as the native 802.11 wireless LAN interface. or NDIS in general.

- Starting with NDIS 6.1, under certain scenarios, a **NET_BUFFER** structure can be associated with multiple memory descriptor lists (MDLs) for the received Ethernet frame. Even though a **NET_BUFFER_LIST** structure must contain a single **NET_BUFFER** structure, using multiple MDLs allows the driver to split the received packet data into separate buffers.

  For example, Ethernet drivers that support the header-data split interface split a received Ethernet frame by using a linked list of multiple MDLs that are associated with a single **NET_BUFFER** structure. For more information, see Header-Data Split.

  For simplicity and performance reasons, we highly recommend that drivers that don't support header-data split use only one MDL for each **NET_BUFFER** structure.

  Note In NDIS 6.0 for Windows Vista, each **NET_BUFFER** structure must contain only one MDL.

- Drivers must not split received Ethernet frames in the middle of the IP header, IPv4 options, IPsec headers, IPv6 extension headers, or upper-layer protocol headers, unless the first MDL contains at least as many bytes as NDIS specified for the lookahead size.

NDIS protocol and filter drivers must support split Ethernet frames in receive indications if such split frames comply with the restrictions that are defined in the preceding list item. The restrictions ensure that the protocol and filter drivers are compatible with future Windows versions.

Derived NET_BUFFER_LIST Structures

Article • 12/15/2021

NDIS provides functions that drivers can use to manage **NET_BUFFER_LIST** structures that are derived from other NET_BUFFER_LIST structures. These functions are typically used by intermediate drivers.

The following NDIS functions can create derived NET_BUFFER_LIST structures from an existing NET_BUFFER_LIST structure:

NdisAllocateCloneNetBufferList

NdisAllocateFragmentNetBufferList

NdisAllocateReassembledNetBufferList

These functions improve system performance because NDIS creates the derived structures without copying the network data. There are three types of **NET_BUFFER_LIST** structures that can be derived from an existing NET_BUFFER_LIST structure:

Clone
A cloned NET_BUFFER_LIST structure is a duplicate that references the original data. Drivers can use this type of structure to efficiently transfer the same data to multiple paths.

Fragment
A fragment **NET_BUFFER_LIST** structure includes a set of **NET_BUFFER** structures that reference the original data; however, the data is divided into units that do not exceed a maximum size. Drivers can use this type of structure to efficiently break up large buffers into smaller buffers.

Reassembled
A reassembled NET_BUFFER_LIST structure contains a NET_BUFFER structure that references the original data from multiple source NET_BUFFER structures. Drivers can use this type of structure to efficiently combine many smaller buffers into a single large buffer.

This following topics provide more information about derived NET_BUFFER_LIST structures:

- Relationships Between NET_BUFFER_LIST Generations
- Cloned NET_BUFFER_LIST Structures
- Fragmented NET_BUFFER_LIST Structures

- Reassembled NET_BUFFER_LIST Structures

Relationships Between NET_BUFFER_LIST Generations

Article • 12/15/2021

Driver writers should understand and maintain the relationship between the parent (original) NET_BUFFER_LIST structures and the child (derived) structures that result from clone, fragment, and reassemble operations.

The caller of a clone/fragment/reassemble function maintains the parent/child relationship, including the parent pointer in the child NET_BUFFER_LIST structure and a child count. The child count ensures that the caller frees the parent after all the children have been freed. The following rules apply:

- After a driver creates child structures from a NET_BUFFER_LIST structure, it should retain the ownership of the parent structure and should pass the child structures to other drivers. The driver should never pass the parent NET_BUFFER_LIST structure to another driver.

- A driver should only update the child count in the parent NET_BUFFER_LIST structure. Because the parent structure is never passed to another driver, there is no risk that the value of the child count could be overwritten. The driver should set the parent pointer in the child structures to point to the parent structure.

- When a driver receives a NET_BUFFER_LIST from another driver, the driver must not overwrite the parent pointer. If the received NET_BUFFER_LIST structure is a child, its parent pointer should be set already. The driver can use the NET_BUFFER_LIST received from another driver as a parent structure.

- NDIS does not enforce the preceding rules. The current owner of a NET_BUFFER_LIST structure must manage the child count and parent pointer. For example, if the current owner will both clone and fragment a NET_BUFFER_LIST structure, it must manage the parent pointer and child counter.

- NDIS sets the child count to zero and the parent pointer to **NULL** when it allocates a NET_BUFFER_LIST structure. NDIS does not change these fields each time a driver passes a NET_BUFFER_LIST structure to another driver.

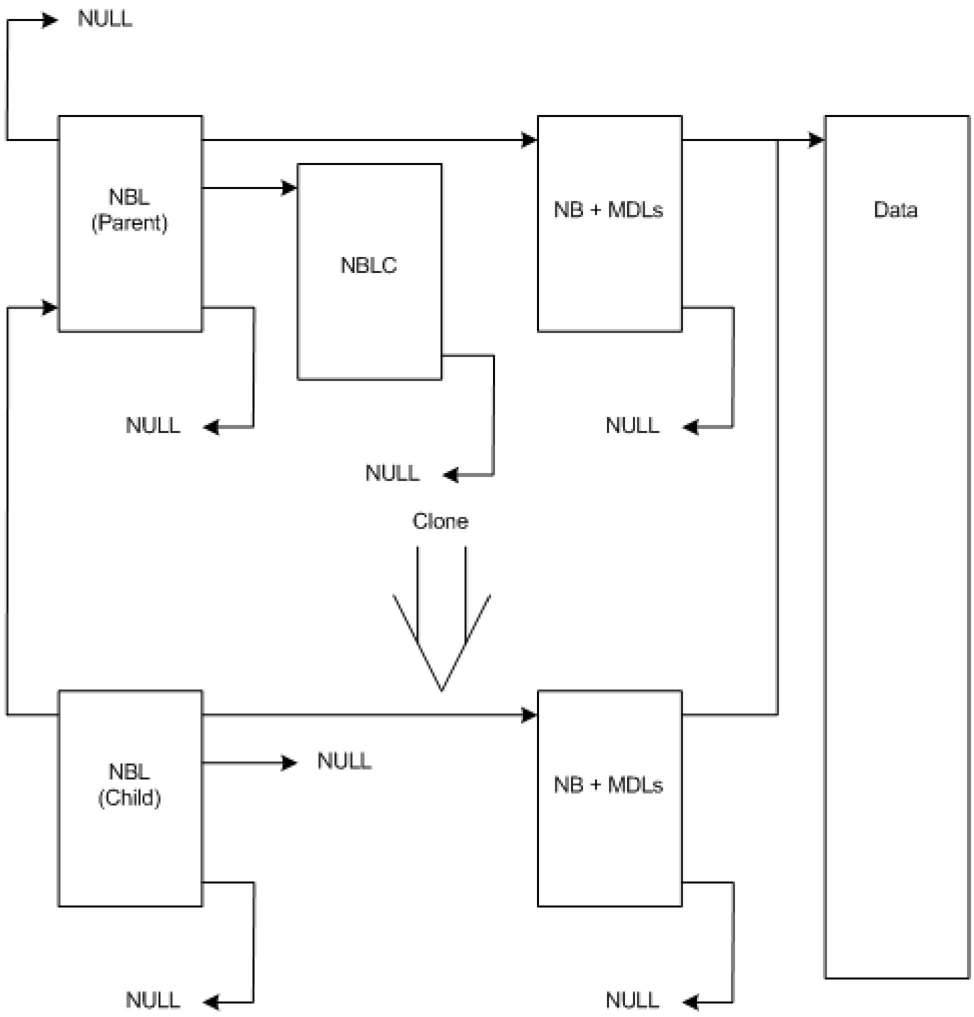
Derived NET_BUFFER_LIST Structures

Cloned NET_BUFFER_LIST Structures

Article • 12/15/2021

An NDIS driver creates a cloned NET_BUFFER_LIST structure from an existing NET_BUFFER_LIST structure. The cloned structure references the original structures data. Drivers can use this type of structure to efficiently transfer the same data to multiple paths.

The following figure shows the relationship between a parent NET_BUFFER_LIST structure and a cloned child structure.



NBLC = NET_BUFFER_LIST_CONTEXT

NBL = NET_BUFFER_LIST

NB = NET_BUFFER

The preceding figure contains a parent NET_BUFFER_LIST structure and a child structure that was derived from that parent. The parent structure has one NET_BUFFER_LIST_CONTEXT structure and one NET_BUFFER structure with MDLs attached. The parent structure's parent pointer is **NULL** indicating that it is not a derived structure.

The child NET_BUFFER_LIST structure has one NET_BUFFER structure with MDLs attached. The child NET_BUFFER_LIST has a pointer to the parent structure. The **NULL** where a NET_BUFFER_LIST_CONTEXT structure pointer would be indicates that the child has no NET_BUFFER_LIST_CONTEXT structure.

Drivers call the **NdisAllocateCloneNetBufferList** function to create a clone **NET_BUFFER_LIST** structure. NDIS allocates new **NET_BUFFER** structures and MDLs with the cloned NET_BUFFER_LIST structure. NDIS does not allocate a **NET_BUFFER_LIST_CONTEXT** structure for the cloned structure. The new NET_BUFFER structures and MDLs describe the same data as in the parent structure. The data is not copied.

Drivers call the **NdisFreeCloneNetBufferList** function to free a NET_BUFFER_LIST structure and all associated NET_BUFFER structures and MDL chains that were previously allocated by calling **NdisAllocateCloneNetBufferList**.

Related topics

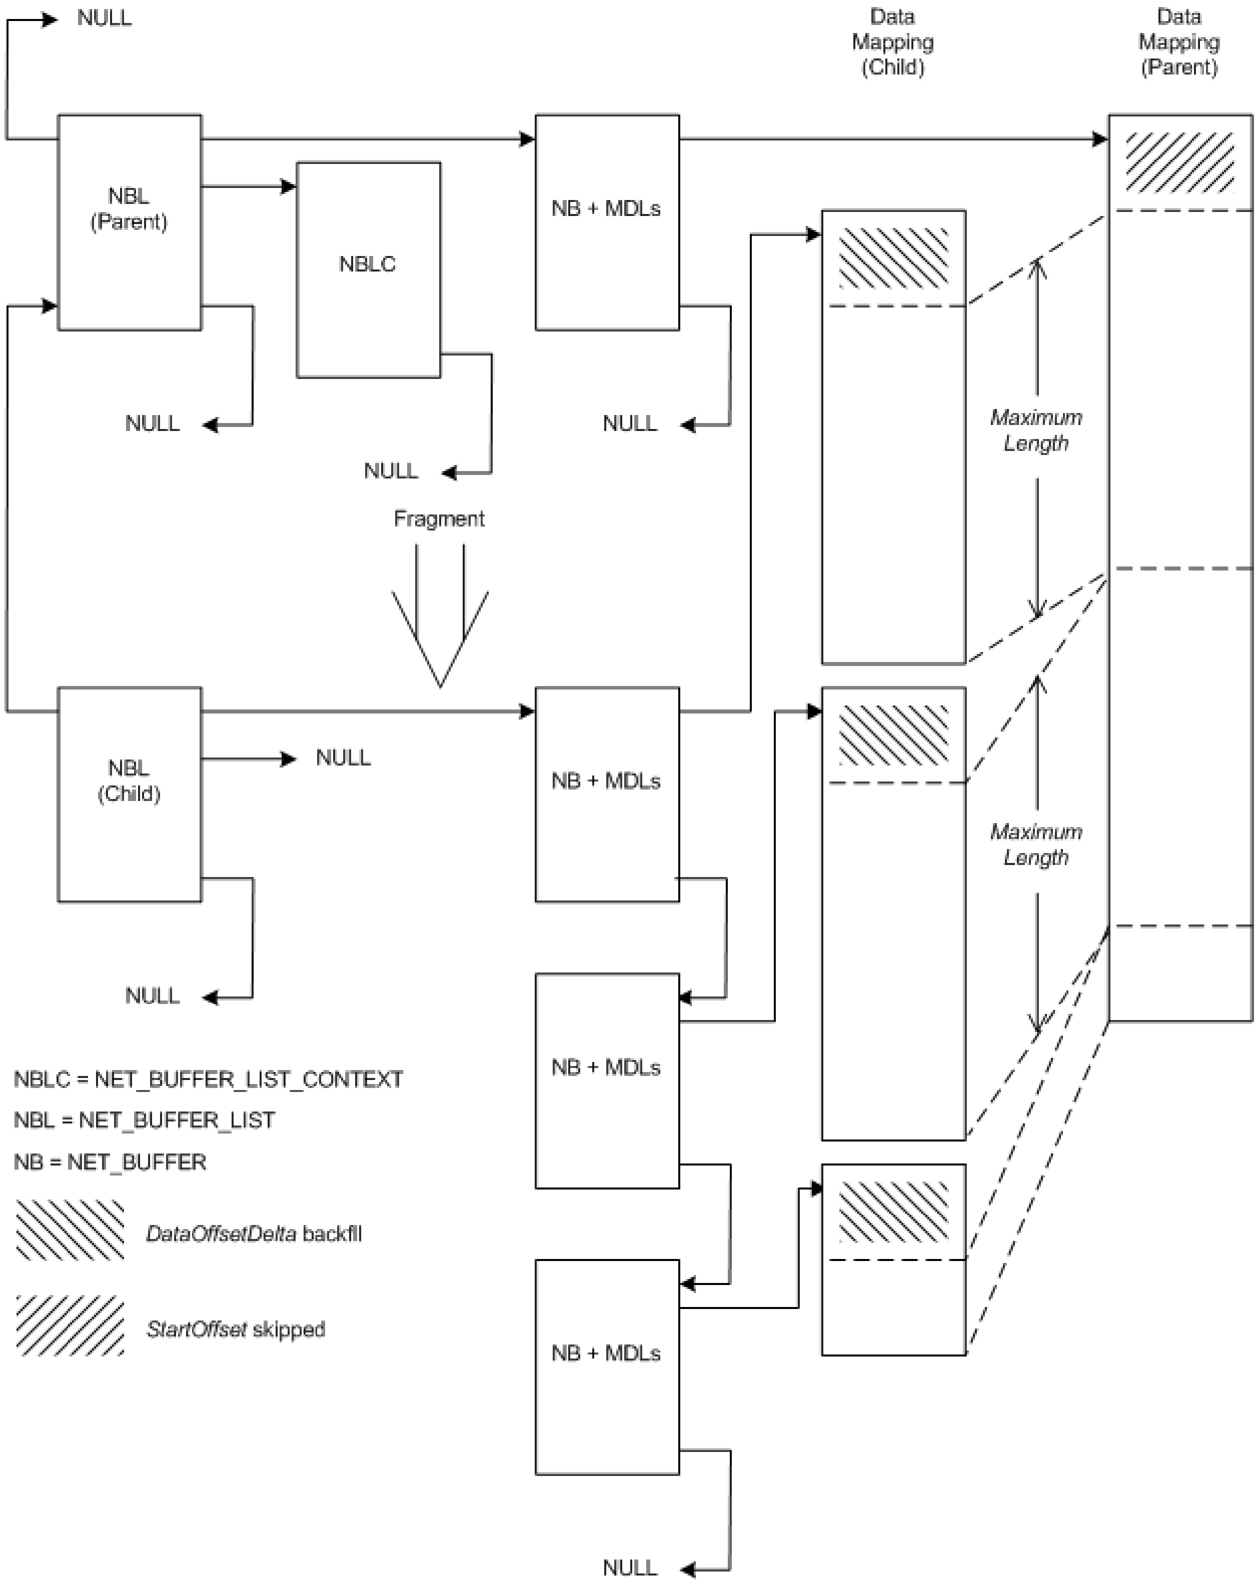
Derived NET_BUFFER_LIST Structures

Fragmented NET_BUFFER_LIST Structures

Article • 12/15/2021

An NDIS driver can create a fragmented **NET_BUFFER_LIST** structure from an existing NET_BUFFER_LIST structure. The fragmented structure references a set of **NET_BUFFER** structures that reference the original data; however, the data is divided into units that do not exceed a maximum size. Drivers can use this type of structure to efficiently break up large buffers into smaller buffers.

The following figure shows the relationship between a parent NET_BUFFER_LIST structure and a fragmented child.



The preceding figure contains a parent NET_BUFFER_LIST structure and a child structure that was derived from that parent. The parent structure has one NET_BUFFER_LIST_CONTEXT structure and one NET_BUFFER structure with MDLs attached. The parent structure's parent pointer is **NULL** indicating that it is not a derived structure.

The child NET_BUFFER_LIST structure has three NET_BUFFER structures with MDLs attached. The child NET_BUFFER_LIST structure has a pointer to the parent structure. The

NULL where a NET_BUFFER_LIST_CONTEXT structure pointer would be indicates that the child has no NET_BUFFER_LIST_CONTEXT structure.

NDIS drivers call the NdisAllocateFragmentNetBufferList function to create a new fragmented NET_BUFFER_LIST structure that is based on the data in an existing NET_BUFFER_LIST structure. NDIS allocates new NET_BUFFER structures and MDLs for the fragmented NET_BUFFER_LIST structure. NDIS does not allocate a NET_BUFFER_LIST_CONTEXT structure for the fragmented structure. The fragment NET_BUFFER structures and MDLs describe the same data as does the parent structure. The data is not copied.

NdisAllocateFragmentNetBufferList creates the fragments, starting from the beginning of the *used data space* in each parent NET_BUFFER structure and offset by the value specified in the *StartOffset* parameter.

NdisAllocateFragmentNetBufferList divides the *used data space* in each source NET_BUFFER structure into fragments. The length of the *used data space* of each fragment is less than or equal to the value specified in the *MaximumLength* parameter. The *used data space* of the last fragment can be less than *MaximumLength* . The data offset of the new NET_BUFFER structures is retreated by the number of bytes specified in the *DataOffsetDelta* parameter.

If there are multiple NET_BUFFER structures in the parent NET_BUFFER_LIST structure (not shown in the illustration) the fragmenting process for each NET_BUFFER structure is the same as for a single structure. For example, if the last piece of data in any parent NET_BUFFER structure is smaller than the maximum size, NDIS does not combine such data with the data at the start of the next NET_BUFFER structure.

NDIS drivers call the NdisFreeFragmentNetBufferList function to free a NET_BUFFER_LIST structure and all associated NET_BUFFER structures and MDL chains that were previously allocated by calling NdisAllocateFragmentNetBufferList.

Related topics

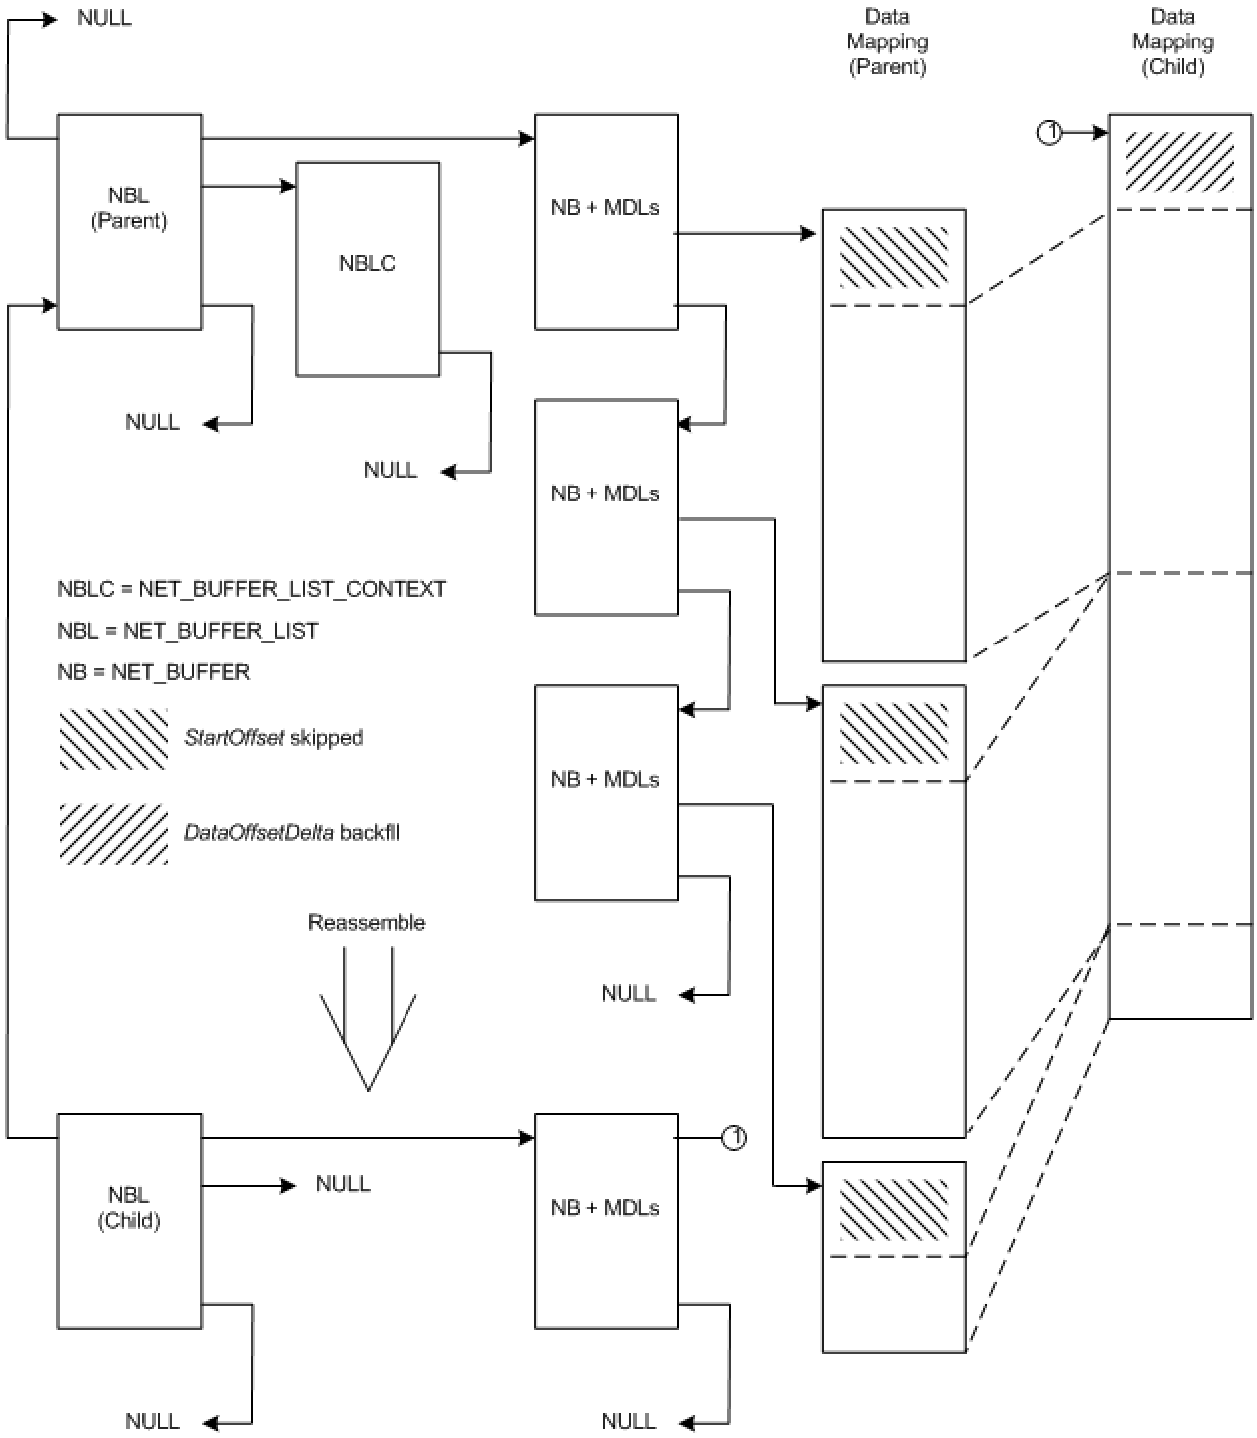
Derived NET_BUFFER_LIST Structures

Reassembled NET_BUFFER_LIST Structures

Article • 12/15/2021

An NDIS driver can create a reassembled **NET_BUFFER_LIST** structure from an existing NET_BUFFER_LIST structure. The reassembled structure references the original data from multiple source **NET_BUFFER** structures. Drivers can use this type of structure to efficiently combine many smaller buffers into a single large buffer.

The following figure shows the relationship between a parent NET_BUFFER_LIST structure and a reassembled child structure:



The preceding figure contains a parent NET_BUFFER_LIST structure and a child structure that was derived from that parent. The parent structure has one NET_BUFFER_LIST_CONTEXT structure and three NET_BUFFER structures with MDLs attached. The parent structure's parent pointer is **NULL** indicating that it is not a derived structure.

The child NET_BUFFER_LIST structure has one NET_BUFFER structure with MDLs attached. The child NET_BUFFER_LIST structure has a pointer to the parent structure. The **NULL** where a NET_BUFFER_LIST_CONTEXT structure pointer would be indicates that the child has no NET_BUFFER_LIST_CONTEXT structure.

NDIS drivers call the NdisAllocateReassembledNetBufferList function to reassemble a fragmented NET_BUFFER_LIST structure. NDIS allocates a new NET_BUFFER structure and MDLs with the reassembled NET_BUFFER_LIST structure. NDIS does not allocate a NET_BUFFER_LIST_CONTEXT structure for the reassembled structure. The reassembled NET_BUFFER structure and MDLs describe the same data as does the parent structure. The data is not copied.

To create the reassembled NET_BUFFER_LIST structure, **NdisAllocateReassembledNetBufferList** skips over the number of bytes specified in the *StartOffset* parameter in each of the parent NET_BUFFER structures. **NdisAllocateReassembledNetBufferList** concatenates the remaining data in each parent NET_BUFFER structure into the MDL chain of one reassembled NET_BUFFER structure. **NdisAllocateReassembledNetBufferList** retreats (increases the used data space in) the reassembled NET_BUFFER structure by the amount specified in *DataOffsetDelta* .

NDIS drivers call the NdisFreeReassembledNetBufferList function to free a reassembled NET_BUFFER_LIST structure and the associated NET_BUFFER structure and MDL chain.

Introduction to the NDIS PacketDirect Provider Interface

Article • 03/14/2023

The PacketDirect Provider Interface (PDPI) extends NDIS with an accelerated I/O model, for both physical and virtual environments, that can increase the number of packets processed per second by an order of magnitude and significantly decrease jitter when compared to the traditional NDIS I/O path.

Background

The traditional I/O model in Windows was implemented to be a multipurpose, general I/O platform that was intended to work with multiple media types with many different characteristics and where networking was only one aspect of the overall system. Today, as network virtualization has become a prevalent technology in datacenters, the traditional NDIS I/O model in the Windows Server OS is not only not sufficient to keep up with the network intensive workloads that we expect to become more and more common but also an inappropriate model to dedicate resources to network I/O processing. In datacenter environments, it is not uncommon to implement a single purpose machine dedicated to networking doing functions that were usually reserved for hardware appliances. Examples of these network appliances include software load balancers, DDoS appliances and forwarding gateways. To make matters worse, there are mechanisms on other OS' to accelerate I/O that make these alternative OS' the preferred platform to build network intensive applications such as virtual appliances.

PacketDirect (PD) extends the current NDIS model with an accelerated network I/O path that is optimized for packet per second (pps) counts an order of a magnitude higher than what has been seen with the traditional NDIS I/O model. This is accomplished through:

- Reduced latency
- Reduced cycles/packet
- Linear speed up with use of additional system resources

PacketDirect exists side-by-side with the traditional model. The new PD path can be used when an application prefers it and there are sufficient hardware resources to accommodate it. PD is not meant to replace the traditional I/O model and assumes that a client writing to the PD interface will have strict partitioning requirements for the underlying resources based on the system topology. PD is meant to be the new high speed data path that will help a Windows system replace high pps workloads that have been traditionally done in hardware, saving data center owners millions in infrastructure costs.

PacketDirect Concepts

PD works by allowing a PD client to explicitly manage networking traffic from a network adapter (NIC). PD gives the PD client control of the high performance send and receive functionality of the NIC through the PacketDirect client interface (PDCI). Internally, the PDCI send/receive functions are mapped directly to the PDPI. PD send/receive functions operate on PD queues created by the PD client on PD-capable NICs. PD provides the PD clients with the ability to set custom filters for very specific types of traffic or very generic traffic, based on the needs of the PD client. This allows the PD client to direct certain incoming packets to its PD queues. Packet processing in the PD model always takes place in an execution context that's owned (or controlled/coordinated) by the PD client. The PD-capable NIC driver is completely passive, meaning it does not actively forward incoming packets or completion indications for sent packets to the PD client in a driver-owned execution context such as a DPC or worker-thread.

If a PD client does not understand how to process a packet or receives a control packet in one of its queues, such as an ARP, LLDP, or other protocol packets, the PD client can reroute the packet back to the current I/O path for processing. This allows PD to continue to process the packets that it has context for and not waste cycles on control traffic.

Important There can be one PD provider and one PD client per net adapter. Therefore, there can be multiple PD clients and PD providers on a single system.

The PD client has control over the resources that are allocated to PD in the system. In cases of high network traffic, the PD client is responsible for minimizing its workload so that the OS can be responsive to other workloads.

The PacketDirect platform implemented by Windows maps the client interface to the provider interface. The platform controls buffer management and ability to re-inject packets received via PD to the current NDIS receive path. It also handles the interaction with PD clients for satisfying the NDIS control path requirements such as NIC disabling, going into low-power, system shutdown, and surprise removal in a fashion that does NOT hamper the PD data path performance.

PacketDirect Provider Interface (PDPI)

The PDPI allows NIC drivers to expose their high-performance send and receive functionality to the Windows OS. The functions implemented are a subset of the complete MiniPort functionality and are generic to all NICs that implement PD. For reference documentation for PDPI, see PacketDirect Provider Interface (PDPI) Reference.

PacketDirect Client Interface (PDCI)

The PDCI allows first-party Windows services/applications (e.g., Load-balancer, NAT, VM-switch, etc.) to speed up their data path by leveraging the PacketDirect I/O model through use of the PD clients. This interface is a layer 2 interface just like the current NDIS send/receive interface. The main functionality PDCI provides (in addition to PDPI access) is PD packet buffer allocation/management, a back-channel for injecting packets back to regular NDIS receive path, handling of NDIS power/PnP events.

Overview of NDIS versions

Article • 09/27/2024

If you're writing an NDIS driver for more than one version of Microsoft Windows, be sure the features that you're using are supported on each Windows version. New features have been added to NDIS with each release. Other features became obsolete and were removed from later NDIS versions.

This set of design guide documentation is targeted at Windows Vista and later operating systems and NDIS 6.0 and later drivers. Documentation for earlier Windows and NDIS versions is contained in prior releases of the documentation. For the Windows XP and NDIS 5.1 documentation, see Windows 2000 and Windows XP Networking Design Guide.

> **Note**
>
> A driver can query the NDIS version by calling the NdisReadConfiguration function with the *Keyword* parameter set to **NdisVersion**.

The following table describes Windows operating system, Microsoft Windows Driver Kit (WDK), and Driver Development Kit (DDK) version support for NDIS versions. This table also describes support for major NDIS features across NDIS versions.

Expand table

Windows Me	Windows NT 4.0 DDK or Windows 98 DDK for Vxds	5.0	X	X	X
Windows 98 SE	Windows NT 4.0 DDK or Windows 98 DDK	5.0. Added support for new INF file format compatible with Windows 95/98/Me, Plug and Play and Power Management, WMI, LBFO, and scatter/gather DMA support	X	X	X

Operating system	Development Kit	Supported NDIS version	CoNDIS	Deserialized driver	Intermediate driver
		for deserialized miniport drivers.			
Windows 98	Windows NT 4.0 DDK or Windows 98 DDK	4.1. Protocol driver is a vxd-type driver.	X	X	X
Windows 95 OSR2	Windows NT 4.0 DDK or Windows 95 DDK	4.0. Protocol driver is a vxd-type driver. Added these features: MiniportSendPackets, ProtocolReceivePacket, MiniportAllocateComplete.			
Windows 95	Windows NT 4.0 DDK or Windows 95 DDK	3.1. Added support for miniport drivers and Plug and Play.			

Introduction to NDIS 6.89

Article • 05/22/2024

This topic introduces Network Driver Interface Specification (NDIS) 6.89 and describes its major design additions. NDIS 6.89 is included in Windows 11, version 24H2 and Windows Server 2022 and later.

NDIS 6.89 is a minor version update to NDIS 6.88. For more information about porting NDIS 6.x drivers to NDIS 6.89, see Porting NDIS 6.x drivers to NDIS 6.89.

Feature updates

NDIS 6.89 adds support for UDP Receive Segment Coalescing Offload (URO). This hardware offload enables NICs to coalesce UDP receive segments. NICs can combine UDP datagrams from the same flow that match a set of rules into a logically contiguous buffer. These combined datagrams are then indicated to the Windows networking stack as a single large packet. Coalescing UDP datagrams reduces the CPU cost to process packets in high-bandwidth flows, resulting in higher throughput and fewer cycles per byte.

Implementing an NDIS 6.89 driver

An NDIS 6.89 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.89 driver must be compliant with the following requirements:

- An NDIS 6.89 driver must report the correct NDIS version when it registers with NDIS.
    - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.89. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 89. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler (see Compiling an NDIS 6.89 driver).
    - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3.

    - Filter drivers must set the **Header** member of NDIS_FILTER_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_3.

    - Protocol drivers must set the **Header** member of NDIS_PROTOCOL_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

- NDIS 6.89 miniport drivers for Windows 11, version 24H2 and Windows Server 2022 and later must use the NDIS 6.89 versions of data structures.

Compiling an NDIS 6.89 driver

The WDK for Windows Server 2022 supports header versioning. Header versioning makes sure that NDIS 6.89 drivers use the appropriate NDIS 6.89 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS689_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS689=1`.

For information on building a driver with the Windows Server 2022 release of the WDK, see Building a Driver.

Introduction to NDIS 6.88

Article • 05/22/2024

This topic introduces Network Driver Interface Specification (NDIS) 6.88 and describes its major design additions. NDIS 6.88 is included in Windows Server 2022 23H2 and later.

NDIS 6.88 is a minor version update to NDIS 6.87. For more information about porting NDIS 6.x drivers to NDIS 6.88, see Porting NDIS 6.x drivers to NDIS 6.88.

Feature updates

NDIS 6.88 is an incremental update to NDIS 6.87 and does not contain any major new features.

Implementing an NDIS 6.88 driver

An NDIS 6.88 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.88 driver must be compliant with the following requirements:

- An NDIS 6.88 driver must report the correct NDIS version when it registers with NDIS.
  - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.88. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 88. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler (see Compiling an NDIS 6.88 driver).
  - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3.
  - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_3.

  - Protocol drivers must set the **Header** member of NDIS_PROTOCOL_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

- NDIS 6.88 miniport drivers for Windows Server 2022 23H2 and later must use the NDIS 6.88 versions of data structures.

Compiling an NDIS 6.88 driver

The WDK for Windows Server 2022 supports header versioning. Header versioning makes sure that NDIS 6.88 drivers use the appropriate NDIS 6.88 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS688_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS688=1`.

For information on building a driver with the Windows Server 2022 release of the WDK, see Building a Driver.

Introduction to NDIS 6.87

Article • 05/22/2024

This topic introduces Network Driver Interface Specification (NDIS) 6.87 and describes its major design additions. NDIS 6.87 is included in Windows 11, version 22H2 and Windows Server 2022 and later.

NDIS 6.87 is a minor version update to NDIS 6.86. For more information about porting NDIS 6.x drivers to NDIS 6.87, see Porting NDIS 6.x drivers to NDIS 6.87.

Feature updates

NDIS 6.87 is an incremental update to NDIS 6.86 and does not contain any major new features.

Implementing an NDIS 6.87 driver

An NDIS 6.87 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.87 driver must be compliant with the following requirements:

- An NDIS 6.87 driver must report the correct NDIS version when it registers with NDIS.
  - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.87. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 87. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler (see Compiling an NDIS 6.87 driver).
  - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3.
  - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_3.

  - Protocol drivers must set the **Header** member of NDIS_PROTOCOL_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

- NDIS 6.87 miniport drivers for Windows 11, version 22H2 and Windows Server 2022 and later must use the NDIS 6.87 versions of data structures.

Compiling an NDIS 6.87 driver

The WDK for Windows Server 2022 supports header versioning. Header versioning makes sure that NDIS 6.87 drivers use the appropriate NDIS 6.87 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS687_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS687=1`.

For information on building a driver with the Windows Server 2022 release of the WDK, see Building a Driver.

Introduction to NDIS 6.86

Article • 03/14/2023

This topic introduces Network Driver Interface Specification (NDIS) 6.86 and describes its major design additions. NDIS 6.86 is included in Windows 11, version 21H2 and Windows Server 2022 and later.

NDIS 6.86 is a minor version update to NDIS 6.85. For more information about porting NDIS 6.x drivers to NDIS 6.86, see Porting NDIS 6.x drivers to NDIS 6.86.

Feature updates

NDIS 6.86 is an incremental update to NDIS 6.85 and does not contain any major new features.

Implementing an NDIS 6.86 driver

An NDIS 6.86 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.86 driver must be compliant with the following requirements:

- An NDIS 6.86 driver must report the correct NDIS version when it registers with NDIS.
  - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.86. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 86. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler (see Compiling an NDIS 6.86 driver).
  - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3.
  - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_3.

    - Protocol drivers must set the **Header** member of NDIS_PROTOCOL_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

- NDIS 6.86 miniport drivers for Windows 11, version 21H2 and Windows Server 2022 and later must use the NDIS 6.86 versions of data structures.

Compiling an NDIS 6.86 driver

The WDK for Windows Server 2022 supports header versioning. Header versioning makes sure that NDIS 6.86 drivers use the appropriate NDIS 6.86 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS686_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS686=1`.

For information on building a driver with the Windows Server 2022 release of the WDK, see Building a Driver.

Introduction to NDIS 6.85

Article • 06/15/2023

This topic introduces Network Driver Interface Specification (NDIS) 6.85 and describes its major design additions. NDIS 6.85 is included in Windows 10, version 21H2 and Windows Server 2022 and later.

NDIS 6.85 is a minor version update to NDIS 6.84. For more information about porting NDIS 6.x drivers to NDIS 6.85, see Porting NDIS 6.x drivers to NDIS 6.85.

Feature updates

NDIS Poll mode

NDIS 6.85 introduces NDIS Poll Mode, an OS controlled polling execution model that drives the network interface datapath. Previously, NDIS drivers typically relied on Deferred Procedure Calls (DPCs) to implement their execution model. NDIS Poll Mode moves the complexity of scheduling decisions away from NIC drivers and into NDIS. For more information, see NDIS Poll Mode.

Network Virtualization using Generic Routing Encapsulation (NVGRE) with UDP segmentation offload (USO)

NDIS 6.85 introduces Supporting NVGRE in UDP Segmentation Offload (USO). NDIS miniport, protocol, and filter drivers, as well as NICs that perform USO, should support NVGRE and VXLAN encapsulations.

Implementing an NDIS 6.85 driver

An NDIS 6.85 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.85 driver must be compliant with the following requirements:

- An NDIS 6.85 driver must report the correct NDIS version when it registers with NDIS.

  - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.85. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 85. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler (see Compiling an NDIS 6.85 driver).

  - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3.

  - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_3.

  - Protocol drivers must set the **Header** member of **NDIS_PROTOCOL_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

- NDIS 6.85 miniport drivers for Windows 10, version 21H2 and Windows Server 2022 and later must use the NDIS 6.85 versions of data structures.

Compiling an NDIS 6.85 driver

The WDK for Windows 10, version 21H2 supports header versioning. Header versioning makes sure that NDIS 6.85 drivers use the appropriate NDIS 6.85 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS685_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS685=1`.

For information on building a driver with the Windows 10, version 21H2 release of the WDK, see Building a Driver.

Introduction to NDIS 6.84

Article • 03/14/2023

This topic introduces Network Driver Interface Specification (NDIS) 6.84 and describes its major design additions. NDIS 6.84 is included in Windows 10, version 2004 and Windows Server 2022 and later.

NDIS 6.84 is a minor version update to NDIS 6.83. For more information about porting NDIS 6.x drivers to NDIS 6.84, see Porting NDIS 6.x drivers to NDIS 6.84.

Feature updates

NDIS 6.84 is an incremental update to NDIS 6.83 and does not contain any major new features.

Implementing an NDIS 6.84 driver

An NDIS 6.84 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.84 driver must be compliant with the following requirements:

- An NDIS 6.84 driver must report the correct NDIS version when it registers with NDIS.
    - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.84. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 84. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler (see Compiling an NDIS 6.84 driver).
    - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3.
    - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_3.

- Protocol drivers must set the **Header** member of NDIS_PROTOCOL_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

- NDIS 6.84 miniport drivers for Windows 10, version 2004 and Windows Server 2022 and later must use the NDIS 6.84 versions of data structures.

Compiling an NDIS 6.84 driver

The WDK for Windows 10, version 2004 supports header versioning. Header versioning makes sure that NDIS 6.84 drivers use the appropriate NDIS 6.84 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS684_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS684=1`.

For information on building a driver with the Windows 10, version 2004 release of the WDK, see Building a Driver.

Introduction to NDIS 6.83

Article • 03/14/2023

This topic introduces Network Driver Interface Specification (NDIS) 6.83 and describes its major design additions. NDIS 6.83 is included in Windows 10, version 1903 and Windows Server 2022 and later.

NDIS 6.83 is a minor version update to NDIS 6.82. For more information about porting NDIS 6.x drivers to NDIS 6.83, see Porting NDIS 6.x drivers to NDIS 6.83.

Feature updates

NDIS 6.83 is an incremental update to NDIS 6.82 and does not contain any major new features.

Implementing an NDIS 6.83 driver

An NDIS 6.83 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.83 driver must be compliant with the following requirements:

- An NDIS 6.83 driver must report the correct NDIS version when it registers with NDIS.
  - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.83. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 83. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler (see Compiling an NDIS 6.83 driver).
  - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3.
  - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_3.

    - Protocol drivers must set the **Header** member of NDIS_PROTOCOL_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

- NDIS 6.83 miniport drivers for Windows 10, version 1903 and Windows Server 2022 and later must use the NDIS 6.83 versions of data structures.

Compiling an NDIS 6.83 driver

The WDK for Windows 10, version 1903 supports header versioning. Header versioning makes sure that NDIS 6.83 drivers use the appropriate NDIS 6.83 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS683_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS683=1`.

For information on building a driver with the Windows 10, version 1903 release of the WDK, see Building a Driver.

Introduction to NDIS 6.82

Article • 03/14/2023

This topic introduces Network Driver Interface Specification (NDIS) 6.82 and describes its major design additions. NDIS 6.82 is included in Windows 10, version 1809 and Windows Server 2019 and later.

NDIS 6.82 is a minor version update to NDIS 6.81. For more information about porting NDIS 6.x drivers to NDIS 6.82, see Porting NDIS 6.x drivers to NDIS 6.82.

Feature updates

NDIS 6.82 is an incremental update to NDIS 6.81 and does not contain any major new features.

Implementing an NDIS 6.82 driver

An NDIS 6.82 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.82 driver must be compliant with the following requirements:

- An NDIS 6.82 driver must report the correct NDIS version when it registers with NDIS.

  - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.82. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 82. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler (see Compiling an NDIS 6.82 driver).

  - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3.

  - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_3.

- Protocol drivers must set the **Header** member of NDIS_PROTOCOL_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

- NDIS 6.82 miniport drivers for Windows 10, version 1809 and Windows Server 2019 and later must use the NDIS 6.82 versions of data structures.

Compiling an NDIS 6.82 driver

The WDK for Windows 10, version 1809 supports header versioning. Header versioning makes sure that NDIS 6.82 drivers use the appropriate NDIS 6.82 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS682_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS682=1`.

For information on building a driver with the Windows 10, version 1809 release of the WDK, see Building a Driver.

Introduction to NDIS 6.81

Article • 03/14/2023

This topic introduces Network Driver Interface Specification (NDIS) 6.81 and describes its major design additions. NDIS 6.81 is included in Windows 10, version 1803 and Windows Server 2016 and later.

NDIS 6.81 is a minor version update to NDIS 6.80. For more information about porting NDIS 6.x drivers to NDIS 6.81, see Porting NDIS 6.x drivers to NDIS 6.81.

Feature updates

NDIS 6.81 is an incremental update to NDIS 6.80 and does not contain any major new features.

Implementing an NDIS 6.81 driver

An NDIS 6.81 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.81 driver must be compliant with the following requirements:

- An NDIS 6.81 driver must report the correct NDIS version when it registers with NDIS.
  - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.81. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 81. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler (see Compiling an NDIS 6.81 driver).
  - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3.
  - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_3.

    - Protocol drivers must set the **Header** member of NDIS_PROTOCOL_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

- NDIS 6.81 miniport drivers for Windows 10, version 1803 and Windows Server 2016 and later must use the NDIS 6.81 versions of data structures.

Compiling an NDIS 6.81 driver

The WDK for Windows 10, version 1803 supports header versioning. Header versioning makes sure that NDIS 6.81 drivers use the appropriate NDIS 6.81 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS681_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS681=1`.

For information on building a driver with the Windows 10, version 1803 release of the WDK, see Building a Driver.

Introduction to NDIS 6.80

Article • 03/14/2023

This topic introduces Network Driver Interface Specification (NDIS) 6.80 and describes its major design additions. NDIS 6.80 is included in Windows 10, version 1709.

NDIS 6.80 is a minor version update to NDIS 6.70 for miniport, protocol, filter, and intermediate drivers. For more information about porting NDIS 6.x drivers to NDIS 6.80, see Porting NDIS 6.x drivers to NDIS 6.80.

For NIC drivers, the NetAdapter class extension (NetAdapterCx) has been updated from version 1.0 to version 1.1 in Windows 10, version 1709.

Feature updates

Synchronous OID requests

NDIS 6.80 introduces a new feature for OIDs, Synchronous OID requests. Synchronous OID calls are low-latency, non-blocking, scalable, and reliable compared to regular OID requests. For more info, see Synchronous OID Request Interface in NDIS 6.80.

RSSv2

In NDIS 6.80, Receive Side Scaling (RSS) has been upgraded to RSS version 2 (RSSv2). RSSv2 improves on RSSv2 by offering per-VPort spreading. For more info, see Receive Side Scaling Version 2 (RSSv2) in NDIS 6.80.

RSSv2 is preview only in Windows 10, version 1709.

Other new networking features

NDIS forms the core foundation for the network driver platform on Windows. For a list of other network driver features that were updated at the same time as NDIS 6.80, see the Windows 10, version 1709 section for Networking on What's new in driver development.

Implementing an NDIS 6.80 driver

An NDIS 6.80 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.80 driver must be compliant with the following requirements:

- An NDIS 6.80 driver must report the correct NDIS version when it registers with NDIS.
    - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.80. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 80. This requirement applies to miniport, protocol and filter drivers.
    - You must also update the version information for the compiler (see Compiling an NDIS 6.80 driver).
    - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_3.
    - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_3 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_3.
    - Protocol drivers must set the **Header** member of **NDIS_PROTOCOL_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

Compiling an NDIS 6.80 driver

NIC drivers

For more information about compiling a NIC driver with the NetAdapterCx, see Porting NDIS miniport drivers to NetAdapterCx (Compilation settings).

Miniport, protocol, and filter drivers

The WDK for Windows 10, version 1709 supports header versioning. Header versioning makes sure that NDIS 6.80 drivers use the appropriate NDIS 6.80 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS680_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS680=1`.

For information on building a driver with the Windows 10, version 1709 release of the WDK, see Building a Driver.

API and data structure changes

New APIs and data structures

The following APIs and data structures are new in NDIS 6.80.

- MINIPORT_SYNCHRONOUS_OID_REQUEST
- FILTER_SYNCHRONOUS_OID_REQUEST
- FILTER_SYNCHRONOUS_OID_REQUEST_COMPLETE
- NdisFSynchronousOidRequest
- NdisSynchronousOidRequest
- OID_GEN_RECEIVE_SCALE_PARAMETERS_V2
- OID_GEN_RSS_SET_INDIRECTION_TABLE_ENTRIES
- NDIS_RECEIVE_SCALE_PARAMETERS_V2
- NDIS_RSS_SET_INDIRECTION_ENTRIES
- NDIS_RSS_SET_INDIRECTION_ENTRY

Updated APIs and data structures

The following APIs and data structures were updated in NDIS 6.80.

- NDIS_MINIPORT_DRIVER_CHARACTERISTICS
- NDIS_FILTER_DRIVER_CHARACTERISTICS
- NDIS_RECEIVE_SCALE_CAPABILITIES

Synchronous OID request interface in NDIS 6.80

Article • 03/14/2023

Windows network drivers use OID requests to send control messages down the NDIS binding stack. Protocol drivers, such as TCPIP or vSwitch, rely on dozens of OIDs to configure each feature of the underlying NIC driver. Before Windows 10, version 1709, OID requests were sent in two ways: Regular and Direct.

This topic introduces a third style of OID call: Synchronous. A Synchronous call is meant to be low-latency, non-blocking, scalable, and reliable. The Synchronous OID request interface is available starting in NDIS 6.80, which is included in Windows 10, version 1709 and later.

Comparison to Regular and Direct OID requests

With Synchronous OID requests, the payload of the call (the OID itself) is exactly the same as with Regular and Direct OID requests. The only difference is in the call itself. Therefore, the *what* is the same across all three types of OIDs; only the *how* is different.

The following table describes the differences between Regular OIDs, Direct OIDs, and Synchronous OIDs.

Attribute	Regular OID	Direct OID	Synchronous OID
Payload	NDIS_OID_REQUEST	NDIS_OID_REQUEST	NDIS_OID_REQUEST
OID types	Stats, Query, Set, Method	Stats, Query, Set, Method	Stats, Query, Set, Method
Can be issued by	Protocols, filters	Protocols, filters	Protocols, filters
Can be completed by	Miniports, filters	Miniports, filters	Miniports, filters
Filters can modify	Yes	Yes	Yes
NDIS allocates memory	For each filter (OID clone)	For each filter (OID clone)	Only if unusually large number of filters (call context)
Can pend	Yes	Yes	No

Attribute	Regular OID	Direct OID	Synchronous OID
Can block	Yes	No	No
IRQL	== PASSIVE	<= DISPATCH	<= DISPATCH
Serialized by NDIS	Yes	No	No
Filters are invoked	Recursively	Recursively	Iteratively
Filters clone the OID	Yes	Yes	No

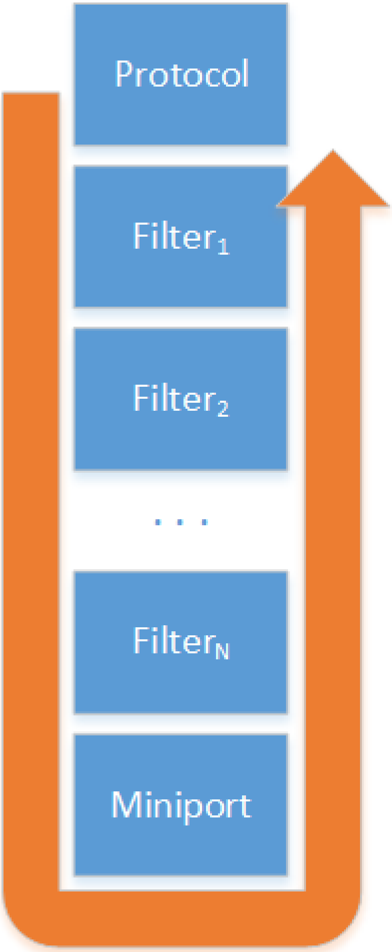
Filtering

Like the other two types of OID calls, filter drivers have full control over the OID request in a Synchronous call. Filter drivers can observe, intercept, modify, and issue Synchronous OIDs. However, for efficiency, the mechanics of a Synchronous OID are somewhat different.

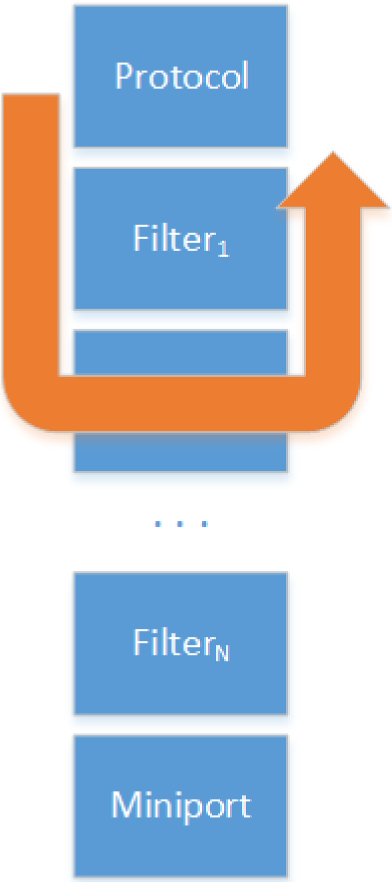
Passthrough, interception, and origination

Conceptually, all OID requests are issued from a higher driver and are completed by a lower driver. Along the way, the OID request may pass through any number of filter drivers.

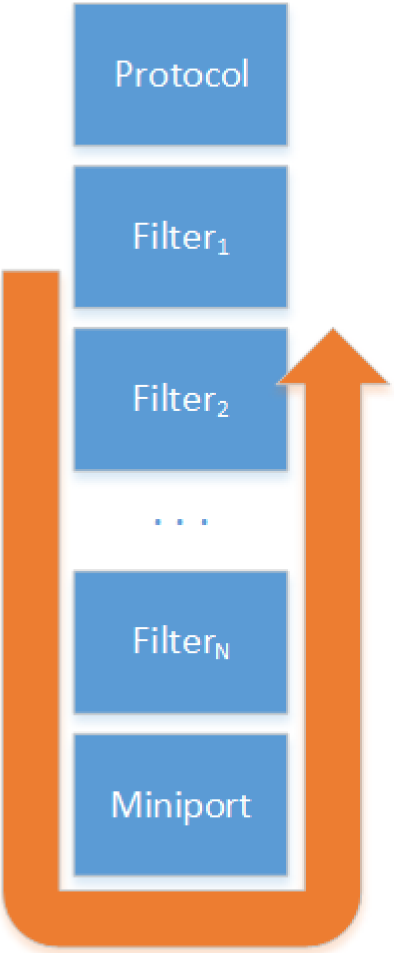
In the most common case, a protocol driver issues an OID request and all filters simply pass the OID request down, unmodified. The following figure illustrates this common scenario.



However, any filter module is allowed to intercept the OID request and complete it. In that case, the request does not pass through to lower drivers, as shown in the following diagram.



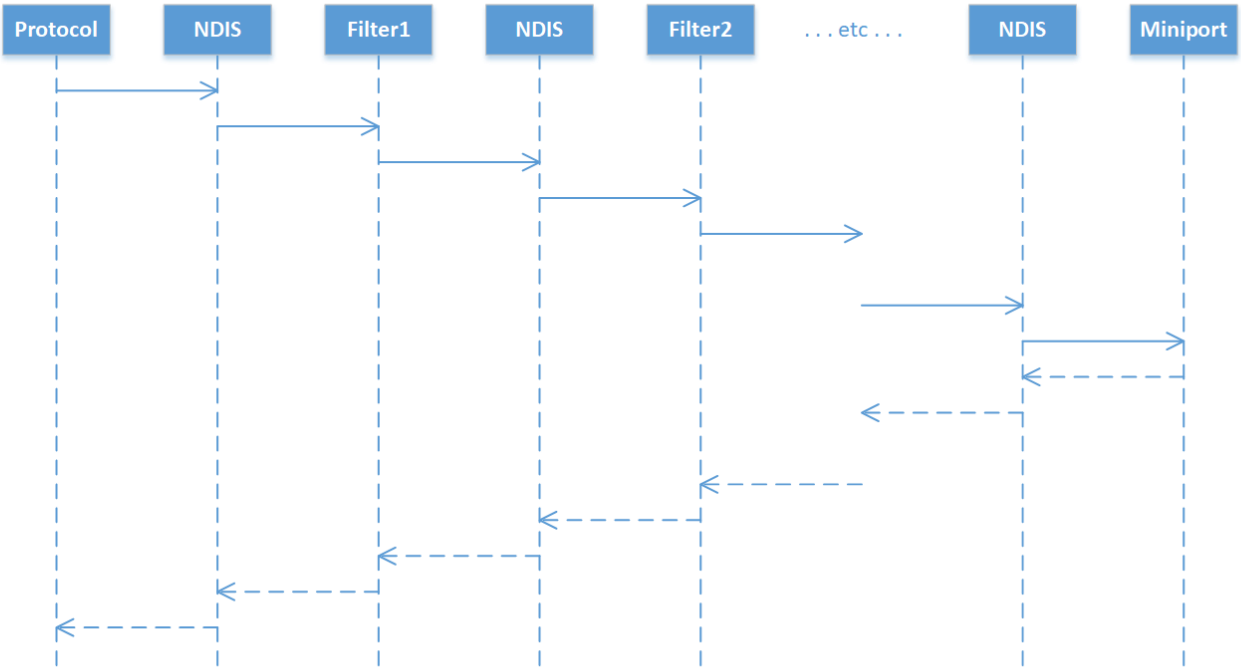
In some cases, a filter module may decide to originate its own OID request. This request starts at the filter module's level and only traverses lower drivers, as the following diagram shows.



All OID requests have this basic flow: a higher driver (either a protocol or filter driver) issues a request and a lower driver (either a miniport or filter driver) completes it.

How Regular and Direct OID requests work

Regular or Direct OID requests are dispatched recursively. The following diagram shows the function call sequence. Note that the sequence itself is much like the sequence described in the diagrams from the previous section, but is arranged to show the recursive nature of the requests.



If there are enough filters installed, NDIS will be forced to allocate a new thread stack to keep recursing deeper.

NDIS considers an NDIS_OID_REQUEST structure to be valid for only a single hop along the stack. If a filter driver wants to pass the request down to the next lower driver (which is the case for the vast majority of OIDs), the filter driver *must* insert several dozen lines of boilerplate code to clone the OID request. This boilerplate has several problems:

1. It forces a memory allocation to clone the OID. Hitting the memory pool is both slow and makes it impossible to guarantee forward progress of the OID request.
2. The OID structure design must remain the same over time because all filter drivers hard-code the mechanics of copying the contents of one NDIS_OID_REQUEST to another.
3. Requiring so much boilerplate obscures what the filter is really doing.

The filtering model for Synchronous OID requests

The filtering model for Synchronous OID requests takes advantage of the synchronous nature of the call, to solve the problems discussed in the previous section.

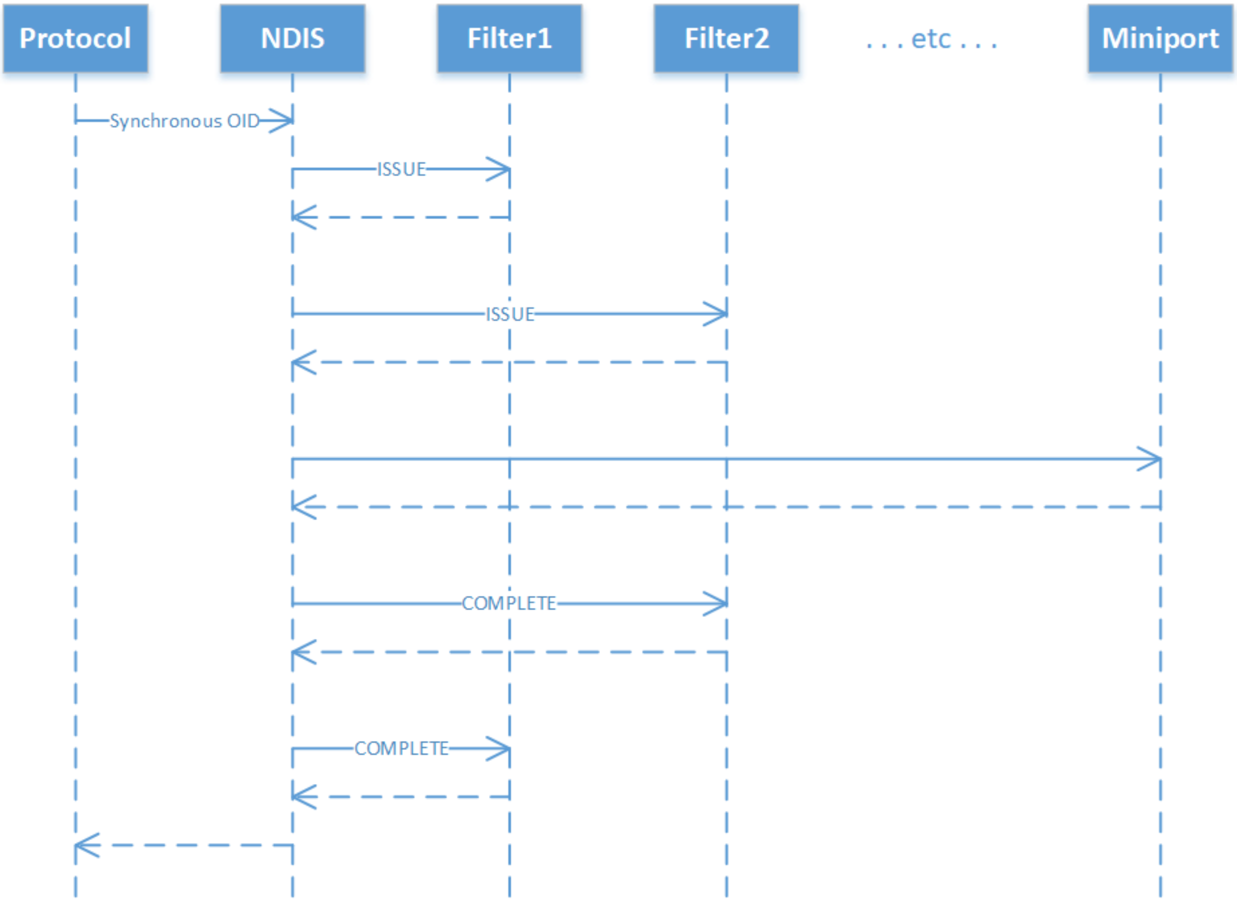
Issue and Complete handlers

Unlike Regular and Direct OID requests, there are two filter hooks for Synchronous OID requests: an Issue handler and a Complete handler. A filter driver can register neither, one, or both hooks.

Issue calls are invoked for each filter driver, starting from the top of the stack down to the bottom of the stack. Any filter's Issue call can stop the OID from continuing downward, and complete the OID with some status code. If no filter decides to intercept the OID, then the OID reaches the NIC driver, which must complete the OID synchronously.

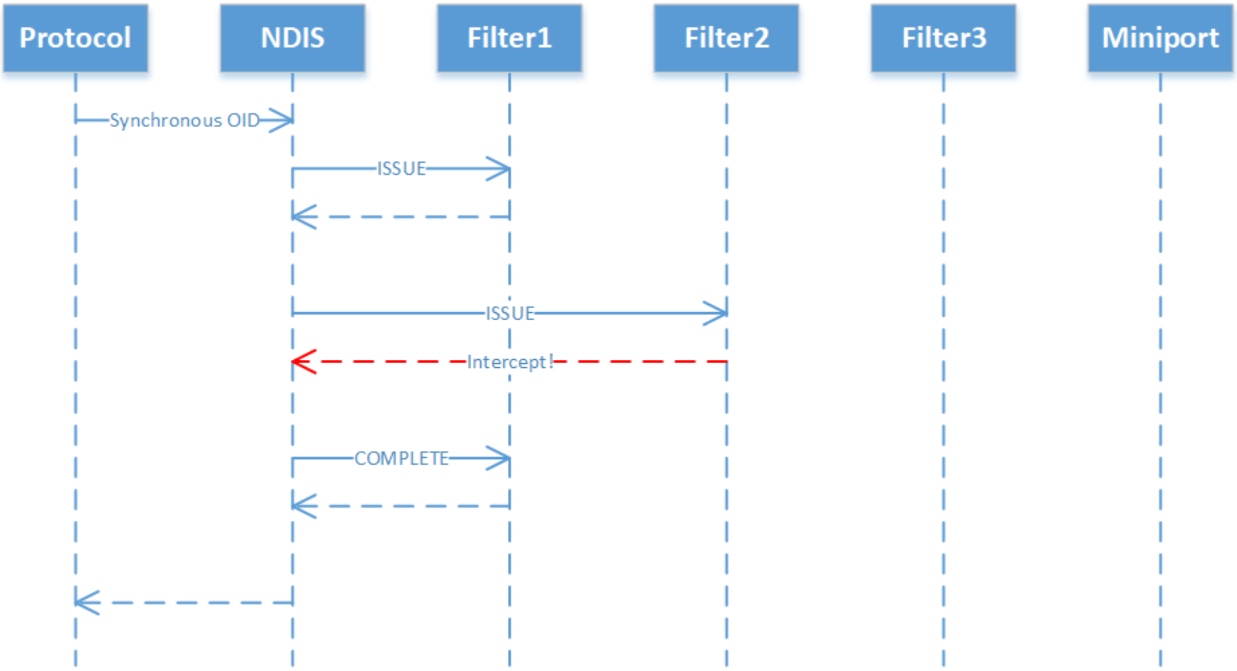
After an OID is completed, Complete calls are invoked for each filter driver, starting from wherever in the stack the OID was completed, up to the top of the stack. A Complete call can inspect or modify the OID request, and inspect or modify the OID's completion status code.

The following diagram illustrates the typical case, where a protocol issues a Synchronous OID request and the filters do not intercept the request.



Note that the call model for Synchronous OIDs is iterative. This keeps stack usage bounded by a constant, eliminating the need to ever expand the stack.

If a filter driver intercepts a Synchronous OID in its Issue handler, the OID is not given to lower filters or the NIC driver. However, Complete handlers for higher filters are still invoked, as shown in the following diagram:



Minimal memory allocations

Regular and Direct OID requests require a filter driver to clone an NDIS_OID_REQUEST. In contrast, Synchronous OID requests are not permitted to be cloned. The advantage of this design is that Synchronous OIDs have lower latency – the OID request isn't repeatedly cloned as it travels down the filter stack – and there are fewer opportunities for failure.

However, that does raise a new problem. If the OID cannot be cloned, where does a filter driver store its per-request state? For example, suppose a filter driver translates one OID to another. On the way down the stack, the filter needs to save off the old OID. On the way back up the stack, the filter needs to restore the old OID.

To solve this problem, NDIS allocates a pointer-sized slot for each filter driver, for each in-flight Synchronous OID request. NDIS preserves this slot across the call from a filter's Issue handler to its Complete handler. This allows the Issue handler to save off state that is later consumed by the Complete handler. The following code snippet shows an example.

C++

```
NDIS_STATUS
MyFilterSynchronousOidRequest(
  _In_ NDIS_HANDLE FilterModuleContext,
  _Inout_ NDIS_OID_REQUEST *OidRequest,
  _Outptr_result_maybenull_ PVOID *CallContext)
{
  if ( . . . should intercept this OID . . . )
  {
    // preserve the original buffer in the CallContext
    *CallContext = OidRequest->DATA.SET_INFORMATION.InformationBuffer;

    // replace the buffer with a new one
    OidRequest->DATA.SET_INFORMATION.InformationBuffer = . . . something . .
.;
  }

  return NDIS_STATUS_SUCCESS;
}

VOID
MyFilterSynchronousOidRequestComplete(
  _In_ NDIS_HANDLE FilterModuleContext,
  _Inout_ NDIS_OID_REQUEST *OidRequest,
  _Inout_ NDIS_STATUS *Status,
  _In_ PVOID CallContext)
{
  // if the context is not null, we must have replaced the buffer.
  if (CallContext != null)
  {
    // Copy the data from the miniport back into the protocol’s original
buffer.
    RtlCopyMemory(CallContext, OidRequest-
>DATA.SET_INFORMATION.InformationBuffer,...);

    // restore the original buffer into the OID request
    OidRequest->DATA.SET_INFORMATION.InformationBuffer = CallContext;
  }
}
```

NDIS saves one PVOID per filter per call. NDIS heuristically allocates a reasonable number of slots on the stack, so that there are zero pool allocations in the common case. This is usually no more than seven filters. If the user sets up a pathological case, NDIS does fall back to a pool allocation.

Reduced boilerplate

Consider the boilerplate on Example boilerplate for handling Regular or Direct OID requests. That code is the cost of entry just to register an OID handler. If you want to issue your own OIDs, you have to add another dozen lines of boilerplate. With Synchronous OIDs, there's no need for the additional complexity of handling asynchronous completion. Therefore, you can cut out much of that boilerplate.

Here's a minimal issue handler with Synchronous OIDs:

```C++
NDIS_STATUS
MyFilterSynchronousOidRequest(
  NDIS_HANDLE FilterModuleContext,
  NDIS_OID_REQUEST *OidRequest,
  PVOID *CallContext)
{
  return NDIS_STATUS_SUCCESS;
}
```

If you want to intercept or modify a particular OID, you can do it by adding just a couple lines of code. The minimal Complete handler is even simpler:

```C++
VOID
MyFilterSynchronousOidRequestComplete(
  NDIS_HANDLE FilterModuleContext,
  NDIS_OID_REQUEST *OidRequest,
  NDIS_STATUS *Status,
  PVOID CallContext)
{
  return;
}
```

Likewise, a filter driver can issue a new Synchronous OID request of its own using only one line of code:

```C++
status = NdisFSynchronousOidRequest(binding->NdisBindingHandle, &oid);
```

In contrast, a filter driver that needs to issue a Regular or Direct OID must set up an asynchronous completion handler and implement some code to distinguish its own OID completions from the completions of OIDs that it just cloned. An example of this boilerplate is shown on Example boilerplate for issuing a Regular OID request.

Interoperability

Although the Regular, Direct, and Synchronous calling styles all use the same data structures, the pipelines do not go to the same handler in the miniport. Furthermore, some OIDs cannot be used in some of the pipelines. For example, OID_PNP_SET_POWER requires careful synchronization and often forces the miniport to make blocking calls. This makes handling it difficult in a Direct OID callback and prevents its use in a Synchronous OID callback.

Therefore, just as with Direct OID requests, Synchronous OID calls can only be used with a subset of OIDs. In Windows 10, version 1709, only the

OID_GEN_RSS_SET_INDIRECTION_TABLE_ENTRIES OID used in Receive Side Scaling Version 2 (RSSv2) is supported in the Synchronous OID path.

Implementing Synchronous OID requests

For more info about implementing the Synchronous OID request interface in drivers, see the following topics:

- Miniport Adapter OID Requests
- Filter Module OID Requests
- Protocol Driver OID Requests

Example boilerplate for handling Regular or Direct OID requests

Article • 12/15/2021

This topic provides example boilerplate code for handling Regular or Direct OID requests, to contrast against the examples in Synchronous OID Request Interface in NDIS 6.80. The Synchronous OID Request Interface is available on Windows 10, version 1709 and later.

C++

```
NDIS_STATUS
FilterOidRequest(
  NDIS_HANDLE     FilterModuleContext,
  PNDIS_OID_REQUEST  Request)
{
  PMS_FILTER       pFilter = (PMS_FILTER)FilterModuleContext;

  Status = NdisAllocateCloneOidRequest(pFilter->FilterHandle,
                     Request,
                     FILTER_TAG,
                    &ClonedRequest);
  if (Status != NDIS_STATUS_SUCCESS)
    return Status;

  Context = (PFILTER_REQUEST_CONTEXT)(&ClonedRequest->SourceReserved[0]);
  *Context = Request;

  ClonedRequest->RequestId = Request->RequestId;

  Status = NdisFOidRequest(pFilter->FilterHandle, ClonedRequest);

  if (Status != NDIS_STATUS_PENDING)
  {
    FilterOidRequestComplete(pFilter, ClonedRequest, Status);
    Status = NDIS_STATUS_PENDING;
  }
  return Status;
}

VOID
FilterOidRequestComplete(
  NDIS_HANDLE     FilterModuleContext,
  PNDIS_OID_REQUEST  Request,
  NDIS_STATUS     Status)
{
  PMS_FILTER             pFilter = (PMS_FILTER)FilterModuleContext;
  PNDIS_OID_REQUEST          OriginalRequest;
  Context = (PFILTER_REQUEST_CONTEXT)(&Request->SourceReserved[0]);
  OriginalRequest = (*Context);

  //
  // Copy the information from the returned request to the original request
  //
  switch(Request->RequestType)
  {
    case NdisRequestMethod:
      OriginalRequest->DATA.METHOD_INFORMATION.OutputBufferLength = Request-
>DATA.METHOD_INFORMATION.OutputBufferLength;
      OriginalRequest->DATA.METHOD_INFORMATION.BytesRead = Request-
>DATA.METHOD_INFORMATION.BytesRead;
      OriginalRequest->DATA.METHOD_INFORMATION.BytesNeeded = Request-
>DATA.METHOD_INFORMATION.BytesNeeded;
      OriginalRequest->DATA.METHOD_INFORMATION.BytesWritten = Request-
>DATA.METHOD_INFORMATION.BytesWritten;
      break;

    case NdisRequestSetInformation:
      OriginalRequest->DATA.SET_INFORMATION.BytesRead = Request-
>DATA.SET_INFORMATION.BytesRead;
      OriginalRequest->DATA.SET_INFORMATION.BytesNeeded = Request-
>DATA.SET_INFORMATION.BytesNeeded;
      break;

    case NdisRequestQueryInformation:
    case NdisRequestQueryStatistics:
    default:
      OriginalRequest->DATA.QUERY_INFORMATION.BytesWritten = Request-
>DATA.QUERY_INFORMATION.BytesWritten;
      OriginalRequest->DATA.QUERY_INFORMATION.BytesNeeded = Request-
>DATA.QUERY_INFORMATION.BytesNeeded;
      break;
  }

  NdisFreeCloneOidRequest(pFilter->FilterHandle, Request);

  NdisFOidRequestComplete(pFilter->FilterHandle, OriginalRequest, Status);
}
```

Example boilerplate for issuing a Regular OID request

Article • 05/30/2023

This topic provides example boilerplate code for issuing a Regular OID request, to contrast against the examples in Synchronous OID Request Interface in NDIS 6.80. The Synchronous OID Request Interface is available on Windows 10, version 1709 and later.

This example is taken from the sample NDIS filter driver.

```C++
Status = filterDoInternalRequest(pFilter,
                 NdisRequestQueryInformation,
                 OID_802_3_CURRENT_ADDRESS,
                 MacAddress,
                 sizeof(MacAddress),
                 0,
                 0,
                 &BytesProcessed);

_IRQL_requires_max_(DISPATCH_LEVEL)
NDIS_STATUS
filterDoInternalRequest(
  _In_ PMS_FILTER          FilterModuleContext,
  _In_ NDIS_REQUEST_TYPE      RequestType,
  _In_ NDIS_OID           Oid,
  _Inout_updates_bytes_to_(InformationBufferLength, *pBytesProcessed)
     PVOID            InformationBuffer,
  _In_ ULONG            InformationBufferLength,
  _In_opt_ ULONG          OutputBufferLength,
  _In_ ULONG            MethodId,
  _Out_ PULONG           pBytesProcessed
  )
{
  FILTER_REQUEST       FilterRequest;
  PNDIS_OID_REQUEST      NdisRequest = &FilterRequest.Request;
  NDIS_STATUS         Status;
  BOOLEAN           bFalse;

  bFalse = FALSE;
  *pBytesProcessed = 0;
  NdisZeroMemory(NdisRequest, sizeof(NDIS_OID_REQUEST));

Receive Side Scaling Version 2 (RSSv2) in NDIS 6.80

Article • 03/14/2023

⚠ Warning

Some information in this topic relates to prereleased product, which may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.

RSSv2 is preview only in Windows 10, version 1809.

Receive Side Scaling improves the system performance related to handling of network data on multiprocessor systems. NDIS 6.80 and later support RSS Version 2 (RSSv2), which extends RSS by offering per-VPort spreading of queues.

RSSv2 uses the NDIS 6.80 Synchronous OID request interface for one of its OIDs. For more info about Synchronous OID calls, see Synchronous OID request interface in NDIS 6.80.

For more info about RSSv2, see Receive Side Scaling Version 2 (RSSv2).

Introduction to NDIS 6.70

Article • 03/14/2023

This topic introduces Network Driver Interface Specification (NDIS) 6.70 and describes its major design additions. NDIS 6.70 is included in Windows 10, version 1703.

NDIS 6.70 is a minor version update to NDIS 6.60 for miniport, protocol, filter, and intermediate drivers. For more information about porting NDIS 6.x drivers to NDIS 6.70, see Porting NDIS 6.x drivers to NDIS 6.70.

Feature updates

NetAdapterCx

Alongside NDIS 6.70, Windows 10, version 1703 includes a major new feature for NIC drivers called the Network Adapter WDF Class Extension, a.k.a. NetAdapterCx. NetAdapterCx is preview only in Windows 10, version 1703. The NetAdapterCx model enables NIC driver developers to harness the full functionality and simplified driver model of WDF, meaning NIC drivers are easier to write.

Other feature updates

NDIS forms the core foundation for the network driver platform on Windows. For a list of other network driver features that were updated at the same time as NDIS 6.70, see the Windows 10, version 1703 section for Networking on What's new in driver development.

Feature deprecations

The following network driver features have been deprecated along with the release of NDIS 6.70:

- TCP Chimney Offload
- IPsec Offload Version 2

Implementing an NDIS 6.70 driver

NIC drivers

For more information about implementing a NIC driver with the NetAdapterCx, see NetAdapterCx.

Miniport, protocol, filter, and intermediate drivers

An NDIS 6.70 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.70 driver must be compliant with the following requirements:

- An NDIS 6.70 driver must report the correct NDIS version when it registers with NDIS.
  - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.70. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 70. This requirement applies to miniport, protocol and filter drivers. You must also update the version information for the compiler (see Compiling an NDIS 6.70 driver).
  - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2.
  - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_2.
  - Protocol drivers must set the **Header** member of **NDIS_PROTOCOL_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

Compiling an NDIS 6.70 driver

NIC drivers

For more information about compiling a NIC driver with the NetAdapterCx, see Porting NDIS miniport drivers to NetAdapterCx (Compilation settings).

Miniport, protocol, and filter drivers

The WDK for Windows 10, version 1703 supports header versioning. Header versioning makes sure that NDIS 6.70 drivers use the appropriate NDIS 6.70 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS670_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS670=1`.

For information on building a driver with the Windows 10, version 1703 release of the WDK, see Building a Driver.

Using NDIS 6.70 driver data structures

NIC drivers

For more information about NetAdapterCx data structures, see NetAdapterCx.

Miniport, protocol, filter, and intermediate drivers

New data structures

The following data structures are new in NDIS 6.70.

- NDIS_STATUS_WWAN_DEVICE_CAPS_EX

Introduction to NDIS 6.60

Article • 03/14/2023

This topic introduces Network Driver Interface Specification (NDIS) 6.60 and describes its major design additions. NDIS 6.60 is included in Windows 10, version 1607 and Windows Server 2016 and later.

NDIS 6.60 is a minor version update to NDIS 6.50. For more information about porting NDIS 6.x drivers to NDIS 6.60, see Porting NDIS 6.x drivers to NDIS 6.60.

Feature updates

NDIS 6.60 is an incremental update to NDIS 6.50 and does not contain any major new features.

Implementing an NDIS 6.60 driver

An NDIS 6.60 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.60 driver must be compliant with the following requirements:

- An NDIS 6.60 driver must report the correct NDIS version when it registers with NDIS.
  - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.60. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 60. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler (see Compiling an NDIS 6.60 driver).
  - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2.
  - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_2.

  - Protocol drivers must set the **Header** member of NDIS_PROTOCOL_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

- NDIS 6.60 miniport drivers for Windows 10, version 1607 and Windows Server 2016 and later must use the NDIS 6.60 versions of data structures. For more information, see Using NDIS 6.60 data structures.

Compiling an NDIS 6.60 driver

The WDK for Windows 10, version 1607 supports header versioning. Header versioning makes sure that NDIS 6.60 drivers use the appropriate NDIS 6.60 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS660_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS660=1`.

For information on building a driver with the Windows 10, version 1607 release of the WDK, see Building a Driver.

Using NDIS 6.60 data structures

Updated data structures

The following data structures were updated in NDIS 6.60.

- NDIS_NIC_SWITCH_CAPABILITIES
- NDIS_RECEIVE_SCALE_PARAMETERS
- NDIS_RECEIVE_SCALE_CAPABILITIES

Introduction to NDIS 6.50

Article • 03/14/2023

This topic introduces Network Driver Interface Specification (NDIS) 6.50 and describes its major design additions. NDIS 6.50 is included in Windows 10, version 1507 and later.

NDIS 6.50 is a minor version update to NDIS 6.40. For more information about porting NDIS 6.x drivers to NDIS 6.50, see Porting NDIS 6.x drivers to NDIS 6.50.

Feature updates

NDIS 6.50 is an incremental update to NDIS 6.40 and does not contain any major new features.

Implementing an NDIS 6.50 driver

An NDIS 6.50 driver must follow the requirements that are defined in Implementing an NDIS 6.30 driver.

In addition, an NDIS 6.50 driver must be compliant with the following requirements:

- An NDIS 6.50 driver must report the correct NDIS version when it registers with NDIS.
    - You must update the major and minor NDIS version number in the NDIS_Xxx_DRIVER_CHARACTERISTICS structure to support NDIS 6.50. The MajorNdisVersion member must contain 6 and the MinorNdisVersion member must contain 50. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler (see Compiling an NDIS 6.50 driver).
    - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2.
    - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_2.

  - Protocol drivers must set the **Header** member of NDIS_PROTOCOL_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

- NDIS 6.50 miniport drivers for Windows 10, version 1507 and later must use the NDIS 6.50 versions of data structures. For more information, see Using NDIS 6.50 data structures.

Compiling an NDIS 6.50 driver

The WDK for Windows 10, version 1507 supports header versioning. Header versioning makes sure that NDIS 6.50 drivers use the appropriate NDIS 6.50 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add `NDIS650_MINIPORT=1`.
- For a filter or protocol driver, add `NDIS650=1`.

For information on building a driver with the Windows 10, version 1507 release of the WDK, see Building a Driver.

Using NDIS 6.50 data structures

New data structures

The following data structures are new in NDIS 6.50.

- OID_WWAN_SYS_CAPS
- OID_WWAN_DEVICE_CAPS_EX
- OID_WWAN_SLOT_INFO_STATUS
- OID_WWAN_NETWORK_IDLE_HINT
- NDIS_STATUS_PD_CURRENT_CONFIG
- NDIS_PD_CAPABILITIES
- NDIS_PD_CLOSE_PROVIDER_PARAMETERS
- NDIS_PD_CONFIG
- NDIS_PD_COUNTER_PARAMETERS
- NDIS_PD_COUNTER_VALUE
- NDIS_PD_FILTER_COUNTER
- NDIS_PD_FILTER_PARAMETERS

- NDIS_PD_ON_RSS_QUEUE_PARAMETERS
- NDIS_PD_OPEN_PROVIDER_PARAMETERS
- NDIS_PD_PROVIDER_DISPATCH
- NDIS_PD_QUEUE
- NDIS_PD_QUEUE_DISPATCH
- NDIS_PD_QUEUE_PARAMETERS
- NDIS_PD_RECEIVE_QUEUE_COUNTER
- NDIS_PD_TRANSMIT_QUEUE_COUNTER
- PD_BUFFER
- PD_BUFFER_8021Q_INFO
- PD_BUFFER_VIRTUAL_SUBNET_INFO

Updated data structures

The following data structures were updated in NDIS 6.50.

- NET_PNP_EVENT_NOTIFICATION
- NDIS_OID_REQUEST
- NDIS_NET_BUFFER_LIST_INFO
- NdisMGetDeviceProperty
- NDIS_SWITCH_OPTIONAL_HANDLERS
- NDIS_SWITCH_NIC_SAVE_STATE
- NDIS_RECEIVE_FILTER_PARAMETERS

NDIS 6.51

NDIS 6.51 is a very minor version update to NDIS 6.50. NDIS 6.51 is included in Windows 10, version 1511 and later. All information for NDIS 6.50 also applies to NDIS 6.51 with the following exceptions:

- The MinorNdisVersion changes from 50 to 51 when registering your driver with NDIS.
- The compiler settings change from `NDIS650_MINIPORT=1` for miniport drivers and `NDIS650=1` for filter or protocol drivers, to `NDIS651_MINIPORT=1` and `NDIS651=1` respectively.

Introduction to NDIS 6.40

Article • 03/14/2023

This section introduces Network Driver Interface Specification (NDIS) 6.40 and describes its major design additions. NDIS 6.40 is included in the Windows 8.1 and Windows Server 2012 R2 and later operating systems.

Feature Updates

Windows 8.1 and Windows Server 2012 R2 introduce minor updates to the following features:

NDKPI

NDKPI 1.2 adds the following new elements to the NDKPI DDI:

- *NdkSendAndInvalidate* (*NDK_FN_SEND_AND_INVALIDATE*) function
- *NdkGetCqResultsEx* (*NDK_FN_GET_CQ_RESULTS_EX*) function
- **NDK_RESULT_EX** structure
- New request callback *Flags* value: **NDK_OP_FLAG_DEFER**
- New **NDK_ADAPTER_INFOAdapterFlags** value: **NDK_ADAPTER_FLAG_RDMA_READ_LOCAL_INVALIDATE_SUPPORTED**

Native 802.11 Wireless LAN

IEEE 802.11ac very-high throughput (VHT) PHY is now supported. The following DDI elements have been updated:

- **DOT11_PHY_TYPE** enumeration
- OID_DOT11_CURRENT_CHANNEL
- OID_DOT11_SUPPORTED_PHY_TYPES
- OID_DOT11_SUPPORTED_OFDM_FREQUENCY_LIST

Sample and Documentation Updates

The Hyper-V Extensible Switch forwarding extension sample has been updated to implement Hybrid Forwarding.

The following documentation sections have been added or significantly expanded:

- Porting NDIS 6.x Drivers to NDIS 6.30
- Network Direct Kernel Provider Interface (NDKPI) Design Guide
- Network Virtualization using Generic Routing Encapsulation (NVGRE) Task Offload
- Receive Segment Coalescing (RSC) Design Guide
- Getting Started Writing a Hyper-V Extensible Switch Extension
- NVGRE Task Offload Reference

The NetDMA interface is not supported in Windows 8 and Windows Server 2012 and later. The documentation has now been updated to reflect this.

This section includes the following topics:

- Implementing an NDIS 6.40 Driver
- Using NDIS 6.40 Data Structures
- Compiling an NDIS 6.40 Driver

Implementing an NDIS 6.40 Driver

Article • 03/14/2023

An NDIS 6.40 driver must follow the requirements that are defined in Implementing an NDIS 6.30 Driver.

In addition, an NDIS 6.40 driver must be compliant with the following requirements:

- An NDIS 6.40 driver must report the correct NDIS version when it registers with NDIS.
  - You must update the major and minor NDIS version number in the NDIS_*Xxx*_DRIVER_CHARACTERISTICS structure to support NDIS 6.40. The **MajorNdisVersion** member must contain **6** and the **MinorNdisVersion** member must contain **40**. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler, see Compiling an NDIS 6.40 Driver.
  - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2.
  - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_2.
  - Protocol drivers must set the **Header** member of **NDIS_PROTOCOL_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.
- NDIS 6.40 miniport drivers for the Windows 8.1 and Windows Server 2012 R2 operating systems must use the NDIS 6.40 versions of data structures. For more information, see Using NDIS 6.40 Data Structures.

Using NDIS 6.40 Data Structures

Article • 03/14/2023

The following structures and enumerations were updated for NDIS 6.40.

The following union was updated for NDIS 6.40:

- NDIS_SWITCH_FORWARDING_DETAIL_NET_BUFFER_LIST_INFO

The following enumeration was updated for NDIS 6.40:

- NDIS_SWITCH_PORT_PROPERTY_TYPE

Compiling an NDIS 6.40 Driver

Article • 03/14/2023

The WDK for Windows 8.1 supports header versioning. Header versioning makes sure that NDIS 6.40 drivers use the appropriate NDIS 6.40 data structures at compile time.

Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add NDIS640_MINIPORT=1.
- For a filter or protocol driver, add NDIS640=1.

For information on building a driver with the Windows 8.1 release of the WDK, see Building a Driver.

For information on converting an driver's build files to a Visual Studio project , see Creating a Driver From Existing Source Files.

Introduction to NDIS 6.30

Article • 03/14/2023

This section introduces Network Driver Interface Specification (NDIS) 6.30 and describes its major design additions. NDIS 6.30 is included in the Windows 8 and Windows Server 2012 and later operating systems.

You should be familiar with earlier versions of NDIS 6.x before learning about NDIS 6.30. For more information about previous NDIS 6.x versions, see the following topics:

Introduction to NDIS 6.0

Introduction to NDIS 6.1

Introduction to NDIS 6.20

This section includes the following topics:

- Virtualized Networking Enhancements in NDIS 6.30
- Power Management Enhancements in NDIS 6.30
- Quality of Service (QoS) Support in NDIS 6.30
- Windows Filtering Platform Enhancements in NDIS 6.30
- Scalable Networking Enhancements in NDIS 6.30
- Implementing an NDIS 6.30 Driver
- Using NDIS 6.30 Data Structures
- Compiling an NDIS 6.30 Driver

Virtualized Networking Enhancements in NDIS 6.30

Article • 03/14/2023

NDIS supports virtualized networking interface that allow Hyper-V parent and child partitions to interface the underlying physical networking interface.

NDIS 6.20 included the virtual machine queue (VMQ) interface to support Microsoft Hyper-V network performance improvements. For more information about VMQ, see Virtual Machine Queue (VMQ).

NDIS 6.30 extends the support for virtualized networking interfaces with the following technologies, as described in Overview of Virtualized Networking:

Single Root I/O Virtualization (SR-IOV)

The SR-IOV interface allows for the partitioning of the hardware resources on a PCI Express (PCIe) network adapter into one or more virtual interfaces, known as *virtual functions (VFs)*. This allows the adapter resources to be shared in a virtual environment. SR-IOV enables network traffic to bypass the virtual software switch layer by assigning a VF to the Hyper-V child partition directly. By doing this, the I/O overhead in the software emulation layer is diminished and network throughput achieves almost the same performance as in non-virtualized environments.

For more information about the SR-IOV interface, see Single Root I/O Virtualization (SR-IOV).

Hyper-V Extensible Switch

The Hyper-V Extensible Switch is a virtualized Ethernet switch that runs in the management operating system of the Hyper-V parent partition. Each instance of the extensible switch routes packets between ports that are connected to the following types of network adapters:

- The external and internal network adapters that are exposed in the management operating system that runs in the Hyper-V parent partition.
- The synthetic or emulated network adapters that are exposed in the guest operating system that runs in a Hyper-V child partition.

Starting with NDIS 6.30, the Hyper-V Extensible Switch supports an extensibility interface. This interface allows instances of NDIS filter drivers (known as *extensions*) to bind within the Hyper-V Extensible Switch driver stack. Once bound and enabled within the driver stack, extensions are exposed to all packet traffic within the extensible switch data path. This allows extensions to monitor, modify, and forward packets to extensible switch ports. This also allows extensions to inspect and inject packets in the virtual network interfaces that are used by the various Hyper-V partitions.

For more information about the Hyper-V extensible switch interface, see Hyper-V Extensible Switch.

Power Management Enhancements in NDIS 6.30

Article • 03/14/2023

NDIS 6.20 included power management new features and improvements to reduce computer power consumption. NDIS 6.30 extends the NDIS 6.20 power management support with the following capabilities, as described in Power Management (NDIS 6.30):

NDIS Packet Coalescing

Starting with NDIS 6.30, network adapters can support NDIS packet coalescing. This feature reduces the processing overhead and power consumption on a host system due to the reception of random broadcast or multicast packets.

For more information, see NDIS Packet Coalescing.

NDIS Selective Suspend

Starting with NDIS 6.30, the NDIS selective suspend interface allows NDIS to suspend an idle network adapter by transitioning the adapter to a low-power state. This enables the system to reduce the power overhead on the CPU and network adapter.

For more information, see NDIS Selective Suspend.

NDIS Wake Reason Status Indications

Starting with NDIS 6.30, miniport drivers issue an NDIS wake reason status indication (**NDIS_STATUS_PM_WAKE_REASON**) to notify NDIS and overlying drivers about the reason for a system wake-up event. If the network adapter generates a wake-up event, the miniport driver immediately issues this NDIS status indication when the system resumes to a full-power state.

Note Support for NDIS wake reason status indications is optional for Mobile Broadband (MB) miniport drivers.

For more information, see NDIS Wake Reason Status Indications.

NDIS No Pause On Suspend

Starting with NDIS 6.30, miniport drivers can specify an attribute flag (**NDIS_MINIPORT_ATTRIBUTES_NO_PAUSE_ON_SUSPEND**) in the **NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES** structure. The driver passes a pointer to this structure in its call to the **NdisMSetMiniportAttributes** function.

If the miniport sets the **NDIS_MINIPORT_ATTRIBUTES_NO_PAUSE_ON_SUSPEND** attribute flag, NDIS does not call the miniport driver's *MiniportPause* function before the object identifier (OID) request of OID_PNP_SET_POWER is issued to the driver. When the miniport driver handles the OID request, it must not assume that it had been previously paused when preparing the miniport adapter for the transition to a low-power state.

For more information, see **NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES**.

Quality of Service (QoS) Support in NDIS 6.30

Article • 03/14/2023

NDIS 6.30 and later provide support for quality of service (QoS). Miniport drivers use NDIS QoS for traffic prioritization of transmit, or *egress*, packets over a network adapter that is compliant with IEEE 802.1 Data Center Bridging (DCB).

IEEE 802.1 Data Center Bridging (DCB) is a collection of standards that defines a unified 802.3 Ethernet media interface, or fabric, for local area network (LAN) and storage area network (SAN) technologies. DCB extends the current 802.1 bridging specification to support the co-existence of LAN- and SAN-based applications over the same networking fabric within a data center. DCB also supports technologies, such as Fibre Channel over Ethernet (FCoE) and iSCSI, by defining link-level policies that prevents packet loss.

NDIS QoS support for DCB allows a miniport driver to be configured with traffic classes that specify a set of policies. Each policy determine how the network adapter handles egress packets for prioritized delivery.

Each traffic class specifies the following policies that are applied to egress packets:

Priority Level and Flow Control
This policy defines the IEEE 802.1p priority level and optional flow control algorithms for the egress traffic.

Traffic Selection Algorithms (TSAs)
This policy specifies how the network adapter selects egress traffic for delivery from its transmit queues. For example, the adapter could select egress packets based on IEEE 802.1p priority or the percentage of the egress bandwidth that is allocated to each traffic class.

For more information about NDIS QoS support for DCB, see NDIS QoS for Data Center Bridging.

Windows Filtering Platform Enhancements in NDIS 6.30

Article • 03/14/2023

Windows filtering platform (WFP) includes the following enhancements for NDIS 6.30 and later drivers:

Layer 2 Filtering Proxied Connections Tracking Virtual Switch Filtering For more information about new WFP features, see New Information for WFP.

Scalable Networking Enhancements in NDIS 6.30

Article • 03/14/2023

Scalable networking includes the following enhancements for NDIS 6.30 and later drivers:

Receive Segment Coalescing (RSC) Network Direct Kernel Provider Interface (NDKPI) Network Virtualization using Generic Routing Encapsulation (NVGRE) Task Offload IPsec Offload Version 2 (IPsecOV2) Updates Receive Side Scaling (RSS) Updates

Note NetDMA is not supported in Windows 8 and later versions of the Windows operating system.

Implementing an NDIS 6.30 Driver

Article • 03/14/2023

An NDIS 6.30 driver must follow the requirements that are defined in Implementing an NDIS 6.20 Driver.

In addition, an NDIS 6.30 driver must be compliant with the following requirements:

- An NDIS 6.30 driver must report the correct NDIS version when it registers with NDIS.
  - You must update the major and minor NDIS version number in the NDIS_*Xxx*_DRIVER_CHARACTERISTICS structure to support NDIS 6.30. The **MajorNdisVersion** member must contain **6** and the **MinorNdisVersion** member must contain **30**. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler, see Compiling an NDIS 6.30 Driver.
  - Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2.
  - Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_2.
  - Protocol drivers must set the **Header** member of **NDIS_PROTOCOL_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.
- To inform NDIS and overlying drivers about device and driver capabilities, NDIS 6.30 drivers must implement the NDIS 6.30 device capability interfaces for the following features:
  - Virtualized Networking
  - Power Management
  - NDIS Quality of Service (QoS)

- NDIS 6.30 miniport drivers for the Windows 8 and Windows Server 2012 operating systems must use the NDIS 6.30 versions of data structures. For more information, see Using NDIS 6.30 Data Structures.

Using NDIS 6.30 Data Structures

Article • 03/14/2023

NDIS can support multiple versions of the same data structure. For the Windows 8 and Windows Server 2012 operating systems, miniport drivers that use an NDIS 6.30 version of a structure must initialize the **Header** member of the structure with the correct version and size values. The **Header** member is an NDIS_OBJECT_HEADER structure, and the driver must initialize the **Revision** member and **Size** member value of the **Header** member to the NDIS 6.30 version and size values.

Note To determine the correct version and size information see the reference pages for each structure that includes a **Header** member. The reference pages for structures that contain a **Header** member and that were updated for NDIS 6.30 include new information for NDIS 6.30 drivers. If there is no update to the structure for NDIS 6.30, the information that is provided for earlier versions of NDIS also applies to NDIS 6.30 drivers.

The following structures were updated for NDIS 6.30:

- NDIS_BIND_PARAMETERS
- NDIS_MINIPORT_ADAPTER_ATTRIBUTES
- NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES
- NDIS_MINIPORT_ADAPTER_HARDWARE_ASSIST_ATTRIBUTES
- NDIS_MINIPORT_ADAPTER_NATIVE_802_11_ATTRIBUTES
- NDIS_NET_BUFFER_LIST_FILTERING_INFO
- NDIS_NIC_SWITCH_CAPABILITIES
- NDIS_OFFLOAD
- NDIS_OFFLOAD_PARAMETERS
- NDIS_PM_CAPABILITIES
- NDIS_PM_PARAMETERS
- NDIS_RECEIVE_FILTER_CAPABILITIES
- NDIS_RECEIVE_FILTER_INFO_ARRAY
- NDIS_RECEIVE_FILTER_PARAMETERS
- NDIS_RECEIVE_QUEUE_INFO
- NDIS_RECEIVE_QUEUE_PARAMETERS
- NDIS_RECEIVE_SCALE_CAPABILITIES
- NDIS_RSS_PROCESSOR_INFO
- NDIS_SHARED_MEMORY_PARAMETERS

Compiling an NDIS 6.30 Driver

Article • 03/14/2023

In the Windows 8 release of the Windows Driver Kit (WDK), the driver development environment is integrated into Visual Studio. Most of the tools you need for coding, building, testing, debugging, deploying, and releasing a driver are available in the Visual Studio user interface. This is a departure from previous releases of the WDK where the various stages of the driver life cycle were performed as separate tasks with stand-alone tools.

The WDK for Windows 8 supports header versioning. Header versioning makes sure that NDIS 6.30 drivers use the appropriate NDIS 6.30 data structures at compile time. Add the following compiler settings to the Visual Studio project for your driver:

- For a miniport driver, add NDIS630_MINIPORT=1.
- For a filter or protocol driver, add NDIS630=1.

For information on building a driver with the Windows 8 release of the WDK, see Building a Driver.

For information on converting an driver's build files to a Visual Studio project , see Creating a Driver From Existing Source Files.

Introduction to NDIS 6.20

Article • 03/14/2023

This section introduces Network Driver Interface Specification (NDIS) 6.20 and describes its major design additions. NDIS 6.20 is included in Windows 7 and Windows Server 2008 R2 and later.

You should be familiar with NDIS 6.0 and NDIS 6.1 before learning about NDIS 6.20:

- For more information about NDIS 6.0, see Introduction to NDIS 6.0.
- For more information about NDIS 6.1, see Introduction to NDIS 6.1.

For a description of the differences between NDIS 6.20 and earlier versions, and for detailed information about porting drivers to NDIS 6.20, see Porting NDIS 6.x Drivers to NDIS 6.20.

This section includes the following topics:

- Power Management Enhancements in NDIS 6.20
- Virtual Machine Queue (VMQ) in NDIS 6.20
- Support for More than 64 Processors in NDIS 6.20
- Receive Side Throttle in NDIS 6.20
- Media Extensibility in NDIS 6.20
- Implementing an NDIS 6.20 Driver
- Using NDIS 6.20 Data Structures
- Compiling an NDIS 6.20 Driver

Related topics

Introduction to NDIS 6.30

Power Management Enhancements in NDIS 6.20

Article • 03/14/2023

NDIS 6.20 introduces power management enhancements to reduce computer power consumption. NDIS 6.20 power management support is mandatory for NDIS 6.20 and later drivers.

The NDIS 6.20 power management interface is backward compatible with NICs and miniport drivers that do not support the latest power management features.

The power management interface in NDIS 6.20 and later supports:

- Wake on LAN (WOL) patterns that are based on the packet type in addition to the NDIS 6.1 and earlier methods that support an offset and pattern match. Therefore, NDIS 6.20 and later WOL patterns can be more specific to avoid unnecessary wake up events. For example, a NIC can identify TCP synchronize (SYN) packets.

- Protocol offloads to NICs for some of the most common protocols. Because the protocols are offloaded to the NIC, it can respond on behalf of the computer to avoid unwanted wake up events. For example, a NIC can handle IPv4 Address Resolution Protocol (ARP) and IPv6 Neighbor Solicitation (NS) protocol packets without waking the computer.

The power management interface in NDIS 6.20 and later also supports:

- WOL WLAN enhancements. If necessary, a NIC can handle IEEE 802.11 group temporal key (GTK) rekey requests in a low power state.

- NDIS 6.20 and later can wake the computer when media connects. The operating system puts the NIC in a low power state when the media is disconnected.

Some of the NDIS device driver interface elements are obsolete for NDIS 6.20 and later drivers. For more information about obsolete interfaces, see Obsolete Interfaces in NDIS 6.20.

For more information about power management for NDIS 6.20 and later versions of NDIS, see Power Management (NDIS 6.20).

Related topics

Power Management Enhancements in NDIS 6.30

Virtual Machine Queue (VMQ) in NDIS 6.20

Article • 03/14/2023

NDIS 6.20 introduces the virtual machine queue (VMQ) interface to support Microsoft Hyper-V network performance improvements. NDIS 6.20 and later drivers must provide information about VMQ capabilities during initialization. However, VMQ support is optional.

The VMQ interface in NDIS 6.20 and later supports:

- Classification of received packets by using the destination MAC address to route the packets to different receive queues.
- NIC ability to use DMA to transfer packets directly to a Hyper-V child partition's shared memory.
- Scaling to multiple processors by processing packets for different Hyper-V partitions on different processors.

Microsoft Hyper-V network performance enhancements also provide chimney support for Hyper-V child partitions with no driver changes.

For more information about VMQ, see Virtual Machine Queue (VMQ).

Support for More than 64 Processors in NDIS 6.20

Article • 03/14/2023

The NDIS 6.20 interface introduces support for more than 64 processors. Previous NDIS versions are limited to no more than 64 processors (32 in x86 versions of the operating system).

To remain backward compatible with older implementations, NDIS supports processor groups. Software that has not been updated to support more than 64 processors can default to processor group zero.

To support more than 64 processors, NDIS 6.20 and later provide updated versions of these interfaces:

- Receive Side Scaling (RSS)
- Processor information device driver interfaces (see NDIS System Information Functions)
- Resource allocation (see NDIS Memory Management Interface)
- Read and write locks (see NDIS Read Write Lock Reference)

Some of the NDIS device driver interface elements are obsolete for NDIS 6.20 and later drivers. For more information about obsolete interfaces, see Obsolete Interfaces in NDIS 6.20.

Receive Side Throttle in NDIS 6.20

Article • 03/14/2023

NDIS 6.20 introduces receive-side throttle (RST) enhancements to reduce the possibility of disruptions during media playback in multimedia applications. RST support is mandatory for NDIS 6.20 and later drivers.

If an NDIS driver spends too much time at dispatch IRQ level in a deferred procedure call (DPC), it increases the scheduling latency for multimedia application threads and might cause disruptions during media playback. To improve media playback with NDIS 6.20 and later drivers, NDIS can control the number of packets that a miniport driver indicates in a receive DPC.

Media Extensibility in NDIS 6.20

Article • 03/14/2023

NDIS 6.20 introduces additional media extensibility features. That is, the network layer of the driver stack is more media independent.

These features in NDIS 6.20 and later reduce the complexity of the code that is required to implement drivers that do not implement IEEE 802.3. In addition, these non-IEEE 802.3 implementations do not have to implement ARP and DHCP.

NDIS 6.20 and later provide *raw IP* frame support with a new media type for raw IP (NdisMediumIP). For example, NDIS WWAN support uses raw IP.

NDIS 6.20 introduces enhanced support for media specific out of band (OOB) data. The media specific information has a tag that Microsoft assigns. NDIS 6.20 and later support multiple media specific information tags.

For more information about media specific information, for more information about media extensibility, see OID_GEN_PHYSICAL_MEDIUM_EX and **NDIS_NBL_MEDIA_SPECIFIC_INFORMATION_EX**.

Implementing an NDIS 6.20 Driver

Article • 03/14/2023

An NDIS 6.20 driver must report the correct NDIS version when it registers with NDIS:

- You must update the major and minor NDIS version number in the NDIS_*Xxx*_DRIVER_CHARACTERISTICS structure to support NDIS 6.20. The **MajorNdisVersion** member must contain 6 and the **MinorNdisVersion** member must contain 20. This requirement applies to miniport, protocol, and filter drivers. You must also update the version information for the compiler, see Compiling an NDIS 6.20 Driver.

- Miniport drivers must set the **Header** member of **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2.

- Filter drivers must set the **Header** member of **NDIS_FILTER_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_2.

- Protocol drivers must set the **Header** member of **NDIS_PROTOCOL_DRIVER_CHARACTERISTICS**: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

The NDIS 6.20 power management services are mandatory for NDIS 6.20 and later miniport drivers. For more information about the NDIS 6.20 power management interface, see Power Management Enhancements in NDIS 6.20.

The NDIS direct OID request interface is mandatory for NDIS 6.20 and later miniport drivers. For more information about the direct OIDs interface, see Direct OID Request Interface in NDIS 6.1.

To inform NDIS and overlying drivers about device and driver capabilities, NDIS 6.20 and later drivers must implement the NDIS 6.20 device capability interfaces for the following features:

- Power Management

- Receive Side Scaling (RSS)

- Virtual Machine Queue (VMQ)

NDIS 6.20 and later drivers must support receive side throttle (RST) in receive interrupts. For more information about RST, see Receive Side Throttle in NDIS 6.20.

Replace code that uses obsolete interfaces with the NDIS 6.20 equivalents. For more information about obsolete functions, see Obsolete Interfaces in NDIS 6.20. For information about updating structures to support NDIS 6.20 versions, see Using NDIS 6.20 Data Structures.

Use NDIS interfaces that support more than 64 processors, for example, use the NDIS 6.20 read and write lock interface. For more information about support for more than 64 processors, see Support for More than 64 Processors in NDIS 6.20.

Using NDIS 6.20 Data Structures

Article • 03/14/2023

NDIS can support multiple versions of the same data structure. NDIS 6.20 and later drivers that use updated structures must report the correct **Revision** member and **Size** member value in the NDIS_OBJECT_HEADER structure that is in the **Header** member of a structure, if any, when the drivers initialize NDIS 6.20 data structures.

Note To determine the correct version and size information see the reference pages for each structure that includes a **Header** member. The reference pages for structures that contain a **Header** member and that have been updated for NDIS 6.20 include new information for NDIS 6.20 and later drivers. If there is no update to the structure for NDIS 6.20, the information that is provided for NDIS 6.0 or NDIS 6.1 drivers also applies to NDIS 6.20 and later drivers.

Compiling an NDIS 6.20 Driver

Article • 03/14/2023

The Build utility for Windows 7 and later supports header versioning. Header versioning makes sure that NDIS 6.20 drivers use the appropriate NDIS 6.20 data structures at compile time. You must update the SOURCES file to indicate NDIS 6.20.

For each type of driver, add information to the SOURCES file as follows:

- For a miniport driver, add NDIS620_MINIPORT=1.
- For a protocol driver, add NDIS620=1.
- For a filter driver, add NDIS620=1.

Introduction to NDIS 6.1

Article • 03/14/2023

This section introduces Network Driver Interface Specification (NDIS) 6.1 and describes its major design additions. NDIS 6.1 is included in the Windows Server 2008 and Windows Vista with Service Pack 1 (SP1) operating systems.

You should be familiar with NDIS 6.0 before learning about NDIS 6.1. For more information about NDIS 6.0, see Introduction to NDIS 6.0.

This section includes the following topics:

- Header-Data Split in NDIS 6.1
- Direct OID Request Interface in NDIS 6.1
- IPsec Task Offload Version 2 in NDIS 6.1
- NETDMA Updates in NDIS 6.1
- Implementing an NDIS 6.1 Driver
- Using NDIS 6.1 Data Structures
- Compiling an NDIS 6.1 Driver

Related topics

Introduction to Network Drivers

Introduction to NDIS 6.20

Introduction to NDIS 6.30

Header-Data Split in NDIS 6.1

Article • 03/14/2023

Header-data split services improve network performance by splitting the header and data in received Ethernet frames into separate buffers. By separating the headers and the data, these services enable the headers to be collected together into smaller regions of memory. Therefore, more headers fit into a single memory page and more headers fit into the system caches, so the overhead for memory accesses in the driver stack is reduced.

The header-data split interface is an optional service that is provided for header-data-split-capable network interface cards (NICs).

For more information about header-data split, see Header-Data Split.

Direct OID Request Interface in NDIS 6.1

Article • 03/14/2023

NDIS provides a direct OID request interface for NDIS 6.1 and later drivers. The *direct OID request path* supports OID requests that are queried or set frequently. For example, the IPsec offload version 2 (IPsecOV2) interface provides the OID_TCP_TASK_IPSEC_OFFLOAD_V2_ADD_SA OID for direct OID requests.

The direct OID request interface is optional for NDIS drivers. To support the direct OID path, drivers provide entry points and NDIS provides **Ndis*Xxx*** functions for protocol, filter, and miniport drivers.

Note NDIS supports specific OIDs for use with the direct OID request interface. To determine whether your driver can use an OID in the direct OIDs interface, see the notes in the OID reference page.

For NDIS 6.1, the only interface that uses the direct OID request interface is IPsecOV2. For more information about IPsecOV2, see IPsec Task Offload Version 2 in NDIS 6.1.

For NDIS 6.1 drivers in the Windows Server 2008 and Windows Vista with Service Pack 1 (SP1) operating systems, you can use only the following OIDs with the direct OID request interface:

- OID_TCP_TASK_IPSEC_OFFLOAD_V2_ADD_SA
- OID_TCP_TASK_IPSEC_OFFLOAD_V2_DELETE_SA
- OID_TCP_TASK_IPSEC_OFFLOAD_V2_UPDATE_SA

Miniport drivers and filter drivers must be able to handle direct OID requests that are not serialized. Unlike the standard OID request interface, NDIS does not serialize direct OID requests with other requests that are sent with the direct OID interface or with the standard OID request interface. Also, miniport drivers and filter drivers must be able to handle direct OID requests at IRQL <= DISPATCH_LEVEL.

For more information about how to implement the direct OID interface in drivers, see the following topics:

- Miniport Adapter OID Requests
- Protocol Driver OID Requests
- Filter Module OID Requests

IPsec Task Offload Version 2 in NDIS 6.1

Article • 03/14/2023

[The IPsec Task Offload feature is deprecated and should not be used.]

IPsec task offload provides offloading services for IPsec network data processing to IPsec offload-capable network interface cards (NICs). NDIS 6.1 and later support IPsec offload version 2 (IPsecOV2). IPsecOV2 extends support for additional crypto-algorithms, IPv6, and co-existence with large send offload (LSO).

IPsecOV2 uses the NDIS 6.1 direct OID request interface. For more information about the direct OID request interface, see Direct OID Request Interface in NDIS 6.1.

For more information about IPsecOV2, see IPsec Offload Version 2.

NetDMA Updates in NDIS 6.1

Article • 03/14/2023

> ⓘ **Important**
>
> The NetDMA interface is not supported in Windows 8 and later.

The NetDMA interface provides offloading of direct memory access (DMA) to network interface cards (NICs) that support a NetDMA DMA engine. The Windows Server 2008 and Windows Vista with Service Pack 1 (SP1) operating systems add NetDMA versions 1.1 and 2.0. NDIS 6.1 and later drivers can use NetDMA version 1.0, 1.1, and 2.0 interfaces. These interfaces manage interactions with the DMA engine and manage DMA transfers at run-time.

The NetDMA interface is an optional service that is provided for NICs and other drivers.

For more information about NetDMA, see NetDMA Drivers.

Implementing an NDIS 6.1 Driver

Article • 03/14/2023

An NDIS 6.1 driver must report the correct NDIS version when it registers with NDIS:

- You must update the major and minor NDIS version number in the NDIS_*Xxx*_DRIVER_CHARACTERISTICS structure to support NDIS 6.1. The **MajorNdisVersion** member must contain 0x06 and the **MinorNdisVersion** member must contain 0x01. This requirement applies to miniport, protocol, and filter drivers.

- Miniport drivers must set the **Header** member of NDIS_MINIPORT_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_MINIPORT_DRIVER_CHARACTERISTICS_REVISION_2.

- Filter drivers must set the **Header** member of NDIS_FILTER_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_FILTER_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_FILTER_DRIVER_CHARACTERISTICS_REVISION_2.

- Protocol drivers must set the **Header** member of NDIS_PROTOCOL_DRIVER_CHARACTERISTICS: Set **Revision** to NDIS_PROTOCOL_CHARACTERISTICS_REVISION_2 and **Size** to NDIS_SIZEOF_PROTOCOL _DRIVER_CHARACTERISTICS_REVISION_2.

Using NDIS 6.1 Data Structures

Article • 03/14/2023

NDIS can support multiple versions of the same data structure. NDIS 6.1 drivers that use updated structures in Windows Server 2008, Windows Vista with Service Pack 1 (SP1), or both operating systems must report the correct **Revision** member and **Size** member value in the **NDIS_OBJECT_HEADER** structure that is in the **Header** member of a structure, if any, when the drivers initialize NDIS 6.1 data structures.

Note To determine the correct version and size information, see the reference pages for each structure that includes a **Header** member. The reference pages for structures that contain a **Header** member and that have been updated for NDIS 6.1 include new information for NDIS 6.1 drivers. If there is no update to the structure for NDIS 6.1, the information that is provided for NDIS 6.0 drivers also applies to NDIS 6.1 drivers.

Compiling an NDIS 6.1 Driver

Article • 03/14/2023

The Build utility for Windows Server 2008 supports header versioning. Header versioning makes sure that NDIS 6.1 drivers use the appropriate NDIS 6.1 data structures at compile time. You must update the SOURCES file to indicate NDIS 6.1.

For each type of driver, add information to the SOURCES file as follows:

- For a miniport driver, add NDIS61_MINIPORT=1.
- For a protocol driver, add NDIS61=1.
- For a filter driver, add NDIS61=1.

Introduction to NDIS 6.0

Article • 03/14/2023

NDIS 6.0 is the next major version of the Network Driver Interface Specification (NDIS) library. NDIS specifies a standard interface between kernel-mode network drivers and the operating system. NDIS also specifies a standard interface between layered network drivers, thereby abstracting lower-level drivers that manage hardware from upper-level drivers, such as network transports. NDIS 6.0 is included in the Windows Vista operating system.

This section provides an introduction to NDIS 6.0 and describes the major design objectives, how these objectives have been met, and the advantages of NDIS 6.0.

This section includes the following topics:

NDIS 6.0 Design Objectives

Enhanced Performance and Scalability

Simplified Driver Model

For a description of the differences between NDIS 6.0 and earlier versions, and for detailed information about porting drivers to NDIS 6.0, see Porting NDIS 5.x Drivers to NDIS 6.0.

Introduction to NDIS 6.30

NDIS 6.0 Design Objectives

Article • 03/14/2023

Two major objectives have guided the design and development of NDIS 6.0:

1. Enhancing driver performance and scalability. (See Enhanced Performance and Scalability for more information.)

   Major improvements in the following provide significant performance gains for both clients and servers:

   - Network data packaging
   - Send and receive paths
   - Run-time reconfiguration capabilities
   - Scatter/gather DMA
   - Filter drivers
   - Multiprocessor scaling of received data handling
   - Offloading TCP tasks to NICs

2. Simplifying the NDIS driver model. (See Simplified Driver Model for more information.)

   The following improvements simplify driver development:

   - Streamlined driver initialization
   - Versioning support for NDIS interfaces
   - Simplified reset handling
   - A standard interface for obtaining management information
   - A filter driver model to replace filter intermediate drivers

Enhanced Performance and Scalability

Article • 12/15/2021

NDIS 6.0 introduced the following features to improve performance and scalability:

- NET_BUFFER Data Packaging
- Improved Send and Receive Paths
- Enhanced Run-time Reconfiguration Abilities
- Receive Side Scaling Support
- New Scatter/Gather DMA Support
- Filter Drivers
- Full TCP Offload

NET_BUFFER Data Packaging

Article • 12/15/2021

Data packaging was redesigned in NDIS 6.0. The send and receive architecture that is based on the NDIS_PACKET structure has been replaced with an architecture that is based on NET_BUFFER and NET_BUFFER_LIST structures. A NET_BUFFER structure is the functional equivalent of an NDIS_PACKET structure. A NET_BUFFER structure specifies a buffer (MDL chain) for network data, as well as reserved space for NDIS, protocol drivers, and miniport drivers. NET_BUFFER structures can be linked together in a list that is described by a NET_BUFFER_LIST structure. A NET_BUFFER_LIST structure also provides storage for out-of-band (OOB) data that applies to all the NET_BUFFER structures in the list.

All components in the Microsoft next generation network driver stack, including the TCP/IP transport and Winsock, use NET_BUFFER data packaging. Uniform data packaging throughout the driver stack eliminates the need to repackage data, simplifies data handling, and reduces the number of function calls.

To accommodate older drivers that use NDIS_PACKET structures, NDIS 6.0 translates NDIS_PACKET structures to NET_BUFFER structures and vice versa. This translation is transparent to NDIS drivers.

NDIS propagates a driver's data backfill requirements to higher-level drivers. When allocating NET_BUFFER and NET_BUFFER_LIST structures for send data, a higher-level driver allocates enough data space to accommodate all lower-level drivers in the stack. As a result, lower-level drivers do not have to allocate additional buffer space to accommodate layer-specific headers. Instead, they can use the preallocated backfill space for this purpose.

For more information about the NET_BUFFER architecture, see NET_BUFFER Architecture.

Improved Send and Receive Paths

Article • 12/15/2021

The NDIS 6.0 send and receive paths have been improved as follows to enhance performance:

- All of the NDIS 6.0 and later driver send and receive functions can transfer a linked list of **NET_BUFFER_LIST** structures and their associated **NET_BUFFER** structures with a single function call. This support for true multipacket send and receive operations substantially reduces the number of function calls that drivers must make.

- When calling a send or receive function, a driver running at DISPATCH_LEVEL can indicate its IRQL to NDIS. When NDIS subsequently makes calls to other drivers in the stack, it is not necessary for these drivers to test the IRQL or set it to DISPATCH_LEVEL. This reduces the overhead that is associated with testing and setting the IRQL in critical code sections.

- When drivers pass packets up and down the driver stack, they can request NDIS to adjust the NET_BUFFER data offsets to accommodate header information. When sending a packet, a driver can expand the used data space to accommodate the driver's header information. When indicating a receive packet, a driver can decrease the used data space after the driver is done accessing its header information. This ability to dynamically adjust the used data space in a NET_BUFFER structure, without allocating and freeing memory or copying data, reduces the overhead that is required to process network data.

For more information about send and receive data handling in NDIS 6.0, see NET_BUFFER Architecture.

Enhanced Run-time Reconfiguration Abilities

Article • 12/15/2021

NDIS 6.0 introduced the ability to pause and restart a driver stack without having to tear down the stack and build a new one. All NDIS 6.0 and later drivers must support pause and restart services.

Pausing the stack eliminates synchronization problems by putting all drivers in a known state before reconfiguration occurs. The ability to pause also gives NDIS the opportunity to query driver characteristics, and reconfigure other characteristics of the stack.

NDIS can pause a driver stack, for example, to temporarily stop data flow before performing a Plug and Play operation, such as adding or removing a filter driver, or binding or unbinding a protocol driver. NDIS restarts the stack after the reconfiguration takes place.

Miniport and filter drivers handle pause and restart services through function interfaces. Protocol drivers handle pause and restart services through Plug and Play event notifications.

For more information about pause and restart operations, see Driver Stack Management.

Receive Side Scaling Support

Article • 12/15/2021

NDIS 6.0 introduced support for the scaling of receive-packet processing across multiple processors. The receive side scaling (RSS) interface accommodates several levels of NIC hardware support.

Based upon its current RSS configuration, a miniport driver or a NIC determines the target processor to associate with the received data. The RSS configuration can be adjusted to make the most efficient use of available target processors.

The miniport driver or NIC assigns the received data to a receive queue that is associated with a target processor. The miniport driver requests NDIS to schedule deferred procedure calls (DPCs) for target processors with non-empty receive queues.

NDIS schedules a DPC on each of the specified target processors. Each DPC processes a particular receive queue on the specified target processor.

For more information about NDIS 6.0 receive side scaling, see Receive Side Scaling.

New Scatter/Gather DMA Support

Article • 12/15/2021

Unlike previous versions of NDIS, NDIS 6.0 passes a send packet to a miniport driver before the packet is mapped for a DMA transfer. After it has obtained the packet, the miniport driver can request NDIS to supply a scatter/gather list for the packet.

This provides the following benefits:

- Because a miniport driver has access to the packet before it is mapped, any changes that the miniport driver makes to the packet are reflected in the associated scatter/gather list data.
- A miniport driver can optimize the transmission of small or highly fragmented packets by copying them to a preallocated buffer, thereby eliminating the need for mapping. This eliminates unnecessary processing.
- NDIS can safely pass multiple **NET_BUFFER** structures to the miniport driver in one function call. This results in fewer calls to the miniport driver and thus improves system performance.
- Because a miniport driver can preallocate memory for a scatter/gather list, NDIS does not have to allocate memory for the scatter/gather list at run time.

For more information about NDIS 6.0 scatter/gather DMA, see NDIS 6.0 Scatter/Gather DMA.

Faster filter drivers

Article • 12/15/2021

The NDIS 6.x filter driver model supersedes the NDIS 5.x filter intermediate driver model. The new filter driver model enhances system performance in several ways:

- Unlike an NDIS filter intermediate driver, an NDIS 6.0 or later filter driver is not implemented as a combination miniport driver and protocol driver. It has a unique interface that is similar to miniport and protocol drivers but is optimized for filtering information that is passed on a driver stack.
- NDIS 6.0 and later filter drivers support bypass capabilities so that the driver does not process data when such processing is not required.
- NDIS 6.0 and later filter drivers can be dynamically inserted into or removed from a driver stack during run time without tearing down bindings. Before such a dynamic operation occurs, NDIS 6.0 pauses all the NDIS drivers in the stack. NDIS restarts the stack when the reconfiguration is complete.

For more information about NDIS 6.0 filter drivers, see NDIS 6.0 Filter Drivers.

Full TCP Offload

Article • 12/15/2021

NDIS 6.0 introduced an architecture for full TCP offload. This architecture is called a "chimney offload" architecture because it provides a direct connection, called a "chimney," between applications and an offload-capable NIC. The chimney enables the NIC to perform TCP processing for offloaded connections, including maintaining the protocol state.

The chimney offload architecture reduces host network processing for network-intensive applications. This allows networked applications to scale more efficiently while also reducing end-to-end latency. Fewer servers are needed to host an application, and servers are able to use the full Ethernet bandwidth.

The TCP chimney offloads all TCP processing for one or more TCP connections. The primary performance gains are obtained from offloading segmentation and reassembly (SAR), offloading processing that ensures reliable connections (for example, ACK processing and TCP retransmission timers), and reducing interrupt loading.

Note The Windows Vista operating system continues to support the individual TCP task offloads available in earlier versions of the operating system. These tasks can be offloaded on connections that have not been offloaded through a chimney. An offload-capable NIC should support both chimney offloads and task offloads. Such a NIC provides the highest degree of offload optimization.

For information on TCP chimney offload in NDIS 6.0 and later, see NDIS TCP Chimney Offload.

Simplified Driver Model

Article • 12/15/2021

The following NDIS 6.0 features simplify driver development:

Easier Initialization

Versioned Interfaces

Simplified Reset Handling

NDIS Interface Information

Easier-to-Write Filter Drivers

Easier Initialization

Article • 12/15/2021

All NDIS 6.0 and later drivers have updated driver registration interfaces. These NDIS interfaces provide simplified driver registration and the ability to register optional services separately from required services.

Miniport drivers require fewer function calls to register. In general, NDIS 6.0 and later function interfaces are more consistent when compared to the NDIS 5.*x* and earlier interfaces. Resources that are allocated also have a reciprocal function to free them.

An NDIS 6.0 or later intermediate driver can register as a miniport-intermediate driver. Such a driver has both a virtual miniport for a virtual device and a miniport adapter for a physical device. Registering as a miniport-intermediate driver simplifies the creation of an intermediate driver that binds only to a vendor's own NIC. The driver can pass network data, OID requests, and status indications between its virtual miniport and physical miniport adapter with internal calls.

Protocol drivers receive most of the information about an underlying adapter in a binding request. Therefore, protocol drivers do not send OID requests for the parameters that NDIS already provided in the bind request.

To initialize a miniport adapter, miniport drivers can receive OID requests that combine the information from many separate OID requests into fewer requests containing the combined information.

Intermediate drivers have fewer specialized functions and make better use of miniport driver and protocol driver interfaces.

A miniport driver can read or write the registry at any time -- not just during initialization. For example, when an application requests through Windows Management Instrumentation (WMI) that a driver change one of its operating parameters, the driver can record this change in the registry so that the change persists across reboots.

NDIS provides a bus-independent function call for reading and writing bus-specific configuration parameters. A driver can call this function regardless of the bus type in the system. This ensures that NDIS will be able to support future buses without the addition of new bus-specific functions.

For more information about driver initialization, see the initialization topics in the following sections:

Writing NDIS Miniport Drivers

Writing NDIS Protocol Drivers

NDIS Filter Drivers

Writing NDIS Intermediate Drivers

Versioned Interfaces

Article • 12/15/2021

NDIS 6.0 supports versioning for key structures. Also, many former function parameters are moved to structures. Moving the function parameters to versioned structures allows the function parameters to be changed in later NDIS versions without changing the function interface.

Versioned structures contain a header that specifies the version of the structure. If the set of function parameters or other structure members are changed, the structure and its version are updated.

This versioning simplifies backward compatibility and extends the life of NDIS 6.0 and later drivers. Also, NDIS drivers can support more than one version of NDIS.

For more information, see **NDIS_OBJECT_HEADER**.

Simplified Reset Handling

Article • 12/15/2021

NDIS 6.0 and later drivers do not reset miniport adapters to cancel send or OID requests. Instead, NDIS provides send cancellation and OID request cancellation functions.

An NDIS miniport driver can complete or cancel a pending send operation or pending OID request at any time -- either before or after completing a reset. The miniport driver does not have to keep track of when it received a request with respect to a reset. Also, the driver does not have to synchronize a canceled request with the completion of a reset.

For more information, see Canceling a Send Operation, OID Requests for an Adapter, Protocol Driver OID Requests, and Filter Module OID Requests.

NDIS Interface Information

Article • 03/14/2023

A standardized interface for querying NDIS management information bases (MIBs) makes it easier for overlying drivers and user-mode applications to query information about network interfaces. A MIB client calls NDIS-supplied functions to request information from an underlying NDIS interface provider. This causes NDIS to issue OID requests to retrieve the information. To supply the information to the client, NDIS calls a callback function that the client registered with NDIS.

For more information about NDIS network interface services, see NDIS Network Interfaces.

NDIS provides enhanced support for Management Instrumentation (WMI). For more information about NDIS 6.0 support for WMI, see NDIS Support for WMI.

Easier-to-Write Filter Drivers

Article • 12/15/2021

NDIS 6.0 filter drivers are easier to write than the previous NDIS filter intermediate drivers.

When compared to filter intermediate drivers, filter drivers provide the following implementation advantages:

- Filter drivers do not include a complete miniport driver interface and a complete protocol driver interfaces.
- Filter drivers do not create and manage a virtual device. There is no virtual miniport in a filter driver.
- If a filter driver filters specific services, the driver can bypass other services. The driver does not require code for services that are bypassed. For example, if a filter driver filters OID requests but does not filter send and receive operations, the filter driver does not require send and receive entry points.

For more information about NDIS 6.0 filter drivers, see NDIS 6.0 Filter Drivers.

Specifying NDIS Version Information

Article • 03/14/2023

This section provides an overview of the support that NDIS and NDIS drivers provide for NDIS version information.

Many NDIS structures include structure version information in a **Header** member. NDIS or NDIS drivers set the version information in such structures. NDIS drivers should check the version information in structures before they access the structure members.

Also, NDIS drivers specify the NDIS version that they support during driver initialization.

This section includes the following topics:

- Overview of NDIS Support for Header Versions
- Version Information Requirements for NDIS Drivers
- Version Information Requirements for NDIS
- Obtaining the NDIS Version
- NDIS Object Version Issues for WMI

Related topics

Overview of NDIS versions

Overview of NDIS Support for Header Versions

Article • 03/14/2023

Many NDIS structures include structure version information. NDIS or NDIS drivers initialize the **Header** member in such structures as required for each structure. NDIS drivers should check the version information, if any, in each structure before they access the structure members.

The **Header** member is an NDIS_OBJECT_HEADER structure. This structure contains the revision number, type, and size of the structure that includes the **Header** member.

Structures that include the **Header** member meet the following requirements:

- The structure will have a new revision value if new information is added to the member list for a new NDIS version. For example, if the NDIS 6.1 version of the structure has new members at the end of the member list, in a union, or in a bitmask, it will have a different revision value from the NDIS 6.0 version.

- After a structure is changed, the size of the later revision of the structure can be equal to or larger than the size of the earlier revision of the structure, but it will not be smaller. If the new size is larger than the size of the earlier revision, the new members are added at the end of the member list.

- A structure will only have a new revision if the earlier revision information is still valid and complete. That is, the new version of the structure contains a superset of the older versions members. **Note** If any of the preceding conditions cannot be met, NDIS provides a new structure with a new name that replaces the existing structure instead of providing a revised version of the existing structure.

- NDIS drivers should always use the predefined revision values. NDIS provides such definitions in the form Xxx_REVISION_Nn, and NDIS_SIZEOF_Xxx_REVISION_Nn, for the **Revision** and **Size** members of NDIS_OBJECT_HEADER respectively. Also, Xxx represents the name of the structure and Nn is the revision number. For example, the revision and size for the first revision of the NDIS_FILTER_PARTIAL_CHARACTERISTICS structure are NDIS_FILTER_PARTIAL_CHARACTERISTICS_REVISION_1 and NDIS_SIZEOF_FILTER_PARTIAL_CHARACTERISTICS_REVISION_1 respectively.

- The **Header.Size** value must be consistent with the **Header.Revision** value. That is, if the **Revision** member contains Xxx_REVISION_1, the **Size** member value must be equal to or greater than NDIS_SIZEOF_Xxx_REVISION_1.

Related topics

Overview of NDIS versions

Specifying NDIS Version Information

Version Information Requirements for NDIS Drivers

Article • 03/14/2023

NDIS structures that provide version information have a **Header** member that is defined as an NDIS_OBJECT_HEADER structure and NDIS drivers must provide support for such version information.

NDIS can support drivers that support a higher or lower NDIS version than the *current version of NDIS* (that is, the version of NDIS that is supported on the version of the operating system that a computer is running). Also the *registered NDIS version* (that is, the version that the driver reported during initialization) of the driver can be lower than the highest version that the driver supports. For example, an NDIS 5.1 driver or an NDIS 6.1 driver can run on a version of the operating system that is running NDIS 6.0. The NDIS 5.1 driver simply registers as an NDIS 5.1 driver during initialization. However, the NDIS 6.1 driver must check the current version of NDIS and must register as a driver that supports the highest level of NDIS that is available (in this example, NDIS 6.0). For more information about how to obtain the current NDIS version, see Obtaining the NDIS Version.

Note A driver is not required to support all the features in a later revision of a structure. For example, a miniport driver can create a version 2 structure and supply values that are appropriate for a version 1 structure.

To access the members in structures that have version information, NDIS drivers must complete the following process:

- Check the **Header.Revision** and **Header.Size** members before accessing any members in the structure.

- For earlier version structures (that is, structures that have a lower revision number than the number that is associated with the NDIS version that the driver supports):
  - The driver must verify that the **Header.Size** value is correct for the **Header.Revision** value. For example, the value of NDIS_SIZEOF_Xxx_REVISION_1 is correct for Xxx_REVISION_1 but it is too small for Xxx_REVISION_2.
  - The **Header.Size** value must be equal to or greater than NDIS_SIZEOF_Xxx_REVISION_Nn (where *Nn* is the revision number of the structure that the driver is using) and the driver must correctly handle the information in the structure as is appropriate for that revision.

- For later version structures (that is, structures that have a higher revision number than the number that is associated with the NDIS version that the driver supports), the driver can use the structure as if it were an older revision of the structure. The higher version structure is always compatible with the older version.

- Drivers must use the correct revision of a structure for the registered NDIS version of the driver. For example, an NDIS 6.1 driver must report its offload capabilities in NDIS_OFFLOAD structures by setting the members in the NDIS_OBJECT_HEADER structure to indicate NDIS_OFFLOAD_REVISION_2. However, the driver does not have to support all the features that are included with NDIS_OFFLOAD_REVISION_2.

- A driver that successfully handles an OID set request must set the **SupportedRevision** member in the NDIS_OID_REQUEST structure upon return from the OID set request. The **SupportedRevision** member notifies the initiator of the request of the revision that the driver supported. For example, a miniport driver can create an Xxx_REVISION_2 structure, supply values that are appropriate for an Xxx_REVISION_1 structure, and fill the rest of the structure with zeros. The miniport driver would report Xxx_REVISION_1 in the **SupportedRevision** member. In this case, a protocol driver that can support an Xxx_REVISION_2 will use Xxx_REVISION_1 information that the miniport driver supported.

- To determine what information was successfully handled by an underlying driver, overlying drivers that issue OID requests must check the value in the **SupportedRevision** member in the NDIS_OID_REQUEST structure after the OID request returns.

Specifying NDIS Version Information

Version Information Requirements for NDIS

Article • 03/14/2023

NDIS supports various header version information requirements that guarantee consistent behavior between NDIS versions. To support header version information, NDIS has the following responsibilities:

- Handles structures with lower revisions. That is, NDIS checks the header information and interprets the structure based upon the revision information in the header.
- Fails a function call and returns an appropriate error code if a driver uses an incorrect structure revision. For example, NDIS fails the function call if an NDIS 6.30 driver uses Xxx_REVISION_1 structures when there is an NDIS 6.30 Xxx_REVISION_2 structure.

Specifying NDIS Version Information

Obtaining the NDIS Version

Article • 03/14/2023

NDIS versions might not be the same as the operating system versions. For example, if you use the **RtlGetVersion** and **RtlVerifyVersionInfo** routines to get the operating system version, you do not get a guaranteed association with a particular NDIS version. Therefore, NDIS drivers must get the NDIS version and the operating system version separately. NDIS drivers can get the NDIS version with the **NdisGetVersion** function.

NDIS Object Version Issues for WMI

Article • 03/14/2023

This topic describes the NDIS object version issues that affect Windows Management Instrumentation (WMI) support.

There is no versioning inside a WMI managed object format (MOF) file. Therefore, if the corresponding NDIS structure has a new revision, more fields have been added to the MOF data objects.

The NDIS_WMI_Xxx_HEADER structures have a new revision when more members are added for a new NDIS version. For a list of the current NDIS_WMI_Xxx_HEADER structures, see NDIS WMI Structures.

When applications access the WMI information for a query operation, they must check the version in the returned buffer before they access any data. For a set operation, applications must check the **SupportedRevision** member in the NDIS_WMI_OUTPUT_INFO structure to determine which version the underlying driver has accepted.

Many WMI objects contain the **MSNdis_ObjectHeader** property, which is equivalent to the **NDIS_OBJECT_HEADER** structure. When populating the **MSNdis_ObjectHeader** property, set the **Type** and **Revision** fields as documented in the **NDIS_OBJECT_HEADER** topic. To ensure seamless portability to 64-bit systems, set the **Size** field to `0xFFFF`.

- Introduction to NDIS 6.0

Porting NDIS 6.x drivers to NDIS 6.60

Article • 03/14/2023

NDIS 6.60 is substantially the same as NDIS 6.50. For detailed information about new features for NDIS 6.60, including implementation and compilation details specific to this version of NDIS, see Introduction to NDIS 6.60.

If you are porting an NDIS 6.x driver to NDIS 6.60, you should be familiar with the changes to each version between your driver's version and 6.60. For more information about previous NDIS 6.x versions, see the following topics:

- Introduction to NDIS 6.50
- Introduction to NDIS 6.40
- Introduction to NDIS 6.30
- Introduction to NDIS 6.20
- Introduction to NDIS 6.1
- Introduction to NDIS 6.0

Porting NDIS 6.x drivers to NDIS 6.50

Article • 03/14/2023

NDIS 6.50 is substantially the same as NDIS 6.40. For detailed information about new features for NDIS 6.50, including implementation and compilation details specific to this version of NDIS, see Introduction to NDIS 6.50.

If you are porting an NDIS 6.x driver to NDIS 6.50, you should be familiar with the changes to each version between your driver's version and 6.50. For more information about previous NDIS 6.x versions, see the following topics:

- Introduction to NDIS 6.40
- Introduction to NDIS 6.30
- Introduction to NDIS 6.20
- Introduction to NDIS 6.1
- Introduction to NDIS 6.0

Porting NDIS 6.x Drivers to NDIS 6.40

Article • 03/14/2023

NDIS 6.40 is substantially the same as NDIS 6.30. For detailed information about new features for NDIS 6.40, including implementation and compilation details specific to this version of NDIS, see Introduction to NDIS 6.40.

If you are porting an NDIS 6.x driver to NDIS 6.40, you should be familiar with the changes to each version between your driver's version and 6.40. For more information about previous NDIS 6.x versions, see the following topics:

- Introduction to NDIS 6.30
- Introduction to NDIS 6.20
- Introduction to NDIS 6.1
- Introduction to NDIS 6.0

Porting NDIS 6.x Drivers to NDIS 6.30

Article • 03/14/2023

This section describes the requirements to port NDIS 6.x drivers to NDIS 6.30.

- For information about porting NDIS 6.x drivers to NDIS 6.20, see Porting NDIS 6.x Drivers to NDIS 6.20.
- For information about porting NDIS 5.x and earlier drivers to NDIS 6.x, see Porting NDIS 5.x Drivers to NDIS 6.0.

For more information about NDIS 6.30 features, see Introduction to NDIS 6.30.

The following topics discuss how to port miniport, protocol, and intermediate drivers to NDIS 6.30:

- NDIS 6.30 Backward Compatibility
- Summary of Changes Required to Port a Miniport Driver to NDIS 6.30
- Summary of Changes Required to Port a Protocol or Filter Driver to NDIS 6.30
- Summary of Changes Required to Port an Intermediate Driver to NDIS 6.30

NDIS 6.30 Backward Compatibility

Article • 03/14/2023

NDIS 6.30 adds backward compatibility features to those that apply to NDIS 6.20 and NDIS 6.0 drivers. For information about NDIS 6.20 compatibility issues, see NDIS 6.20 Backward Compatibility. For information about NDIS 6.0 compatibility issues, see NDIS 6.0 Backward Compatibility.

For more information about NDIS 6.30 features, see Introduction to NDIS 6.30.

Features that are no longer supported

The following features are not supported in Windows 8 and later:

- TCP chimney offload is no longer supported for virtual machines. However, it is still supported for native use.
- IPsec task offload version 1. All drivers that support IPsec task offload should be updated to support IPsec task offload version 2.
- Filter intermediate drivers. Instead, use the NDIS 6.*x* filter driver interface. For more information about filter drivers, see NDIS Filter Drivers.
- 802.11 drivers that emulate 802.3. NDIS 802.11 drivers must support the native 802.11 interface. For more information about native 802.11, see Native 802.11 Wireless LAN.
- NDIS WAN drivers. NDIS WAN drivers must be ported to the NDIS 6.0 CoNDIS WAN driver model. For more information about CoNDIS WAN, see WAN Miniport Drivers.

Features that have been removed

The following features have been removed from Windows 8 and later:

- NDIS 5.x and earlier
- IrDA miniport drivers
- NetDMA
- Token Ring (802.5)

Other changes

- The TCP/IP protocol driver that ships with Windows 8 has been updated to NDIS 6.30. However, this change was relatively minor, so it's not worth porting your driver just for this feature. The TCP/IP protocol driver is backward compatible with NDIS 6.20 and earlier drivers in the driver stack.

Summary of Changes Required to Port a Miniport Driver to NDIS 6.30

Article • 03/14/2023

To update an NDIS 6.x miniport driver to support NDIS 6.30, you must modify it as outlined in the following sections.

- Build Environment and Testing
- General Porting Requirements
- Wi-Fi Direct Miniport Drivers
- USB-Based WWAN (Mobile Broadband) Miniport Drivers

For more information about NDIS 6.30 features, see Introduction to NDIS 6.30.

Build Environment and Testing

- Replace the preprocessor definition NDIS60_MINIPORT or NDIS61_MINIPORT or NDIS620_MINIPORT with NDIS630_MINIPORT. For more information, see Compiling an NDIS 6.30 Driver

- Replace the preprocessor definition NDIS60 or NDIS61 or NDIS620, if present, with NDIS630. **Note** This item applies only to NDIS intermediate, protocol, and filter drivers. Most NDIS miniport drivers don't need this preprocessor definition.

- In NDIS 6.30, NDIS can call *MiniportInitializeEx* twice in parallel if there are two adapters plugged into the system at the same time or during system startup. Be sure to test your miniport driver under this "parallel startup" condition.

General Porting Requirements

- Update the major and minor NDIS version number in the NDIS_*Xxx*_DRIVER_CHARACTERISTICS structure as described in Implementing an NDIS 6.30 Driver.
- For all structures that were updated for NDIS 6.30, miniport drivers need to update the **Header** member of the structure with the correct **Revision** and **Size** values. For more information, see Using NDIS 6.30 Data Structures.
- All miniport drivers should implement the no-pause-on-suspend feature. For more information, see:
  - Power Management Enhancements in NDIS 6.30
  - **NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES**

    - **NET_PNP_EVENT**
    - OID_PNP_SET_POWER

Wi-Fi Direct Miniport Drivers

During *MiniportInitializeEx*, a Wi-Fi Direct-capable miniport driver must initialize the default 802.11 MAC entity. It must also report its Wi-Fi Direct and Virtual Wi-Fi capabilities using the **NdisMSetMiniportAttributes** function.

Note The driver is not required to register with NDIS the NDIS port corresponding to the default MAC entity.

USB-Based WWAN (Mobile Broadband) Miniport Drivers

For USB-based Mobile Broadband devices, Windows 8 provides a class driver that works with devices conforming to the MBIM specification. This model is referred to as the Mobile Broadband (MB) Class Driver. However, a class driver cannot support all of the functionality exposed by an MB device. For this reason, the MB feature provides a well-defined mechanism that you can use to extend the class driver functionality. For more information, see MB Device Services.

If your USB-based WWAN miniport driver cannot implement the MB class driver, it must at least implement the NDIS Selective Suspend feature.

Summary of Changes Required to Port a Protocol or Filter Driver to NDIS 6.30

Article • 03/14/2023

To update an NDIS 6.x protocol or filter driver to support NDIS 6.30, you must modify it as outlined in the following sections.

- Build Environment
- General Porting Requirements for Protocol Drivers
- General Porting Requirements for Filter Drivers

Build Environment

- Replace the preprocessor definition NDIS60 or NDIS61 or NDIS620, if present, with NDIS630.
- Update the major and minor NDIS version number in the NDIS_*Xxx*_DRIVER_CHARACTERISTICS structure as described in Implementing an NDIS 6.30 Driver.

General Porting Requirements for Protocol Drivers

A protocol driver should always complete **NetEventSetPower** without waiting for packets. For more information, see:

- Power Management Enhancements in NDIS 6.30
- Handling PnP Events and Power Management Events in a Protocol Driver

For more information about NDIS 6.30 features, see Introduction to NDIS 6.30.

General Porting Requirements for Filter Drivers

A filter driver should always complete **NetEventSetPower** without waiting for packets. For more information, see:

- Power Management Enhancements in NDIS 6.30
- **NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES**
- **NET_PNP_EVENT**
- OID_PNP_SET_POWER

For more information about NDIS 6.30 features, see Introduction to NDIS 6.30.

Summary of Changes Required to Port an Intermediate Driver to NDIS 6.30

Article • 03/14/2023

To update an NDIS 6.x intermediate (IM) driver to support NDIS 6.30, you must modify it as outlined in the following sections.

Build Environment

- Replace the preprocessor definition NDIS60 or NDIS61 or NDIS620, if present, with NDIS630.
- Update the major and minor NDIS version number in the NDIS_*Xxx*_DRIVER_CHARACTERISTICS structure as described in Implementing an NDIS 6.30 Driver.

General Porting Requirements

- Except where noted otherwise, protocol driver and miniport driver changes also apply to intermediate drivers. For more information about porting these drivers, see the Summary of Changes Required to Port a Protocol or Filter Driver to NDIS 6.30 and Summary of Changes Required to Port a Miniport Driver to NDIS 6.30.

Porting NDIS 6.x Drivers to NDIS 6.20

Article • 03/14/2023

This section describes the requirements to port NDIS 6.0 and 6.1 drivers to NDIS 6.20.

For information about porting NDIS 5.x or earlier drivers to NDIS 6.x, see Porting NDIS 5.x Drivers to NDIS 6.0.

For more information about NDIS 6.20 features, see Introduction to NDIS 6.20.

For more information about NDIS 6.1 features, see Introduction to NDIS 6.1.

The following topics describe how to port miniport, protocol, and intermediate drivers to NDIS 6.20 in more detail:

- NDIS 6.20 Backward Compatibility
- NDIS 6.20 Updates to NDIS 6.1 Features
- Obsolete Interfaces in NDIS 6.20
- Summary of Changes Required to Port a Miniport Driver to NDIS 6.20
- Summary of Changes Required to Port a Protocol Driver to NDIS 6.20
- Summary of Changes Required to Port a Filter Driver to NDIS 6.20
- Summary of Changes Required to Port an Intermediate Driver to NDIS 6.20

NDIS 6.20 Backward Compatibility

Article • 03/14/2023

NDIS 6.20 adds backward compatibility features to those that apply to NDIS 6.0 drivers. For information about NDIS 6.0 compatibility issues, see NDIS 6.0 Backward Compatibility. In addition to the translation features that NDIS 6.0 provides for NDIS 5.x and earlier drivers, NDIS 6.20 also provides translation for the power management interface. NDIS 6.20 drivers must support the NDIS 6.20 power management interface.

NDIS 6.20 supports updated versions of the features that were added for NDIS 6.1. For more information about updates to NDIS 6.1 features, see NDIS 6.20 Support for NDIS 6.1 Features.

Note The NDIS 6.20 interface supports more than 64 processors. Previous NDIS versions are limited to no more than 64 processors (32 in x86 versions of the operating system).

To remain backward compatible with older NDIS versions, drivers that have not been updated to support more than 64 processors default to processor group zero. For more information about processor groups, see the Kernel-Mode Driver Architecture Design documentation for processor groups.

Some NDIS 6.1 and earlier functions are obsolete and cannot be used with NDIS 6.20 drivers. See the requirements section of the reference page for a particular function to determine its NDIS version compatibility. For a list of obsolete interfaces, see Obsolete Interfaces in NDIS 6.20.

The TCP/IP protocol driver that ships with Windows 7 has been updated to NDIS 6.20. The TCP/IP protocol driver is backward compatible with NDIS 6.1 and earlier drivers in the driver stack. However, to obtain the best performance on the Windows 7 driver stack, all drivers should be updated to NDIS 6.20.

NDIS 5.x and earlier NDIS drivers are deprecated in Microsoft Windows versions after Windows 7. No new NDIS 5.x drivers will be WHQL certified. All new drivers should be NDIS 6.0 or later drivers.

IrDA miniport drivers will not be supported in Microsoft Windows versions after Windows 7.

IPsec task offload version 1 will not be supported in Microsoft Windows versions after Windows 7. All drivers that support IPsec task offload should be updated to support IPsec task offload version 2.

Filter intermediate drivers will not be supported in Microsoft Windows versions after Windows 7. You should use the NDIS 6.0 filter drivers interface. For more information about filter drivers, see NDIS Filter Drivers.

802.11 drivers that emulate 802.3 will not be supported in Microsoft Windows versions after Windows 7. NDIS 802.11 drivers must support the native 802.11 interface. For more information about native 802.11, see Native 802.11 Wireless LAN.

NDIS WAN drivers will not be supported in Microsoft Windows versions after Windows 7. NDIS WAN drivers must be ported to the NDIS 6.0 CoNDIS WAN driver model. For more information about CoNDIS WAN, see WAN Miniport Drivers.

ATM and Token Ring drivers will not be supported in Microsoft Windows versions after Windows 7.

NDIS 6.20 Updates to NDIS 6.1 Features

Article • 03/14/2023

NDIS 6.1 added the following interfaces to NDIS 6.0:

Header-Data Split

Direct OID Requests

IPsec Task Offload Version 2

NetDMA 1.1 and 2.0

For more information about NDIS 6.1, see Introduction to NDIS 6.1.

NDIS 6.1 also includes updates to support MSI-X dynamic configuration for receive side scaling (RSS). For more information about NDIS 6.1 changes in RSS, see NDIS MSI-X. RSS is updated in NDIS 6.20 to provide support for more than 64 processors.

The direct OID request interface is optional for NDIS 6.1 drivers but it is mandatory for NDIS 6.20 miniport drivers.

After NDIS 6.20 IPsec task offload version 1 will not be supported. All drivers that support IPsec task offload should be updated to support IPsec task offload version 2.

NetDMA 1.1 and 2.0 were introduced with NDIS 6.1. NetDMA 2.1 is introduced with NDIS 6.20 to provide support for more than 64 processors.

Obsolete Interfaces in NDIS 6.20

Article • 03/14/2023

Some NDIS 6.1 application interface elements are obsolete for NDIS 6.20 drivers.

The following table lists NDIS 6.1 interface elements and their NDIS 6.20 replacements.

Obsolete interface	Use instead
LOCK_STATE	LOCK_STATE_EX
NDIS_CURRENT_PROCESSOR_NUMBER	NdisCurrentProcessorIndex
NDIS_MAX_PROCESSOR_COUNT(constant)	NdisGroupMaxProcessorCount
NDIS_RW_LOCK	NDIS_RW_LOCK_EX
MAXIMUM_PROCESSORS(constant)	NdisGroupMaxProcessorCount
NdisSystemProcessorCount	NdisGroupMaxProcessorCount
NdisSystemActiveProcessorCount	NdisGroupActiveProcessorCount
NdisGetProcessorInformation	NdisGetProcessorInformationEx
NdisMQueueDpc	NdisMQueueDpcEx
Do not use the *TargetProcessors* parameter of MINIPORT_ISR_HANDLER (*MiniportInterrupt*)	NdisMQueueDpcEx
Do not use the *TargetProcessors* parameter of MINIPORT_MSI_ISR_HANDLER (*MiniportMessageInterrupt*)	NdisMQueueDpcEx
NDIS_NBL_MEDIA_SPECIFIC_INFORMATION	NDIS_NBL_MEDIA_SPECIFIC_INFORMATION_EX
OID_GEN_PHYSICAL_MEDIUM	OID_GEN_PHYSICAL_MEDIUM_EX
OID_PNP_ADD_WAKE_UP_PATTERN	OID_PM_ADD_WOL_PATTERN
OID_PNP_CAPABILITIES	OID_PM_CURRENT_CAPABILITIES
OID_PNP_ENABLE_WAKE_UP	OID_PM_PARAMETERS
OID_PNP_REMOVE_WAKE_UP_PATTERN	OID_PM_REMOVE_WOL_PATTERN
OID_PNP_WAKE_UP_PATTERN_LIST	OID_PM_WOL_PATTERN_LIST

Summary of Changes Required to Port a Miniport Driver to NDIS 6.20

Article • 03/14/2023

This topic summarizes the changes that are required to port an NDIS 6.x miniport driver to NDIS 6.20.

NDIS 6.20 retains backward compatibility with earlier NDIS versions. For more information about backward compatibility, see NDIS 6.20 Backward Compatibility.

To update a miniport driver to support the NDIS 6.20 environment, you must modify the NDIS 6.x miniport driver as follows:

Build Environment
Replace the preprocessor definition NDIS60_MINIPORT_DRIVER or NDIS61_MINIPORT_DRIVER with NDIS620_MINIPORT_DRIVER.

General Porting Requirements

- Replace obsolete interfaces with NDIS 6.20 versions. For more information about obsolete interfaces, see Obsolete Interfaces in NDIS 6.20.

- Update the following interfaces to support more than 64 processors:
  - Receive side scaling (RSS)
  - Processor information device driver interfaces
  - Resource allocation
  - Read and write locks

  For more information about supporting more than 64 processors, see Support for More than 64 Processors in NDIS 6.20.

Driver Initialization

- Set the NDIS version to 6.20 in the **MajorNdisVersion** and **MinorNdisVersion** members of the **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** structure, which is passed to the **NdisMRegisterMiniportDriver** function.

- Set the miniport driver version in the **MajorDriverVersion** and **MinorDriverVersion** members of the NDIS_MINIPORT_DRIVER_CHARACTERISTICS structure to an appropriate driver-specific value.

- Define direct OID request entry points in the NDIS_MINIPORT_DRIVER_CHARACTERISTICS structure. Support for the direct OID request interface was optional for NDIS 6.1 drivers but it is mandatory for NDIS 6.20 drivers. For more information about the miniport driver direct OID request interface, see Miniport Adapter OID Requests.

Miniport Adapter Initialization

- Use the latest version of the miniport adapter capabilities advertisement interfaces. The following interfaces have updated capabilities:
  - Power Management
  - Receive side scaling (RSS)
  - Hardware assist (VMQ)

- Use the updated versions of these structures:
  - **NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES**
  - **NDIS_RESTART_GENERAL_ATTRIBUTES**
  - **NDIS_RECEIVE_SCALE_PARAMETERS**
  - **NDIS_MINIPORT_ADAPTER_HARDWARE_ASSIST_ATTRIBUTES**

  For information about NDIS structure version information, see Specifying NDIS Version Information.

Send and Receive Code Paths

- NDIS 6.20 drivers must support receive-side throttle (RST) in processing receive interrupts. The *ReceiveThrottleParameters* parameters of the *MiniportInterruptDPC* and *MiniportMessageInterruptDPC* DPC handler functions point to an **NDIS_RECEIVE_THROTTLE_PARAMETERS** structure. On entry to the deferred procedure call (DPC) handler, the **MaxNblsToIndicate** member of the NDIS_RECEIVE_THROTTLE_PARAMETERS structure specifies the maximum number of **NET_BUFFER_LIST** structures that the miniport driver should indicate in the DPC. For more information about RST, see Receive Side Throttle in NDIS 6.20.

- Use the updated version of the **NET_BUFFER** structure.

- Optionally support the virtual machine queue (VMQ) interface. For more information about VMQ, see Virtual Machine Queue (VMQ) in NDIS 6.20.

Summary of Changes Required to Port a Protocol Driver to NDIS 6.20

Article • 03/14/2023

This topic summarizes the changes that are required to port an NDIS 6.*x* protocol driver to NDIS 6.20.

NDIS 6.20 retains backward compatibility with earlier NDIS versions. For more information about backward compatibility, see NDIS 6.20 Backward Compatibility.

To update a protocol driver to support the NDIS 6.20 environment, you must modify the NDIS 6.x protocol driver as follows:

Build Environment
Replace the preprocessor definition NDIS61 or NDIS60 with NDIS620.

General Porting Requirements

- Replace obsolete interfaces with NDIS 6.20 versions. For more information about obsolete interfaces, see Obsolete Interfaces in NDIS 6.20.

- Update the following interfaces to support more than 64 processors:
  - Receive side scaling (RSS)
  - Processor information device driver interfaces
  - Resource allocation
  - Read and write locks

  For more information about supporting more than 64 processors, see Support for More than 64 Processors in NDIS 6.20.

Driver Initialization

- Set the NDIS version to 6.20 in the **MajorNdisVersion** and **MinorNdisVersion** members of the **NDIS_PROTOCOL_DRIVER_CHARACTERISTICS** structure that is passed to the **NdisRegisterProtocolDriver** function.

- Set the protocol driver version in the **MajorDriverVersion** and **MinorDriverVersion** members of the NDIS_PROTOCOL_DRIVER_CHARACTERISTICS structure to an appropriate driver-specific value.

Protocol Bind and Unbind Operations

- Use the latest version of the miniport adapter capabilities advertisement interfaces. The following interfaces have updated capabilities:
  - Power Management
  - Power Management
  - Receive side scaling (RSS)
  - Hardware assist (VMQ)

- Use the updated versions of these structures:
  - **NDIS_BIND_PARAMETERS**
  - **NDIS_OFFLOAD_PARAMETERS**

  For information about NDIS structure version information, see Specifying NDIS Version Information.

Send and Receive Data Paths

- Use the updated version of the **NET_BUFFER** structure.

- Optionally support the virtual machine queue (VMQ) interface. For more information about VMQ, see Virtual Machine Queue (VMQ) in NDIS 6.20.

Summary of Changes Required to Port a Filter Driver to NDIS 6.20

Article • 03/14/2023

This topic summarizes the changes that are required to port an NDIS 6.*x* filter driver to NDIS 6.20.

NDIS 6.20 retains backward compatibility with earlier NDIS versions. For more information about backward compatibility, see NDIS 6.20 Backward Compatibility.

To update a filter driver to support the NDIS 6.20 environment, you must modify the NDIS 6.x filter driver as follows:

Build Environment
Replace the preprocessor definition NDIS61 or NDIS60 with NDIS620.

General Porting Requirements

- Replace obsolete interfaces with NDIS 6.20 versions. For more information about obsolete interfaces, see Obsolete Interfaces in NDIS 6.20.

- Update the following interfaces to support more than 64 processors:
  - Receive side scaling (RSS)
  - Processor information device driver interfaces
  - Resource allocation
  - Read and write locks

  For more information about supporting more than 64 processors, see Support for More than 64 Processors in NDIS 6.20.

Driver Initialization

- Set the NDIS version to 6.20 in the **MajorNdisVersion** and **MinorNdisVersion** members of the **NDIS_FILTER_DRIVER_CHARACTERISTICS** structure that is passed to the **NdisFRegisterFilterDriver** function.

- Set the filter driver version in the **MajorDriverVersion** and **MinorDriverVersion** members of the NDIS_FILTER_DRIVER_CHARACTERISTICS structure to an appropriate driver-specific value.

Filter Module Attach and Detach Operations

- Use the latest version of the miniport adapter capabilities advertisement interfaces. The following interfaces have updated capabilities:
  - Power Management
  - Receive-side scaling (RSS)
  - Hardware assist (VMQ)

- Use the updated versions of these structures:
  - **NDIS_FILTER_ATTACH_PARAMETERS**
  - **NDIS_OFFLOAD_PARAMETERS**

  For information about NDIS structure version information, see Specifying NDIS Version Information.

Send and Receive Data Paths

- Use the updated version of the **NET_BUFFER** structure.

- Optionally support the virtual machine queue (VMQ) interface. For more information about VMQ, see Virtual Machine Queue (VMQ) in NDIS 6.20.

Summary of Changes Required to Port an Intermediate Driver to NDIS 6.20

Article • 03/14/2023

This topic summarizes the changes that are required to port an NDIS 6.*x* intermediate driver to NDIS 6.20.

To update an intermediate driver to support the NDIS 6.20 environment, you must modify the NDIS 6.*x* intermediate driver as follows:

Build Environment

- Replace the preprocessor definition NDIS60_MINIPORT_DRIVER or NDIS61_MINIPORT_DRIVER with NDIS620_MINIPORT_DRIVER.

- Replace the preprocessor definition NDIS61 or NDIS60 with NDIS620.

General Porting Requirements

- Except where noted otherwise, protocol driver and miniport driver changes also apply to intermediate drivers. For more information about porting these drivers, see the protocol driver porting summary at Summary of Changes Required to Port a Protocol Driver to NDIS 6.20 and the miniport driver porting summary at Summary of Changes Required to Port a Miniport Driver to NDIS 6.20.

- NDIS 5.x filter intermediate drivers will not be supported in Microsoft Windows versions after Windows 7. You should use the NDIS filter drivers interface for all filter drivers. For more information about NDIS filter drivers, see Summary of Changes Required to Port a Filter Driver to NDIS 6.20.

Roadmap for Developing NDIS Miniport Drivers

Article • 03/14/2023

To create a Network Driver Interface Specification (NDIS) miniport driver package, follow these steps:

- Step 1: Learn about Windows architecture and drivers.

  You must understand the fundamentals of how drivers work in Windows operating systems. Knowing the fundamentals will help you make appropriate design decisions and let you streamline your development process. For more information about driver fundamentals, see Concepts for all driver developers.

- Step 2: Learn about NDIS.

  For general information about NDIS and NDIS drivers, see the following topics:

  Windows Network Architecture and the OSI Model

  Network Driver Programming Considerations

  Driver Stack Management

  NET_BUFFER Architecture

- Step 3: Determine additional Windows driver design decisions.

  For more information about how to make additional Windows design decisions, see Creating Reliable Kernel-Mode Drivers, Programming Issues for 64-Bit Drivers, and Creating International INF Files.

- Step 4: Learn about the Windows driver build, test, and debug processes and tools.

  Building a driver differs from building a user-mode application. For more information about Windows driver build, debug, and test processes, driver signing, and Windows Hardware Lab Kit (HLK) testing, see Building, Debugging, and Testing Drivers. For more information about building, testing, verifying, and debugging tools, see Driver Development Tools.

- Step 5: Read the miniport driver introduction topics:

  Types of NDIS Miniport Drivers

Network Interface Card Support

Sample NDIS Miniport Drivers

- Step 6: Read the writing miniport drivers section.

  This section provides an overview of the primary miniport driver interfaces. These interfaces included functions that miniport drivers provide (*MiniportXxx* functions) and NDIS calls to initiate operations. NDIS provides **Ndis*Xxx*** functions that miniport drivers call to perform NDIS operations.

- Step 7: Review the NDIS miniport driver sample in the Windows driver samples repository on GitHub.

- Step 8: (optional reading) Additional considerations for Miniport Drivers.

  Additional considerations include topics that expand on the primary interfaces that are described in the writing miniport drivers section.

  Obtaining and Setting Miniport Driver Information and NDIS Support for WMI

  NDIS MSI-X

  NDIS Scatter/Gather DMA

  NDIS Power Management

  Plug and Play for NDIS Miniport Drivers

  Reset, Halt, and Shutdown Functions

  Miniport Driver with a WDM Lower Interface

  WAN Miniport Drivers

  Scalable Networking

- Step 9: Develop (or port), build, test, and debug your NDIS driver.

  See the porting guides if you are porting an existing driver:
  - Porting NDIS 5.x Drivers to NDIS 6.0
  - Porting NDIS 6.x Drivers to NDIS 6.20
  - Porting NDIS 6.x Drivers to NDIS 6.30

  For more information about iterative building, testing, and debugging, see Overview of Build, Debug, and Test Process. This process will help ensure that you build a driver that works.

- Step 10: Create a driver package for your driver.

  For more information about how to install drivers, see Providing a Driver Package. For more information about how to install an NDIS driver, see Components and Files Used for Network Component Installation and Notify Objects for Network Components.

- Step 11: Sign and distribute your driver.

  The final step is to sign (optional) and distribute the driver. If your driver meets the quality standards that are defined for the Windows Hardware Lab Kit (HLK), you can distribute it through the Microsoft Windows Update program. For more information about how to distribute a driver, see Get started with the hardware submission process.

These are the basic steps. Additional steps might be necessary based on the needs of your individual driver.

Deserialized NDIS Miniport Drivers

Article • 03/14/2023

All NDIS 6.0 and later drivers are *deserialized*.

A *deserialized NDIS miniport driver* serializes the operation of its own *MiniportXxx* functions and queues internally all send requests rather than relying on NDIS to perform these functions. As a result, a deserialized miniport driver can achieve significantly better full-duplex performance than a serialized miniport driver.

The deserialized driver model is the default model for NDIS miniport drivers. Connection-oriented miniport drivers, as well as miniport drivers with a WDM lower edge, must be deserialized drivers. When writing a new NDIS miniport driver, you should write a deserialized driver. If possible, you should also port older drivers to NDIS 6.0 or later. For more information about porting drivers, see:

- Porting NDIS 5.x Drivers to NDIS 6.0
- Porting NDIS 6.x Drivers to NDIS 6.20
- Porting NDIS 6.x Drivers to NDIS 6.30

A deserialized miniport driver must meet the following requirements when it interfaces with NDIS:

- A deserialized miniport driver must identify itself as such to NDIS during initialization.

- A deserialized miniport driver must complete all send requests asynchronously. To complete a send request, connectionless NDIS 6.0 and later miniport drivers call the **NdisMSendNetBufferListsComplete** function. Connection-oriented NDIS 6.0 and later miniport drivers call the **NdisMCoSendNetBufferListsComplete** function.

- A deserialized miniport driver that supports NDIS 6.0 or later sets the **Status** member of the NET_BUFFER_LIST structure that it will pass to **NdisMSendNetBufferListsComplete**.

- If a deserialized miniport driver cannot immediately complete send requests, it cannot return the requests to NDIS for requeuing. Instead, the miniport driver must queue send requests internally until sufficient resources are available to transmit the data.

- A deserialized miniport driver must not examine the structures that it passes to NDIS in receive indications until after NDIS returns them. NDIS returns

NET_BUFFER_LIST structures to a miniport driver's *MiniportReturnNetBufferLists* function.

A deserialized miniport driver must meet the following driver-internal requirements:

- A deserialized miniport driver must protect its network buffer queues with spin locks. A deserialized miniport driver must also protect its shared state from simultaneous access by its own *MiniportXxx* functions.

- A deserialized miniport driver's *MiniportXxx* functions can run at IRQL <= DISPATCH_LEVEL. Consequently, the driver writer cannot assume that *MiniportXxx* functions will be called in the sequence in which they process requests. One *MiniportXxx* function can preempt another *MiniportXxx* function that is running at a lower IRQL.

- A deserialized miniport driver is responsible for network buffer-queue management. When the miniport driver experiences a resource problem, it cannot return send requests to NDIS for requeuing. Instead, the miniport driver must queue internally all send requests until sufficient resources are available to send the data.

- A deserialized miniport driver should complete send requests in the protocol-determined order.

For more information about send and receive requirements for NDIS drivers, see Send and Receive Operations.

Note that a deserialized miniport driver usually completes send requests in protocol-determined order. However, a miniport driver that supports packet priority (for example, IEEE 802.1p) can reorder send requests based on priority information.

Serialized NDIS Miniport Drivers

Article • 03/14/2023

Serialized NDIS miniport drivers are obsolete for Windows Vista and later versions. Serialized miniport drivers are not supported for NDIS 6.0 drivers. Windows Vista supports serialized miniport drivers only for NDIS 5.1 and earlier drivers. Unlike deserialized miniport drivers, a serialized miniport driver relies on NDIS to serialize the operation of its own *MiniportXxx* functions and to manage the queue for sending network data packets.

If you are writing a new miniport driver, you should write a deserialized driver. If possible, you should also port older drivers to NDIS 6.0 or later. For more information about porting drivers to NDIS 6.0, see Porting NDIS 5.x Drivers to NDIS 6.0.

Connection-Oriented NDIS Miniport Drivers

Article • 03/14/2023

A *connection-oriented miniport driver* controls one or more miniport adapters for connection-oriented media. Connection-oriented miniport drivers must be deserialized. For more information about deserialized drivers, see Deserialized NDIS Miniport Drivers.

A connection-oriented miniport driver provides an interface between connection-oriented protocol drivers (connection-oriented clients and call managers) and NIC hardware (for example, physical miniport adapters). For a summary of connection-oriented operations performed by a connection-oriented miniport driver, see Connection-Oriented Operations Performed by Miniport Drivers.

A connection-oriented miniport driver must register the following *MiniportXxx* functions that are specific to connection-oriented operations:

- **MiniportCoCreateVc**
- **MiniportCoDeleteVc**
- **MiniportCoActivateVc**
- **MiniportCoDeactivateVc**
- **MiniportCoSendNetBufferLists**
- **MiniportCoOidRequest**

For more information about registering these functions, see **NdisMRegisterMiniportDriver**.

NDIS Miniport Drivers with a WDM Lower Edge

Article • 03/14/2023

You can write an NDIS miniport driver that controls a device on a bus — for example, the Universal Serial Bus (USB) or the IEEE 1394 (firewire) bus. Such a miniport driver must expose a standard NDIS miniport driver interface at its upper edge and use the class interface for the particular bus at its lower edge. The miniport driver communicates with devices that are attached to the bus by sending I/O request packets (IRPs) to the bus through its Microsoft Windows Driver Model (WDM) lower interface.

A miniport driver with a WDM lower edge must be deserialized. For more information about deserialized drivers, see Deserialized NDIS Miniport Drivers.

For more information about miniport drivers with a WDM lower edge, see Miniport Drivers with a WDM Lower Interface.

Network Interface Card Support

Article • 12/15/2021

This topic describes the types of Network Interface Cards (NICs) that an NDIS miniport driver can manage, as well as how the different kinds of NICs affect the way a driver transfers network data.

Reporting a NIC's medium type to NDIS

To report a medium type for a NIC, a miniport driver passes a pointer to an NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES structure in the *MiniportAttributes* parameter of the NdisMSetMiniportAttributes function. A miniport driver calls **NdisMSetMiniportAttributes** from its *MiniportInitializeEx* function during initialization. Miniport drivers should set the *MiniportAttributes* attributes after setting the registration attributes in the NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES structure and before setting any other attributes. Setting the *MiniportAttributes* attributes is mandatory. The driver sets the **MediaType** member of the **NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES** structure to the appropriate media type when setting the *MiniportAttributes* attributes.

When an overlying NDIS protocol driver calls NdisOpenAdapterEx to bind to a specified miniport adapter, it provides a list of medium types on which it can operate. NDIS uses the information from the miniport driver and from the protocol driver to set up a binding. This binding provides the path for transferring network data up and down the driver stack.

Physical NICs

The steps that a miniport driver completes to initialize a miniport adapter and to send and receive network data can depend on the features of a physical device, as follows.

- NDIS-WDM NICs

  With NDIS-WDM NICs, such as USB-based NICs, the way the miniport driver manages memory with DMA does not matter to NDIS and is not visible to it.

- Bus-master DMA NICs

  These NICs can directly access host memory through an on-board DMA controller that manages the transfer of data between the network and host memory without using the host CPU.

To send, the miniport driver sets up the NIC to map the outgoing buffers. The miniport driver then causes the device to start its transfer from this memory. The NIC DMA controller transfers the data from shared system memory onto the network and interrupts the CPU when the send is complete. To receive, the DMA controller transfers incoming data to host memory before notifying the host with an interrupt.

A bus-master DMA NIC typically has an onboard ring buffer that the miniport driver maps to a set of buffers in system memory. Typically, the NIC can be programmed to efficiently handle several packets. A miniport driver that manages such a NIC typically supports multipacket sends and receives because the NIC can efficiently handle several packets and thereby improve its I/O throughput.

- Nonbusmaster DMA NICs

  Currently, nonbusmaster DMA NICs include the following:

  - System DMA NICs

    A miniport driver that manages such a NIC uses the system DMA controller to manage the transfer of packet data to and from the network. Transfer of the data requires the cooperation of the host CPU.

Virtual NICs and miniports

In a virtual machine, NDIS miniport drivers can manage either software-only resources as a virtual miniport, or they can manage a virtual NIC that represents hardware resources. The following table explains the differences between a virtual miniport and a virtual NIC.

Attribute	Virtual miniport	Virtual NIC
Definition	An NDIS miniport driver that maps to a software-enumerated PnP device.	A NIC managed by the host OS hypervisor. The hypervisor makes the virtual machine think that it has some hardware, but no such hardware actually exists in the physical world.
Has interrupts	No	Yes
Can use DMA	No	Yes

Attribute	Virtual miniport	Virtual NIC
Is created or destroyed by...	The guest OS	The host OS
Can reach outside of a guest VM	No	Yes

MiniportXxx Functions

Article • 12/15/2021

The typical miniport driver uses a small number of functions to communicate through NDIS with the upper layers and hardware. Not all of these functions are required. For more information about which functions are optional, which are required, and why, see Initializing a Miniport Driver.

NDIS miniport drivers and upper-layer drivers use the NDIS Library (Ndis.sys) to communicate with each other through calls to **Ndis*Xxx*** functions.

Many miniport driver functions can operate either synchronously or asynchronously. The asynchronous functions have **Ndis*Xxx*Complete** functions that must be called when an operation is finished. For example, if a protocol driver calls **NdisOidRequest** to query miniport driver information, the miniport driver's *MiniportOidRequest* function can pend the reset operation by returning NDIS_STATUS_PENDING. Eventually, the miniport driver must call **NdisMOidRequestComplete** to indicate the final status of the query request.

Linking to the NDIS Library

Article • 03/14/2023

The NDIS Library is packaged in Ndis.sys, a kernel-mode export library, as a set of functions, with emphasis on macros for maximum performance. (An export library is a .sys file that functions similarly to a dynamic-link library.) All NDIS drivers link themselves to the NDIS Library. The NDIS Library functions are described in the Network Reference sections of the Microsoft Windows Driver Kit (WDK) documentation.

The WDK provides Ndis.h as the main header file for miniport drivers. This file defines the entry points for the miniport driver, the NDIS Library functions, and common data structures. The Network Reference section describes the miniport driver, protocol driver, and **Ndis*Xxx*** functions and the common data structures and OIDs.

Miniport Adapter Context

Article • 12/15/2021

NDIS uses a software object called a *miniport adapter* to represent each virtual or physical network device in the system. This object is maintained by NDIS and is opaque to the miniport driver and to protocol drivers. NDIS passes a handle to this structure to the miniport driver's *MiniportInitializeEx* function. The miniport driver subsequently supplies this handle in all calls to **Ndis*Xxx*** functions that pertain to the miniport adapter that the handle specifies.

When a miniport driver is called to initialize a miniport adapter that it manages, it creates its own internal data structure to represent the miniport adapter. The driver uses this structure, referred to as the *miniport adapter context*, to maintain device-specific state information that the driver needs to manage the miniport adapter. The driver passes a handle to this structure to NDIS. For more information about specifying the miniport adapter context, see Initializing an Adapter.

When NDIS calls one of the miniport driver's *MiniportXxx* functions that pertains to a miniport adapter, NDIS passes the miniport adapter context to identify the correct miniport adapter to the driver. The miniport adapter context is owned and maintained by the miniport driver and is opaque to NDIS and to protocol drivers.

Virtual Connection Context

Article • 12/15/2021

Before making a call, a connection-oriented client requests a connection-oriented miniport driver to set up a virtual connection (VC) over which packets can be transmitted or received. Similarly, before indicating an incoming call to a connection-oriented client, a call manager or integrated miniport call manager (MCM) driver requests the miniport driver to set up a VC for the incoming call.

A VC is a logical connection between two connection-oriented entities. Connection-oriented transmissions and receptions always occur on a specific VC.

A connection-oriented miniport driver maintains state information in a miniport driver-allocated context area about each VC that it sets up. This per-VC context is maintained by the miniport driver and is opaque to NDIS and to protocol drivers. In its **MiniportCoCreateVc** function, a connection-oriented miniport driver passes a handle to the VC context area to NDIS, and NDIS passes an *NdisVcHandle* that uniquely identifies the created VC back to the miniport driver, to the appropriate connection-oriented client, and to the call manager or integrated miniport call manager (MCM) driver.

Before data can be sent or received on a VC, the VC must be activated. The call manager initiates activation of the VC by calling **Ndis(M)CmActivateVc** and passing call parameters that include the characteristics of the VC to be activated. In response to this call, NDIS calls the miniport driver's **MiniportCoActivateVc** function, which activates the VC.

After a call is complete or a VC is otherwise not needed, the call manager can deactivate the VC by calling **Ndis(M)CmDeactivateVc**, which causes NDIS to call the miniport driver's **MiniportCoDeactivateVc** function. Either the connection-oriented client or the call manager can initiate the deletion of the VC by calling **NdisCoDeleteVc**, which causes NDIS to call the miniport driver's **MiniportCoDeleteVc** function.

For more information about miniport driver operations on VCs, see Operations on VCs.

Debugger 2PF KDNET Support

Article • 08/23/2023

This topic describes how to enable your miniport NDIS driver for 2PF debugger support to allow increased performance for high speed adapters, often used in data centers. This feature is available in Windows 11 and later.

When enabling kernel debugging on a NIC, the kernel debugging support takes over the physical device to provide both a kernel debugging and network connection on the box. This works fine on consumer low bandwidth NICs (1-10 Gbps), but on high throughput devices that support 10-40+ Gbps the kernel debugging extensibility modules that talk to the hardware generally cannot keep up with the amount of traffic that comes from Windows networking stack, so this degrades overall system performance.

Using the PCI multiple Physical Function (PF) feature for KDNET allows for debugging to be enabled with almost no performance impact.

The Physical Function (PF) is a PCI Express (PCIe) function of a network adapter that supports the single root I/O virtualization (SR-IOV) interface. The PF includes the SR-IOV Extended Capability in the PCIe Configuration space. The capability is used to configure and manage the SR-IOV functionality of the network adapter, such as enabling virtualization and exposing PCIe Virtual Functions (VFs).

The PF supports the SR-IOV Extended Capability structure in its PCIe configuration space. This structure is defined in the PCI-SIG Single Root I/O Virtualization and Sharing 1.1 specification .

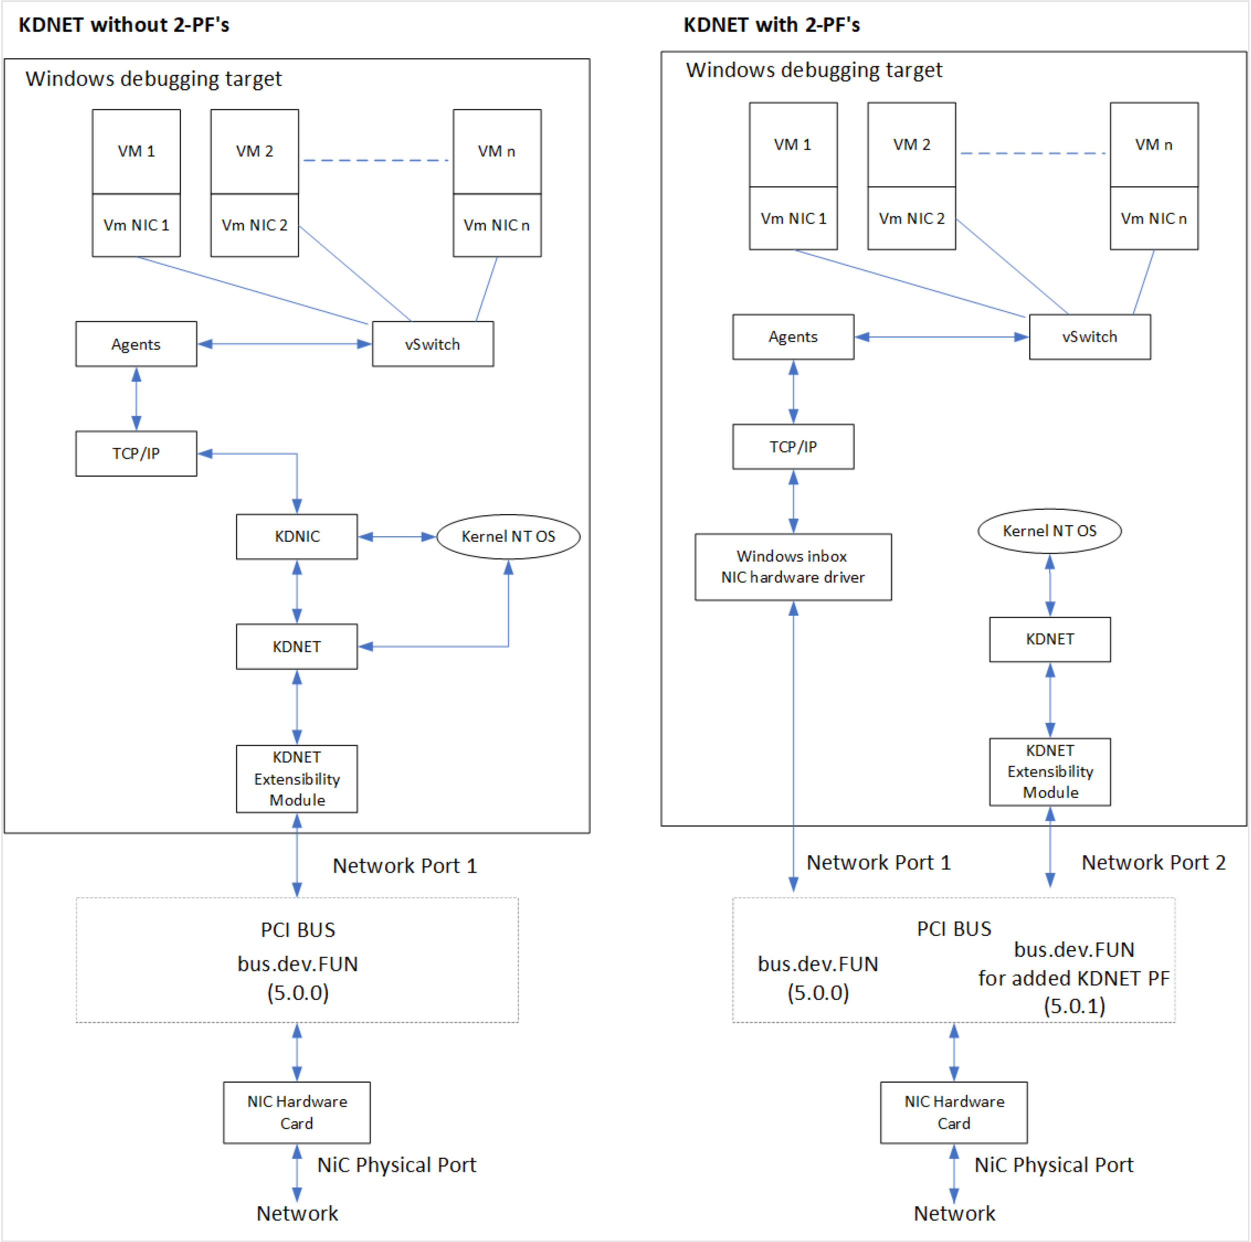
The debugger transport will take advantage of multiple or 2PF enabled miniport drivers. To allow debugging of systems of high speed servers, it is recommended that NIC vendors enable 2PF in all NICs that support multiple PF in the the network card firmware.

For information on configuring 2PF support to test a connection, see Setting Up 2PF Kernel-Mode Debugging using KDNET.

Multiple PF KDNET architecture overview

- The Multiple PF (2PF) functionality is to add/assign a new PF to the original PCI network port (e.g. Bus.dev.fun0.0).

- The new added PF (e.g. bus.dev.fun0.1) is used only by KDNET to route Debugger packets to/from the target.
- The original PF will be used by the Windows inbox NIC driver to route the Windows networking packets (TCP/IP) .
- Using this approach both drivers can work in parallel w/o interfering with each other work.
- Both drivers will run over the partitioned PCI configuration space
    - Windows Inbox driver will run out of the original network port at bus.dev.**fun0.0**
    - KDNET-KDNET-Ext. module will run out of the added PF at bus.dev.**fun0.1**, This way ensures that the Windows inbox NIC driver does not get impacted by sharing the NIC with KDNET.
- The kdnet.exe user mode tool configures the 2PF feature using the Windows inbox driver by adding specific IOCTL codes to add/remove KDNET PF.



Multiple PFs feature design requirements

1. The KDNET 2PF feature needs to work for all current KD scenarios whether it is the pre-NT OS (e.g. Boot Manager, OS loader, WinResume, Hyper-V, SK, etc.), NT OS, or Windows Desktop.

2. Rebooting the system will be required when adding a new PF for a device results in a change needed to the BCD configuration for debugging settings. This means that the configuration for an additional PF must be persistent across boots.

3. The KDNET 2PF should be used only by the debugger to ensure that there is not any other Windows/UEFI ethernet driver accessing/running from the PCI 2PF location when the debugger owns the debug device (the 2PF location is configured using dbgsettings::busparams).

4. Windows or UEFI Ethernet drivers cannot run out of the added KDNET 2PF even when KDNET is not enabled in the system.

5. The 2PF feature should support a dynamic mechanism for adding/enabling and removing/disabling the functionality on the current NIC.

6. The Windows miniport drivers will implement the 2PF feature via servicing the following NDIS OIDs.

OID Name	Description
OID_KDNET_ENUMERATE_PFS	Enumerates PFs on the current bus.dev.fun (BDF), where the miniport driver is running.
OID_KDNET_ADD_PF	Adds a PF to the current BDF, where the miniport driver is running.
OID_KDNET_REMOVE_PF	Removes the added PF, from the passed in BDF.
OID_KDNET_QUERY_PF_INFORMATION	Queries PF information data from the passed in BDF.

The OIDs and their structures are defined in ntddndis.h and kdnetpf.h files that are released with the public WDK.

See the details below on Input/Output parameters for each OID and the information provided in the kdnetpf.h header file.

7. KDNET should be configured via the KDNET 2PF feature on NICS where multiple PF feature is available, and the NIC enables 2PF functionality by following all of the requirements described above.

KDNET Multiple PF Interface for Windows NIC Drivers

To support the KDNET Multiple PF Interface Miniport drivers will need to implement the handling of the following four NDIS OIDs.

- OID_KDNET_ENUMERATE_PFS
- OID_KDNET_ADD_PF
- OID_KDNET_REMOVE_PF
- OID_KDNET_QUERY_PF_INFORMATION

These OIDs and structures are populated in the ntddndis.h and kdnetpf.h files in the public WDK release on this path:

`<WDK root directory>\ddk\inc\ndis`

These files also are available in the Windows SDK, and can be found in this directory.

`\Program Files (x86)\Windows Kits\10\Include\<Version for example 10.0.21301.0>\shared`

The client tool (kdnet.exe) uses a private NDIS IOCTL to route the KDNET 2PF NDIS OIDs to the miniport drivers.

The Multiple PF feature NDIS OIDs

The Multiple PF feature is operated by using these four NDIS OIDs.

1. Enumerate PFs on the miniport BDF primary port using OID: *OID_KDNET_ENUMERATE_PFS*, see definition below.

- *OID_KDNET_ENUMERATE_PFS* returns a list of all BDFs associated to the given primary port from where the miniport driver is running from. The port is represented by the bus.dev.fun (BDF). The operation will list/enumerate the list of PFs that are **associated only** to the bus.dev.fun (BDF port) from where the miniport driver is running on the system, since every miniport driver can determine its BDF location.

- The list of PFs will be returned to the client via a NDIS Query operation.

- The ***OID_KDNET_ENUMERATE_PFS*** OID is associated with the NDIS_KDNET_ENUMERATE_PFS structure.

- The ***OID_KDNET_ENUMERATE_PFS*** driver handler will return a buffer containing the PFs list with each PF element described by the type NDIS_KDNET_PF_ENUM_ELEMENT.

  The PfNumber field contains the PF Function Number, (e.g. bus.dev.**fun**)

  The PfState field contains the PF state possible values- each element type described by NDIS_KDNET_PF_STATE enum.

  NDIS_KDNET_PF_STATE::NdisKdNetPfStatePrimary - This is a primary PF and it's usually used only by the miniport driver.

NDIS_KDNET_PF_STATE::NdisKdnetPfStateEnabled - This is an added secondary PF, that is used by KDNET.

NDIS_KDNET_PF_STATE::NdisKdnetPfStateConfigured - This is an added PF, but it is only added/configured and is not used.

- If the PF list output buffer size is not large enough to allocate the actual PFs list, then the OID handler needs to return `E_NOT_SUFFICIENT_BUFFER` error return value, together with the required buffer size, so the client tool can allocate the required size buffer, and then the client can make another call with the correct buffer size allocated. In addition, the that the OID request status field (described by NDIS_IOCTL_OID_REQUEST_INFO.status) should be set to equal to `NDIS_STATUS_BUFFER_TOO_SHORT`.

2. Add PCI PF to the miniport BDF primary port (OID: *OID_KDNET_ADD_PF,* see definition below)

- Add a PF to the miniport primary port. The port is represented by the BDF.
- The newly added PF will be returned to the client via a NDIS Query operation.
- The *OID_KDNET_ADD_PF* OID is associated with the NDIS_KDNET_ADD_PF structure.
- The *OID_KDNET_ADD_PF* driver handler will return an ULONG containing the *added* PF function number.
- This OID request will have only one Output parameter: `AddedFunctionNumber`. The `AddedFunctionNumber` indicates the added Function number value at the miniport PCI location (the BDF miniport). The kdnet.exe utility will receive this value and setup dbgsettings::busparams to points to the added PF.

> ⓘ Note
>
> The added PF can be used exclusively by KDNET, so Windows NIC drivers are rigged to expressly *NOT* run on an added PF, so this also applies when KDNET is *NOT* enabled on the system and the PF has been added to the port.

3. Remove PCI PF (OID: *OID_KDNET_REMOVE_PF*, see definition below)

- Remove a PF from the given port. The port is represented by the BDF.

- The ***OID_KDNET_REMOVE_PF*** OID is associated with the NDIS_KDNET_REMOVE_PF structure.
- The ***OID_KDNET_REMOVE_PF*** OID has an input BDF port and returns an ULONG containing the *removed* PF function number via a NDIS Method operation.
- This function will succeed only on the PFs that has been added via using the ***OID_KDNET_ADD_PF*** OID.
- This OID request will have the input BDF port from where needs to be removed the BDF. This function has an Output parameter of `FunctionNumber`. The output `FunctionNumber` will contain the removed Function number value.

4. Query PCI PF information (OID: *OID_KDNET_QUERY_PF_INFORMATION*, see definition below)

- This OID code allows querying specific PF data on a given port. The port is represented by the BDF.
- The requested PF information will be returned to the client via a NDIS Method operation.
- The ***OID_KDNET_QUERY_PF_INFORMATION*** OID is associated with the NDIS_KDNET_QUERY_PF_INFORMATION structure.
- The ***OID_KDNET_QUERY_PF_INFORMATION*** OID has an input BDF port and returns a buffer containing the following data:
    - MAC Address: Network address of the assigned new KDNET PF if there is any.
    - Usage Tag: Describes the entity that owns the PF port. It contains a constant value described by NDIS_KDNET_PF_USAGE_TAG enum.
    - Maximum Number of PFs: Contains an ULONG with the maximum number of PFs that can be added to the given BDF.
    - Device ID: Contains the device ID associated to the given BDF port. This is required for cases where the NIC FW assigns a new device ID to the new added KDNET PF port.
- This OID requests the information for any passed in BDF port (BDF is an input parameter for this operation), so it’s *not* necessarily related to the current BDF from where the driver is running from.

NDIS OIDs for KDNET on 2PF

Ntddndis.h file defines the OIDs.

C++

```
#if (NDIS_SUPPORT_NDIS686)

 //

 // Optional OIDs to handle network multiple PF feature.

 //
#define OID_KDNET_ENUMERATE_PFS 0x00020222
#define OID_KDNET_ADD_PF 0x00020223
#define OID_KDNET_REMOVE_PF 0x00020224
#define OID_KDNET_QUERY_PF_INFORMATION 0x00020225
#endif // (NDIS_SUPPORT_NDIS686)
```

Kdnetpf.h file describes the type and structures associated with the NDIS OIDs.

C++

```
#if (NDIS_SUPPORT_NDIS686)

 //
 // Used to query/add/remove Physical function on a network port.
 // These structures are used by these OIDs:
 // OID_KDNET_ENUMERATE_PFS
 // OID_KDNET_ADD_PF
 // OID_KDNET_REMOVE_PF
 // OID_KDNET_QUERY_PF_INFORMATION
 // These OIDs handle PFs that are primary intended to be used by  KDNET.
 //
 //

Network OIDs

Article • 12/15/2021

A miniport driver maintains information about its capabilities and current status, as well as information about each miniport adapter that it manages. Each information type is identified by an object identifier (OID). OIDs are system-defined. NDIS handles many of the OID requests for miniport drivers and NDIS does not pass such requests on to the miniport driver. The miniport driver reports many of its capabilities, which were formerly reported in response to OID queries, in its attributes during initialization. For more information about reporting attributes, see Initializing an Adapter.

NDIS and higher level drivers can query and, in some cases, set information by using OIDs.

- Higher level drivers for connectionless media call **NdisOidRequest** to query or set information in a connectionless miniport driver. To perform a query or a set operation, NDIS calls the miniport driver's *MiniportOidRequest* function.

- Higher level drivers for connection-oriented media call **NdisCoOidRequest** to query or set information in a connection-oriented miniport driver. To perform both query and set operations, NDIS calls the miniport driver's **MiniportCoOidRequest** function.

NDIS maps many of the system-defined OIDs for miniport drivers to globally unique identifiers (GUIDs). NDIS registers these GUIDs with the kernel-mode Microsoft Windows Management Instrumentation (WMI) that supports user-mode Web-Based Enterprise Management (WBEM) applications. When a WMI client queries or sets one of these GUIDs, NDIS translates the request to a query OID operation or a set OID operation, as appropriate, and then passes any returned information and the status back to WMI. You can map custom GUIDs to custom OIDs or miniport driver status. A miniport driver must register custom GUID-to-OID or GUID-to-status mappings with NDIS during initialization.

For more information about querying and setting OIDs, creating custom OIDs, and NDIS support for WMI, see Obtaining and Setting Miniport Driver Information and NDIS Support for WMI.

Sample NDIS Miniport Drivers

Article • 03/14/2023

The Network driver samples in the Windows driver samples repository on GitHub includes sample code for miniport drivers that manage several types of network cards. You can modify these sample drivers to your needs. The sample drivers contain functions that can be adapted to a new but similar driver. There are always hardware-dependent functions that you must write. However, many functions are fairly standard. For example, functions that communicate with the NDIS Library instead of a network interface card are typically standard. For these driver functions, the code in a sample driver might be usable with little or no modification.

Initializing a Miniport Driver

Article • 12/15/2021

When a networking device becomes available, the system loads the NDIS miniport driver to manage the device (if the driver is not already loaded). Every miniport driver must provide a DriverEntry function. The system calls **DriverEntry** after it loads the driver. **DriverEntry** registers the miniport driver's characteristics with NDIS (including the supported NDIS version and the driver entry points).

The system passes two arguments to DriverEntry:

- A pointer to the driver object, which was created by the I/O system.
- A pointer to the registry path, which specifies where driver-specific parameters are stored.

In DriverEntry, miniport drivers pass both of these pointers in a call to the NdisMRegisterMiniportDriver function. Miniport drivers export a set of standard *MiniportXxx* functions by storing their entry points in an **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** structure and passing that structure to **NdisMRegisterMiniportDriver**.

DriverEntry for miniport drivers returns the value that is returned by the call to **NdisMRegisterMiniportDriver**.

A miniport driver also performs any other driver-specific initialization that it requires in DriverEntry. The driver performs adapter-specific initialization in the *MiniportInitializeEx* function. For more information about adapter initialization, see Initializing an Adapter.

DriverEntry can allocate the **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** structure on the stack because the NDIS library copies the relevant information to its own storage. **DriverEntry** should clear the memory for this structure with NdisZeroMemory before setting any driver-supplied values in its members. The **MajorNdisVersion** and **MinorNdisVersion** members must contain the major and minor versions of NDIS that the driver supports. In each Xxx**Handler** member of the characteristics structure, **DriverEntry** must set the entry point of a driver-supplied *MiniportXxx* function, or the member must be **NULL**.

To enable a miniport driver to configure optional services, NDIS calls the MiniportSetOptions function within the context of the miniport driver's call to NdisMRegisterMiniportDriver. For more information about optional services, see Configuring Optional Miniport Driver Services.

Drivers that call NdisMRegisterMiniportDriver must be prepared for NDIS to call their *MiniportInitializeEx* functions any time after **DriverEntry** returns. Such a driver must have sufficient installation and configuration information stored in the registry or available from calls to an **NdisXxx** bus-type-specific configuration function to set up any NIC-specific resources the driver will need to carry out network I/O operations.

The miniport driver must eventually call **NdisMDeregisterMiniportDriver** to release resources that it allocated by calling **NdisMRegisterMiniportDriver**. If the driver initialization fails after the call to **NdisMRegisterMiniportDriver** succeeded, the driver can call **NdisMDeregisterMiniportDriver** from within DriverEntry. Otherwise, the miniport driver must release the driver-specific resources that it allocates in its *MiniportDriverUnload* function. In other words, if NdisMRegisterMiniportDriver does not return NDIS_STATUS_SUCCESS, **DriverEntry** must release any resources that it allocated before it returns control. The driver will not be loaded if this occurs. For more information, see Unloading a Miniport Driver.

Unloading a Miniport Driver

Article • 12/15/2021

The driver object that is associated with an NDIS miniport driver specifies an **Unload** routine. The system calls the *Unload* routine when all the devices that the driver services have been removed. NDIS provides the *Unload* routine for miniport drivers. NDIS calls a miniport driver's *MiniportDriverUnload* function from the *Unload* routine.

A miniport driver must call **NdisMDeregisterMiniportDriver** from *MiniportDriverUnload*.

A miniport driver's *MiniportDriverUnload* function should also release any driver-specific resources. The system will complete a driver unload operation after *MiniportDriverUnload* returns.

The functionality of the *MiniportDriverUnload* function is driver-specific. As a general rule, *MiniportDriverUnload* should undo the operations that were performed during driver initialization. For more information about driver initialization, see Initializing a Miniport Driver.

Miniport Adapter States and Operations

Article • 12/15/2021

For each adapter that it manages, an NDIS 6.0 or later miniport driver must support the following set of operational states:

Halted
The Halted state is the initial state of all adapters. When an adapter is in the Halted state, NDIS can call the driver's *MiniportInitializeEx* function to initialize the adapter.

Shutdown
In the Shutdown state, a system shutdown and restart must occur before the system can use the adapter again.

Initializing
In the Initializing state, a miniport driver completes any operations that are required to initialize an adapter.

Paused
In the Paused state, the adapter does not indicate received network data or accept send requests.

Restarting
In the Restarting state, a miniport driver completes any operations that are required to restart send and receive operations for an adapter.

Running
In the Running state, a miniport driver performs send and receive processing for an adapter.

Pausing
In the Pausing state, a miniport driver completes any operations that are required to stop send and receive operations for an adapter.

In the following table, the headings are the adapter states. Major events are listed in the first column. The rest of the entries in the table specify the next state that the adapter enters after an event occurs within a state. The blank entries represent invalid event/state combinations.

Event \ State	**Halted**	**Shutdown**	**Initializing**	**Paused**	**Restarting**	**Running**	**Pausing**
MiniportInitializeEx	Initializing						
Initialize is complete			Paused				
MiniportShutdownEx				Shutdown	Shutdown	Shutdown	Shutdown
MiniportHaltEx				Halted			

Event \ State	Halted	Shutdown	Initializing	Paused	Restarting	Running	Pausing
MiniportRestart				Restarting			
Restart is complete					Running		
MiniportPause						Pausing	
Pause is complete							Paused
Initialize failed			Halted				
Restart failed					Paused		
Send and receive operations						Running	Pausing
OID requests				Paused	Restarting	Running	Pausing

Note The events listed in the preceding table are the primary events for an NDIS 6.0 or later adapter.

Note The reset operation does not affect miniport adapter operational states. The state of the adapter might change while a reset operation is in progress. For example, NDIS might call a driver's pause handler when there is a reset operation in progress. In this case, the driver can complete either the reset or the pause operation in any order while following the normal requirements for each operation. For a reset operation, the driver can fail transmit request packets or it can keep them queued and complete them later. However, you should note that an overlying driver cannot complete a pause operation while its transmit packets are pending.

The primary miniport driver events are defined as follows:

MiniportInitializeEx
NDIS called the driver's *MiniportInitializeEx* function to initialize an adapter. For more information about adapter initialization, see Initializing a Miniport Adapter.

Initialize is complete
After *MiniportInitializeEx* returns successfully, the initialize operation is complete and the adapter is in the Paused state.

MiniportShutdownEx
NDIS called the driver's *MiniportShutdownEx* function to shutdown an adapter. For more information, see Miniport Adapter Shutdown.

MiniportHaltEx
NDIS called the driver's *MiniportHaltEx* function to halt an adapter. For more information, see Halting a Miniport Adapter.

MiniportRestart
NDIS called the driver's **MiniportRestart** function to restart a paused adapter. Because an

adapter is in the Paused state after initialization, this event is also required to start the adapter after adapter initialization is complete. For more information, see Starting an Adapter.

Restart is complete
After the driver is ready to handle send and receive operations, the restart operation is complete and the adapter is in the Running state.

MiniportPause
NDIS called the driver's *MiniportPause* function to pause an adapter. For more information, see Pausing an Adapter.

Pause is complete
After the driver has completed all operations that are necessary to stop send and receive operations, the pause operation is complete and the adapter is in the Paused state.

Note The driver must wait for NDIS to return all its outstanding receive indications before the pause operation is complete.

Initialize failed
If NDIS calls a driver's *MiniportInitializeEx* function and the initialization attempt fails, the adapter returns to the Halted state.

Restart failed
If NDIS calls a driver's **MiniportRestart** function and the restart attempt fails, the adapter remains in the Paused state.

Send and Receive Operations
A driver must handle send and receive operations in the Running and Pausing states. For more information about send and receive operations, see Miniport Driver Send and Receive Operations.

OID Requests
A driver must handle OID Requests in the Running, Restarting, Paused, and Pausing states. For more information about OID requests, see OID Requests for an Adapter.

Initializing a Miniport Adapter

Article • 08/29/2023

When a networking device becomes available, the system loads the required NDIS miniport driver, if it is not already loaded. Subsequently, the Plug and Play (PnP) manager sends NDIS a Plug and Play IRP to start the device. NDIS calls the miniport driver's *MiniportInitializeEx* function to initialize an adapter for network I/O operations. NDIS can call *MiniportInitializeEx* at any time after the driver is initialized. For more information about miniport driver initialization, see Initializing a Miniport Driver.

Until *MiniportInitializeEx* returns, NDIS submits no requests for the adapter being initialized. The adapter is in the Initializing state.

A miniport driver typically performs the following tasks in *MiniportInitializeEx*:

1. Obtains configuration information for the adapter.

2. Obtains information about the hardware resources for the adapter.

3. Calls the **NdisMSetMiniportAttributes** and provides the following attributes that are associated with the adapter:

    - A pointer to a driver-allocated context area.
    - Appropriate attributes flags.
    - The time-out interval for calling its *MiniportCheckForHangEx* function.
    - The interface type.

4. Initializes adapter-specific resources.

The miniport driver specifies the adapter attributes in the **NDIS_MINIPORT_ADAPTER_ATTRIBUTES** structure that *MiniportInitializeEx* passes to **NdisMSetMiniportAttributes**.

Typically, *MiniportInitializeEx* allocates adapter-specific resources in the following order:

1. Nonpaged pool memory.

2. **NET_BUFFER** and **NET_BUFFER_LIST** pools (see Miniport Driver Send and Receive Operations).

3. Spin locks.

4. Timers.

5. IO ports.

6. DMA (see Scatter/Gather DMA).

7. Shared memory.

8. Interrupts (see Managing Interrupts).

After *MiniportInitializeEx* returns successfully, the adapter is in the Paused state. NDIS can call the **MiniportRestart** function to transition the adapter to the Running state. For more information, see Starting a Miniport Adapter.

If *MiniportInitializeEx* returns NDIS_STATUS_SUCCESS, the driver should release all the resources for the adapter in the *MiniportHaltEx* function. For more information, see Halting a Miniport Adapter.

The driver must call **NdisMSetMiniportAttributes** and set the **GeneralAttributes** in the **NDIS_MINIPORT_ADAPTER_ATTRIBUTES** structure if it returns NDIS_STATUS_SUCCESS.

If *MiniportInitializeEx* failed, *MiniportInitializeEx* must release all resources that it allocated before it returns and the adapter returns to the Halted state.

NDIS calls an NDIS miniport driver's *MiniportHaltEx* function to deallocate resources when an adapter is removed from the system, and to stop the hardware. NDIS can call *MiniportHaltEx* after the driver's *MiniportInitializeEx* function returns successfully. For more information about *MiniportInitializeEx*, see Initializing a Miniport Adapter.

MiniportHaltEx must free any resources that the driver allocated for a device. The driver must call the reciprocals of the **Ndis*Xxx*** functions with which it originally allocated the resources. As a general rule, a *MiniportHaltEx* function should call the reciprocal **Ndis*Xxx*** functions in the reverse order used during initialization.

If an adapter generates interrupts, a miniport driver's *MiniportHaltEx* function can be preempted by the driver's *MiniportInterrupt* function until *MiniportHaltEx* disables interrupts.

NDIS does not call *MiniportHaltEx* if there are outstanding OID requests or send requests. NDIS submits no further requests for the affected device after NDIS calls *MiniportHaltEx*.

After *MiniportHaltEx* returns, the miniport driver is in the Halted state.

Writing NDIS Miniport Drivers

Starting and Pausing a Miniport Adapter Overview

Article • 12/15/2021

NDIS pauses an adapter to stop data flow that could interfere with Plug and Play operations, such as adding or removing a filter driver, or requests, such as setting a packet filter or multicast address list on the NIC. For more information about how to modify a running driver stack, see Modifying a Running Driver Stack.

NDIS restarts an adapter from the Paused state. The adapter enters the Paused start after adapter initialization is complete or after a pause operation is complete.

The following topics provide more information about starting and pausing and adapter:

- Starting an Adapter
- Pausing an Adapter

Starting an Adapter

Article • 12/15/2021

NDIS calls a miniport driver's MiniportRestart function to initiate a restart request for an adapter that is in the Paused state. The driver can resume indicating received data immediately after NDIS calls *MiniportRestart* and before the miniport driver completes the restart operation, either synchronously or asynchronously.

When it calls a miniport driver's MiniportRestart function, NDIS passes a pointer to an NDIS_RESTART_ATTRIBUTES structure to the miniport driver in the **RestartAttributes** member of the NDIS_MINIPORT_RESTART_PARAMETERS structure.

To complete the restart operation asynchronously, *MiniportRestart* returns NDIS_STATUS_PENDING and the driver must call the NdisMRestartComplete function after the operation is complete.

The miniport driver should be ready to accept send requests after it completes the restart operation. NDIS does not initiate any other Plug and Play operations, such as halt, initialize, or a pause request, until the restart operation is complete.

After the driver is ready to handle send and receive operations, the adapter is in the Running state.

Pausing an Adapter

Article • 12/15/2021

NDIS calls a miniport driver's *MiniportPause* function to initiate a pause operation. The adapter remains in the Pausing state until the pause operation is complete.

In the Pausing state, the miniport driver must complete outstanding receive operations. The driver must also complete any outstanding send operations and it should reject any new send requests.

To complete receive operations, the driver waits for all calls to the **NdisMIndicateReceiveNetBufferLists** function to return and NDIS must return all outstanding **NET_BUFFER_LIST** structures to the miniport driver's *MiniportReturnNetBufferLists* function.

To complete outstanding send operations, the miniport driver should call the **NdisMSendNetBufferListsComplete** function for all of the outstanding NET_BUFFER_LIST structures. The driver should reject any new send requests made to its *MiniportSendNetBufferLists* function immediately.

After a miniport driver completes all outstanding send and receive operations, the driver must complete the pause request either synchronously or asynchronously. If the pause operation is completed asynchronously, the driver calls **NdisMPauseComplete** to complete the pause request. After completing the pause request, the miniport driver is in the Paused state.

NDIS does not initiate other Plug and Play operations, such as halt, initialize, power change, or restart operations, while the miniport driver is in the Pausing state. NDIS can initiate these Plug and Play operations after a miniport driver is in the Paused state.

Configuring Optional Miniport Driver Services

Article • 12/15/2021

NDIS calls a miniport driver's *MiniportSetOptions* function to allow the driver to configure optional services. NDIS calls *MiniportSetOptions* within the context of the miniport driver's call to the **NdisMRegisterMiniportDriver** function.

MiniportSetOptions registers the default entry points for optional *MiniportXxx* functions and can allocate other driver resources. To register optional *MiniportXxx* functions, the miniport driver calls the **NdisSetOptionalHandlers** function and passes a characteristics structure at the *OptionalHandlers* parameter.

Starting with NDIS 6.0, the valid characteristics structures include the following:

NDIS_MINIPORT_CO_CHARACTERISTICS

NDIS_MINIPORT_PNP_CHARACTERISTICS

NDIS_CO_CALL_MANAGER_OPTIONAL_HANDLERS

NDIS_PROVIDER_CHIMNEY_OFFLOAD_GENERIC_CHARACTERISTICS (see NDIS 6.0 TCP chimney offload documentation)

NDIS_PROVIDER_CHIMNEY_OFFLOAD_TCP_CHARACTERISTICS (see NDIS 6.0 TCP chimney offload documentation)

Starting with NDIS 6.30, the valid characteristics structures also include the following:

NDIS_MINIPORT_SS_CHARACTERISTICS

NDIS_NDK_PROVIDER_CHARACTERISTICS

Miniport Driver Send and Receive Operations

Article • 12/15/2021

Miniport drivers handle send requests from overlying drivers and originate receive indications. In a single function call, NDIS miniport drivers can indicate a linked list with multiple received **NET_BUFFER_LIST** structures. Miniport drivers can handle send requests for lists of multiple NET_BUFFER_LIST structures with multiple **NET_BUFFER** structures on each NET_BUFFER_LIST structure.

Miniport drivers must manage receive buffer pools. Most miniport drivers create pools that preallocate a single NET_BUFFER structure with each NET_BUFFER_LIST structure.

The following topics provide more information about miniport driver buffer management, send operations, and receive operations:

Miniport Driver Buffer Management

Sending Data from a Miniport Driver

Canceling a Send Request in a Miniport Driver

Indicating Received Data from a Miniport Driver

Miniport Driver Buffer Management

Article • 12/15/2021

Miniport drivers typically call NdisAllocateNetBufferListPool from *MiniportInitializeEx* to create a pool of NET_BUFFER_LIST structures. Miniport drivers use these structures to indicate received data.

Typically, a miniport driver that allocates a NET_BUFFER_LIST structure will allocate and queue one NET_BUFFER structure on that NET_BUFFER_LIST structure. It is more efficient to preallocate NET_BUFFER structures when you allocate a pool of NET_BUFFER_LIST structures than to allocate NET_BUFFER_LIST structures and NET_BUFFER structures separately.

Miniport drivers can call **NdisAllocateNetBufferListPool** and set the *AllocateNetBuffer* parameter to **TRUE** to indicate that NET_BUFFER structures are preallocated. In this case, a NET_BUFFER structure is preallocated with each NET_BUFFER_LIST structure that the driver allocates from the pool. Such drivers must call NdisAllocateNetBufferAndNetBufferList to allocate structures from this pool.

Typically, a miniport driver calls **NdisAllocateNetBufferAndNetBufferList** from *MiniportInitializeEx* to allocate as many buffers as it will require for subsequent receive operations. In this case, the driver manages an internal list of free buffers.

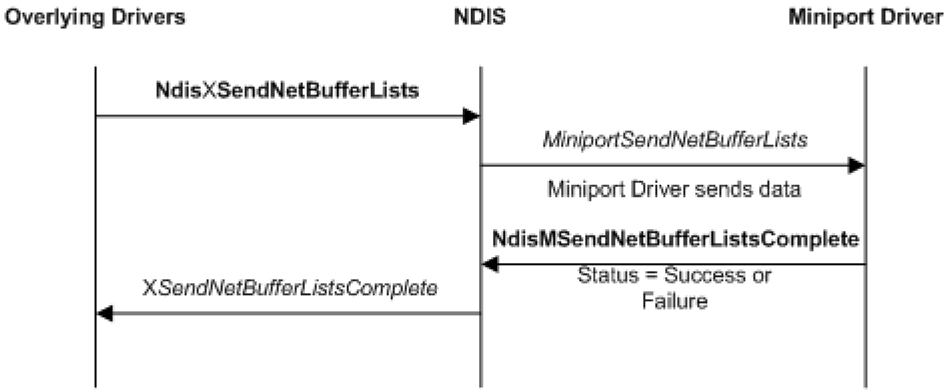
The *MiniportReturnNetBufferLists* function can prepare a returned NET_BUFFER_LIST structure for reuse in a subsequent receive indication. Although *MiniportReturnNetBufferLists* could return the NET_BUFFER_LIST structures to a pool (for example, it could call NdisFreeNetBufferList), it can be more efficient to reuse the structures without returning them to the pool.

A miniport driver should free all the NET_BUFFER_LIST structures and associated data when NDIS halts the adapter. A driver can call **NdisFreeNetBufferList** to free the structures and the NdisFreeNetBufferListPool function to free the NET_BUFFER_LIST pool.

Sending Data from a Miniport Driver

Article • 12/15/2021

The following figure illustrates a miniport driver send operation.



Overlying Drivers
NDIS
Miniport Driver
NdisXSendNetBufferLists
MiniportSendNetBufferLists
Miniport Driver sends data
NdisMSendNetBufferListsComplete
Status = Success or Failure
XSendNetBufferListsComplete

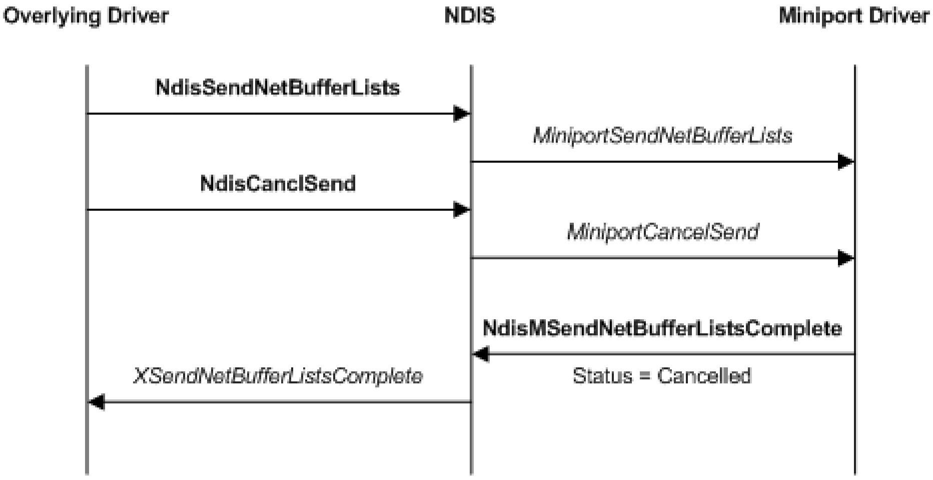
NDIS calls a miniport driver's *MiniportSendNetBufferLists* function to transmit the network data that is described by a linked list of **NET_BUFFER_LIST** structures.

Miniport drivers call the **NdisMSendNetBufferListsComplete** function to return a linked list of NET_BUFFER_LIST structures to an overlying driver and to return the final status of a send request.

Canceling a Send Request in a Miniport Driver

Article • 12/15/2021

The following figure illustrates a miniport driver cancel send operation.



Protocol, filter, and intermediate drivers can call **NdisCancelSendNetBufferLists** to cancel outstanding send requests. These overlying drivers must mark the send data with a cancellation ID before making a send request.

NDIS calls a miniport driver's *MiniportCancelSend* function to cancel the transmission of all **NET_BUFFER_LIST** structures that are marked with a specified cancellation identifier.

A miniport driver's *MiniportCancelSend* function performs the following operations:

1. Traverses its list of outstanding send requests for the specified adapter and calls **NDIS_GET_NET_BUFFER_LIST_CANCEL_ID** to obtain the cancellation identifier for each NET_BUFFER_LIST structure. The miniport driver compares the cancellation ID that NDIS_GET_NET_BUFFER_LIST_CANCEL_ID returns with the cancellation ID that NDIS passed to *MiniportCancelSend*.

2. Removes from all NET_BUFFER_LIST structures whose cancellation identifiers match the specified cancellation identifier from its list of outstanding send requests.

3. Calls the **NdisMSendNetBufferListsComplete** function for all canceled NET_BUFFER_LIST structures to return the structures.The miniport driver sets the status field of the NET_BUFFER_LIST structures to NDIS_STATUS_SEND_ABORTED.

NDIS Poll Mode

Article • 01/17/2024

Overview of NDIS Poll Mode

NDIS Poll Mode is an OS controlled polling execution model that drives the network interface datapath.

Previously, NDIS had no formal definition of a datapath execution context. NDIS drivers typically relied on Deferred Procedure Calls (DPCs) to implement their execution model. However using DPCs can overwhelm the system when long indication chains are made and avoiding this problem requires a lot of code that's tricky to get right. NDIS Poll Mode offers an alternative to DPCs and similar execution tools.

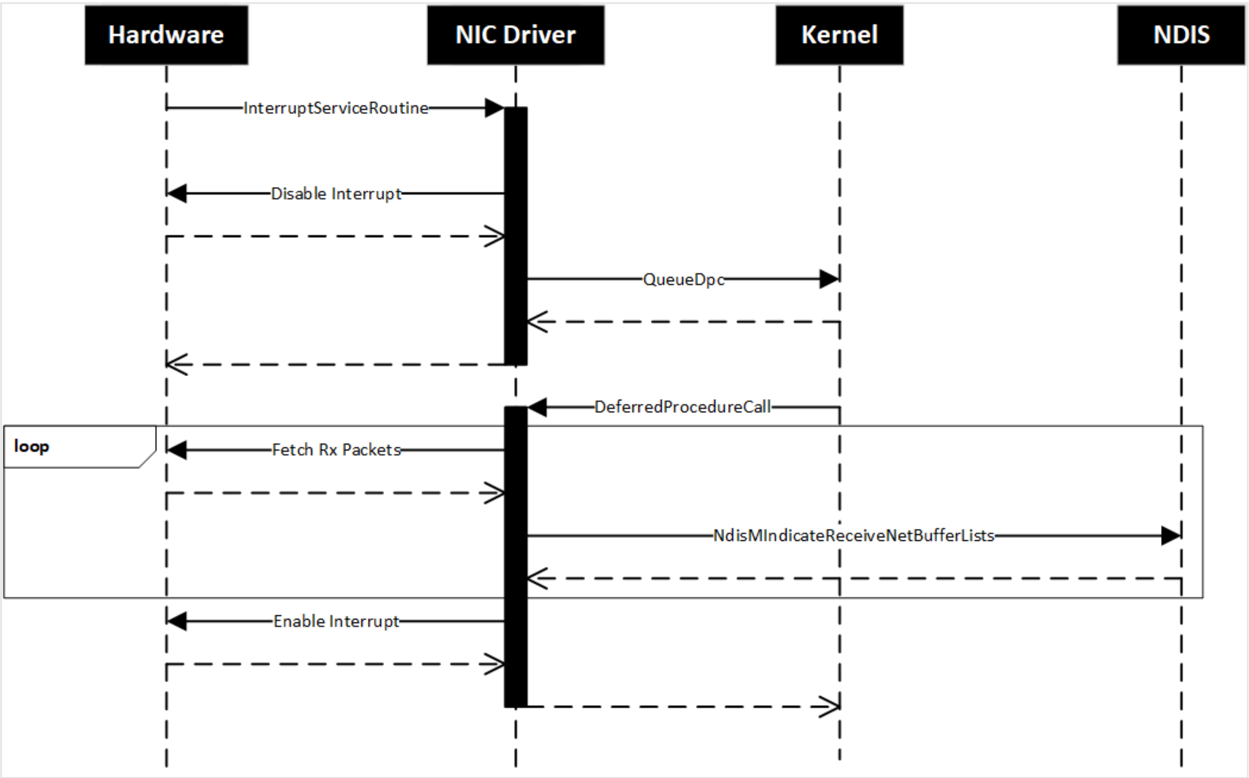
NDIS Poll Mode moves the complexity of scheduling decisions away from NIC drivers and into NDIS, where NDIS sets work limits per iteration. To achieve this Poll Mode provides:

1. A mechanism for the OS to exert back pressure on the NIC.
2. A mechanism for the OS to finely control interrupts.

NDIS Poll Mode is available to NDIS 6.85 and later miniport drivers.

Problems with the DPC model

The following sequence diagram illustrates a typical example of how an NDIS miniport driver handles a burst of Rx packets using a DPC. In this example the hardware is standard in terms of PCIe NICs. It has a receive hardware queue and an interrupt mask for that queue.



When there's no network activity the hardware has the Rx interrupt enabled. When an Rx packet arrives:

1. The hardware generates an interrupt and NDIS calls the driver's *MiniportInterrupt* function (ISR).

2. The driver does very little work in the ISR because they run at a very high IRQL. The driver disables the interrupt from the ISR and defers the hardware processing to a *MiniportInterruptDPC* function (DPC).

3. NDIS eventually calls the driver's DPC and the driver drains any completions from the hardware queue and indicates them to the OS.

Two pain points can affect the network stack when the driver defers I/O operations to a DPC:

1. The driver doesn't know if the system is capable of processing all of the data that is being indicated, so the driver has no choice but to drain as many elements as possible from its hardware queue and indicate them up the stack.

2. Since the driver is using a DPC to defer work from its ISR, all the indications are made at DISPATCH_LEVEL. This can overwhelm the system when long indication chains are made and cause Bug Check 0x133 DPC_WATCHDOG_VIOLATION.

Avoiding these pain points requires a lot of tricky code in your driver. While you can check if the DPC watchdog is close to the limit with the **KeQueryDpcWatchdogInformation** function and break out of the DPC, you still need to build an infrastructure around this in your driver: You need some way to pause for a bit, then continue to indicate the packets, and at the same time you need to synchronize all this with the lifetime of the datapath.

Introduction to Poll objects

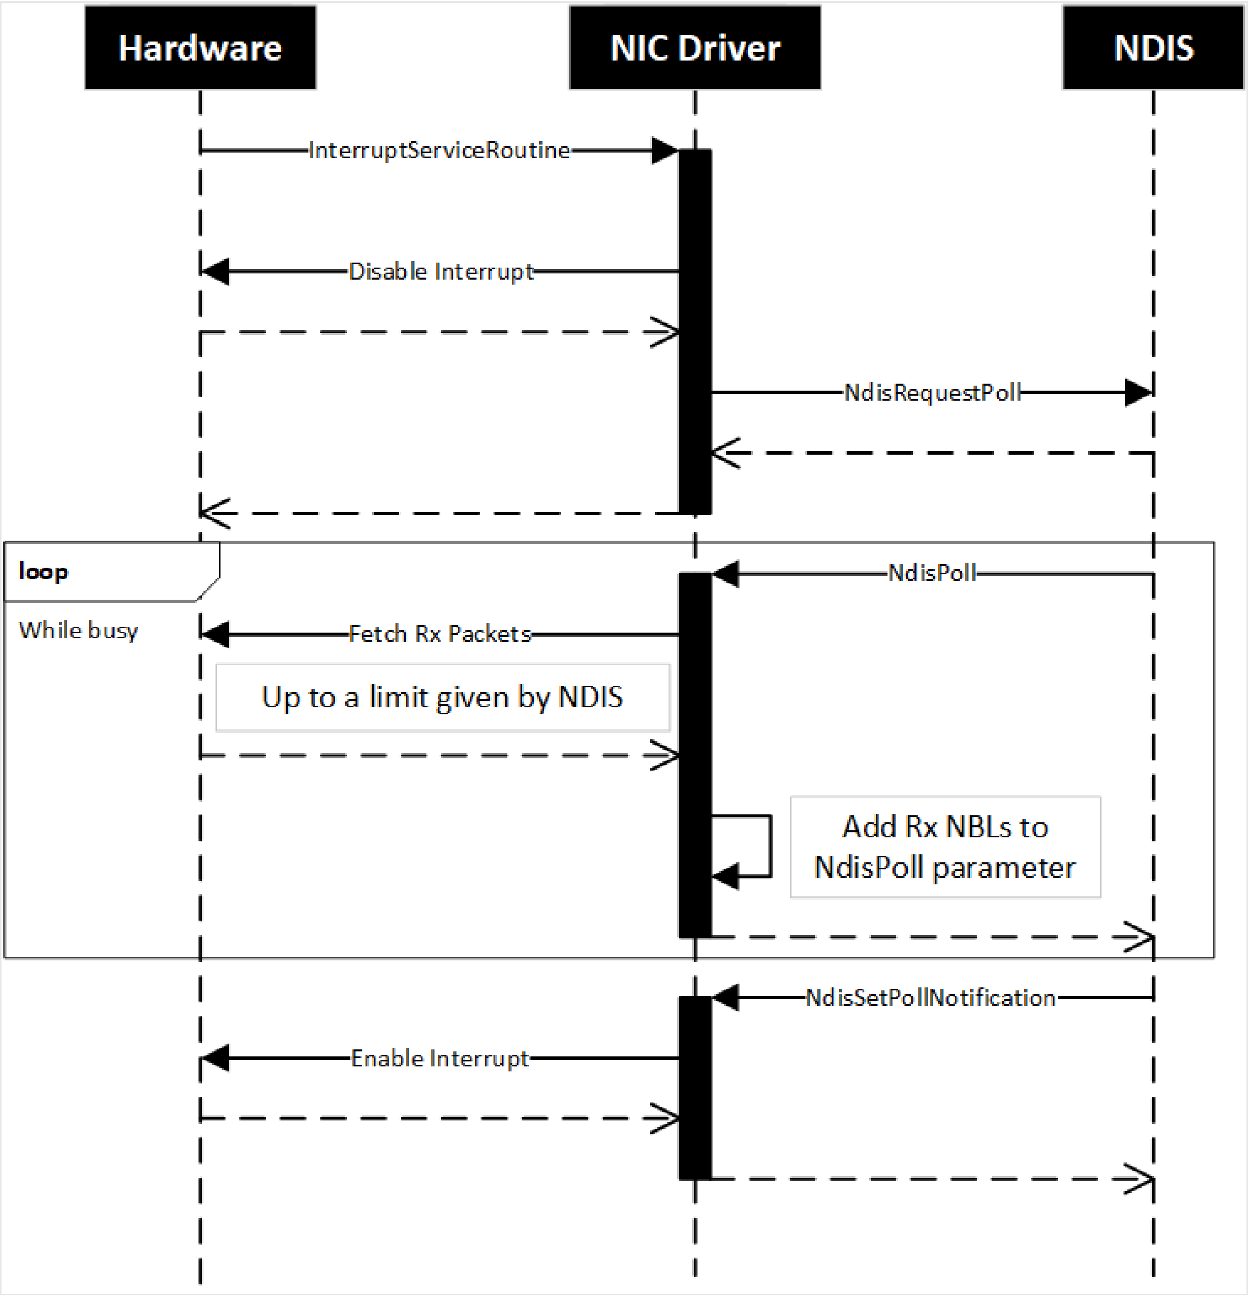
NDIS Poll Mode introduces the Poll object to resolve the pain points associated with DPCs. A Poll object is an execution context construct. Miniport drivers can use a Poll object in place of a DPC when dealing with datapath operations.

A Poll object offers the following:

- It provides a way for NDIS to set work limits per iteration.
- It is closely tied to a notification mechanism. This keeps the OS and the NIC in sync regarding when work needs to be processed.
- It has a concept of iteration and interrupts built in. When using DPCs, drivers are forced to re-enable the interrupt every time they finish a DPC. When using Poll objects, drivers don't need to re-enable the interrupt each polling iteration because Poll Mode will let your driver know when it's done polling and it's time to re-enable the interrupt again.
- When making scheduling decisions, the system can be smart about whether to run at DISPATCH_LEVEL or PASSIVE_LEVEL. This can allow fine-tuned prioritization of traffic from different NICs and lead to a fairer workload distribution on the machine.
- It has serialization guarantees. Once you are running code from within a Poll object's execution context you are guaranteed that no other code related to the same execution context will run. This allows a NIC driver to have a lock free implementation of its datapath.

The NDIS Poll Mode model

The following sequence diagram illustrates how the same hypothetical PCIe NIC driver handles a burst of Rx packets using a Poll object instead of a DPC.



Like the DPC model, when an Rx packet arrives the hardware generates an interrupt, NDIS calls the driver's ISR, and the driver disables the interrupt from the ISR. At this point the Poll Mode model diverges:

1. Instead of queueing a DPC, the driver queues a Poll object (that it previously created) from the ISR to notify NDIS that new work is ready to be processed.

2. At some point in the future NDIS calls the driver's poll iteration handler to process the work. Unlike a DPC, the driver is not allowed to indicate as many Rx NBLs as there are elements ready in its hardware queue. The driver should instead check the handler's poll data parameter to get the maximum number of NBLs it can indicate.

   Once the driver fetches up to the maximum number of Rx packets it should initialize NBLs, add them to the NBL queue provided by the poll handler, and exit the callback. The driver shouldn't enable the interrupt before exiting.

3. NDIS continues to poll the driver until it assesses that the driver is no longer making forward progress. At this point NDIS will stop polling and ask the driver to re-enable the interrupt.

Standardized INF keyword for NDIS Poll Mode

The following keyword must be used to enable or disable support for NDIS Poll Mode:

***NdisPoll** Enumeration standardized INF keywords have the following attributes:

SubkeyName
The name of the keyword that you must specify in the INF file and that appears in the registry.

ParamDesc
The display text that is associated with SubkeyName.

Value
The enumeration integer value that is associated with each option in the list. This value is stored in NDI\params\ *SubkeyName**Value*.

EnumDesc
The display text that is associated with each value that appears in the menu.

Default
The default value for the menu.

⛶ Expand table

SubkeyName	ParamDesc	Value	EnumDesc
***NdisPoll**	Ndis Poll Mode	0	Disabled
		1 (Default)	Enabled

For more information about using enumeration keywords, see Enumeration Keywords.

Creating a Poll object

To create a Poll object, the miniport driver does the following in its *MiniportInitializeEx* callback function:

1. Allocates a private miniport context.
2. Allocates an **NDIS_POLL_CHARACTERISTICS** structure to specify entry points for the *NdisPoll* and *NdisSetPollNotification* callback functions.
3. Calls **NdisRegisterPoll** to create the Poll object and store it in the miniport context.

The following example shows how a miniport driver might create a Poll object for a receive queue flow. Error handling is omitted for simplicity.

```C++
NDIS_SET_POLL_NOTIFICATION NdisSetPollNotification;
NDIS_POLL NdisPoll;

NDIS_STATUS
MiniportInitialize(
    _In_ NDIS_HANDLE NdisAdapterHandle,
    _In_ NDIS_HANDLE MiniportDriverContext,
    _In_ NDIS_MINIPORT_INIT_PARAMETERS * MiniportInitParameters
)
{
    // Allocate a private miniport context
    MINIPORT_CONTEXT * miniportContext = ...;

    NDIS_POLL_CHARACTERISTICS pollCharacteristics;
    pollCharacteristics.Header.Type = NDIS_OBJECT_TYPE_DEFAULT;
    pollCharacteristics.Header.Revision = NDIS_POLL_CHARACTERISTICS_REVISION
_1;
    pollCharacteristics.Header.Size = NDIS_SIZEOF_NDIS_POLL_CHARACTERISTICS_
REVISION_1;
    pollCharacteristics.SetPollNotificationHandler =
NdisSetPollNotification;
    pollCharacteristics.PollHandler = NdisPoll;

    // Create a Poll object and store it in the miniport context
    NdisRegisterPoll(
        NdisAdapterHandle,
        miniportContext,
        &pollCharacteristics,
        &miniportContext->RxPoll);

    return NDIS_STATUS_SUCCESS;
}
```

Queuing a Poll object for execution

From an ISR, miniport drivers call **NdisRequestPoll** to queue a Poll object for execution. The following example shows receive handling but ignores the sharing of interrupt lines for simplicity.

```C++
BOOLEAN
MiniportIsr(
  KINTERRUPT * Interrupt,
  void * Context
)
{
    auto miniportContext = static_cast<MINIPORT_CONTEXT *>(Context);
    auto hardwareContext = miniportContext->HardwareContext;

    // Check if this interrupt is due to a received packet
    if (hardwareContext->ISR & RX_OK)
    {
        // Disable the receive interrupt and queue the Poll
        hardwareContext->IMR &= ~RX_OK;
        NdisRequestPoll(miniportContext->RxPoll, nullptr);
    }

    return TRUE;
}
```

Implementing the Poll iteration handler

NDIS invokes the miniport driver's *NdisPoll* callback to poll for receive indications and send completions. NDIS first invokes *NdisPoll* when the driver calls NdisRequestPoll to queue a Poll object. NDIS will keep invoking *NdisPoll* while the driver is making forward progress on receive indications or transmit completions.

For receive indications, the driver should do the following in *NdisPoll*:

1. Check the **receive** parameter of the NDIS_POLL_DATA structure to get the maximum number of NBLs it can indicate.
2. Fetch up to the maximum number of Rx packets.
3. Initialize the NBLs.
4. Add them to the NBL queue provided by the NDIS_POLL_RECEIVE_DATA structure (located in the NDIS_POLL_DATA structure of the *NdisPoll* **PollData** parameter).
5. Exit the callback.

For transmit completions, the driver should do the following in *NdisPoll*:

1. Check the **transmit** parameter of the NDIS_POLL_DATA structure to get the maximum number of NBLs it can complete.
2. Fetch up to the maximum number of Tx packets.
3. Complete the NBLs.

4. Add them to the NBL queue provided by the NDIS_POLL_TRANSMIT_DATA structure (located in the NDIS_POLL_DATA structure of the *NdisPoll* **PollData** parameter).
5. Exit the callback.

The driver shouldn't enable the Poll object's interrupt before exiting the *NdisPoll* function. NDIS will keep polling the driver until it assesses that no forward progress is being made. At this point NDIS will stop polling and ask the driver to re-enable the interrupt.

Here's how a driver might implement *NdisPoll* for a receive queue flow.

C++

```
_Use_decl_annotations_
void
NdisPoll(
    void * Context,
    NDIS_POLL_DATA * PollData
)
{
    auto miniportContext = static_cast<MINIPORT_CONTEXT *>(Context);
    auto hardwareContext = miniportContext->HardwareContext;

    // Drain received frames
    auto & receive = PollData->Receive;
    receive.NumberOfRemainingNbls = NDIS_ANY_NUMBER_OF_NBLS;
    receive.Flags = NDIS_RECEIVE_FLAGS_SHARED_MEMORY_VALID;

    while (receive.NumberOfIndicatedNbls < receive.MaxNblsToIndicate)
    {
        auto rxDescriptor = HardwareQueueGetNextDescriptorToCheck(hardwareCo
ntext->RxQueue);

        //
If this descriptor is still owned by hardware stop draining packets
        if ((rxDescriptor->Status & HW_OWN) != 0)
            break;

        auto nbl = MakeNblFromRxDescriptor(miniportContext-
>NblPool, rxDescriptor);

        AppendNbl(&receive.IndicatedNblChain, nbl);
        receive.NumberOfIndicatedNbls++;

        // Move to next descriptor
        HardwareQueueAdvanceNextDescriptorToCheck(hardwareContext->RxQueue);
    }
}
```

Managing interrupts

Miniport drivers implement the *NdisSetPollNotification* callback to enable or disable the interrupt associated with a Poll object. NDIS typically invokes the *NdisSetPollNotification* callback when it detects that the miniport driver is not making forward progress in *NdisPoll*. NDIS uses *NdisSetPollNotification* to tell the driver that it will stop invoking *NdisPoll*. The driver should invoke **NdisRequestPoll** when new work is ready to be processed.

Here's how a driver might implement *NdisSetPollNotification* for a receive queue flow.

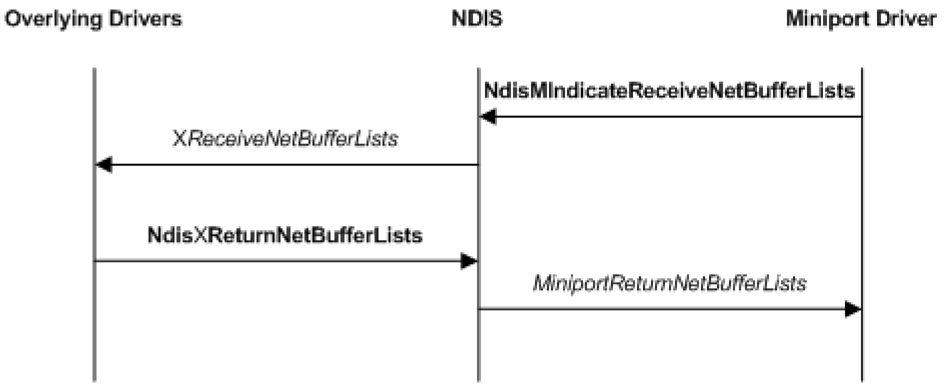
```C++
_Use_decl_annotations_
void
NdisSetPollNotification(
    void * Context,
    NDIS_POLL_NOTIFICATION * Notification
)
{
    auto miniportContext = static_cast<MINIPORT_CONTEXT *>(Context);
    auto hardwareContext = miniportContext->HardwareContext;

    if (Notification->Enabled)
    {
        hardwareContext->IMR |= RX_OK;
    }
    else
    {
        hardwareContext->IMR &= ~RX_OK;
    }
}
```

Indicating Received Data from a Miniport Driver

Article • 12/15/2021

The following figure illustrates a miniport driver receive indication.



Overlying Drivers
NDIS
Miniport Driver
NdisMIndicateReceiveNetBufferLists
XReceiveNetBufferLists
NdisXReturnNetBufferLists
MiniportReturnNetBufferLists

Miniport drivers call the NdisMIndicateReceiveNetBufferLists function to indicate the receipt of data from the network. The **NdisMIndicateReceiveNetBufferLists** function passes the indicated list of NET_BUFFER_LIST structures up the stack to overlying drivers.

If a miniport driver sets the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of NdisMIndicateReceiveNetBufferLists, this indicates that the miniport driver must regain ownership of the NET_BUFFER_LIST structures immediately. In this case, NDIS does not call the miniport driver's *MiniportReturnNetBufferLists* function to return the **NET_BUFFER_LIST** structures. The miniport driver regains ownership immediately after **NdisMIndicateReceiveNetBufferLists** returns.

If a miniport driver does not set the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of NdisMIndicateReceiveNetBufferLists, NDIS returns the indicated NET_BUFFER_LIST structures to the miniport driver's *MiniportReturnNetBufferLists* function. In this case, the miniport driver relinquishes ownership of the indicated structures until NDIS returns them to *MiniportReturnNetBufferLists*.

Registering and Deregistering Interrupts

Article • 12/15/2021

A miniport driver calls NdisMRegisterInterruptEx to register an interrupt. The driver allocates and initializes an NDIS_MINIPORT_INTERRUPT_CHARACTERISTICS structure to specify the interrupt characteristics and function entry points. The driver passes the structure to **NdisMRegisterInterruptEx**.

Drivers call the NdisMDeRegisterInterruptEx function to release resources that were previously allocated with **NdisMRegisterInterruptEx**.

Handling interrupts for NDIS miniport drivers

Article • 03/14/2023

NDIS calls the *MiniportInterrupt* function when a NIC, or another device that shares the interrupt with the NIC, generates an interrupt.

MiniportInterrupt should return **FALSE** immediately if the underlying NIC did not generate the interrupt. Otherwise, it returns **TRUE** after processing the interrupt.

A miniport driver should do as little work as possible in its *MiniportInterrupt* function. It should defer I/O operations to the *MiniportInterruptDPC* function. NDIS calls *MiniportInterruptDPC* to complete the deferred processing of an interrupt.

To queue additional DPCs after *MiniportInterrupt* returns, the miniport driver sets the bits of the **TargetProcessors** parameter of the *MiniportInterrupt* function. To request additional DPCs from *MiniportInterrupt* or *MiniportInterruptDPC*, the miniport driver calls the **NdisMQueueDpc** function.

The miniport driver can call **NdisMQueueDpc** to request additional DPC calls for other processors.

Synchronizing with Interrupts

Article • 12/15/2021

If a miniport driver's *MiniportInterrupt* function shares resources, such as NIC registers or state variables, with another *MiniportXxx* function that runs at a lower IRQL, that *MiniportXxx* function must call **NdisMSynchronizeWithInterruptEx**. This call ensures that the miniport driver's *MiniportSynchronizeInterrupt* function accesses the shared resources in a synchronized and multiprocessor-safe manner.

Interrupt Moderation

Article • 12/15/2021

To reduce the number of interrupts, many NICs use *interrupt moderation*. With interrupt moderation, the NIC hardware will not generate an interrupt immediately after it receives a packet. Instead, the hardware waits for more packets to arrive, or for a time-out to expire, before generating an interrupt. The hardware vendor specifies the maximum number of packets, time-out interval, or other interrupt moderation algorithm.

The measured round-trip time for a packet is one of the most commonly used techniques to determine the network bandwidth between two endpoints. However, when interrupt moderation is enabled, receiving a packet does not generate an immediate interrupt and therefore the perceived round-trip time for a particular packet becomes larger than the average time. To allow accurate measurement of round trip time for a packet, NDIS provides the ability to disable and enable interrupt moderation on demand.

All NDIS 6.0 and later miniport drivers must support the OID_GEN_INTERRUPT_MODERATION OID. If a miniport driver does not support interrupt moderation, the driver must specify **NdisInterruptModerationNotSupported** in the **InterruptModeration** member of the **NDIS_INTERRUPT_MODERATION_PARAMETERS** structure.

NDIS 6.0 and later miniport drivers must support both the OID_GEN_INTERRUPT_MODERATION OID set and query requests. The set request directs the miniport driver to enable or disable interrupt moderation and the query request reports the current state of interrupt moderation.

A miniport driver that supports interrupt moderation should turn this capability on by default unless the **InterruptModeration** standard keyword in the registry disables it. For more information about the standard keywords, see Standardized INF Keywords for Network Devices.

Miniport Adapter OID Requests

Article • 12/15/2021

NDIS defines object identifier (OID) values to identify miniport adapter parameters, which include operating parameters such as device characteristics, configurable settings and statistics. For more information about OIDs, see NDIS OIDs.

For NDIS 6.1 and later miniport drivers, NDIS provides a Direct OID Request Interface. The *Direct OID request path* supports OID requests that are queried or set frequently. The Direct OID Request Interface is optional for NDIS drivers.

For NDIS 6.80 and later miniport drivers, NDIS provides a Synchronous OID Request Interface. The *Synchronous OID request path* supports OIDs that require synchronization or OIDs that should not be queued by filter drivers, such as RSSv2 OIDs. The Synchronous OID Request Interface is optional for NDIS drivers but is required if the miniport driver advertises support for RSSv2.

The following topics provide more information about miniport driver OID requests:

Handling OID Requests In a Miniport Adapter

Miniport Adapter OID Request Serialization

Miniport Adapter Direct OID Requests

Miniport Adapter Synchronous OID Requests

Miniport adapter OID request serialization

Article • 12/15/2021

All OID requests to a miniport adapter are serialized by NDIS except for direct OID requests, which were designed not be serialized. A miniport adapter will not receive a new OID request until any pending request is completed. Therefore, miniport adapters must complete OIDs promptly.

> ⓘ **Note**
>
> We recommend completing an OID request in less than 1000ms, or 1 second, so the user will not notice any delay in performance. For specific information about timing OID requests, see the **NdisTimedOidComplete** Driver Verifier rule.

One exception to this OID serialization rule is for Wi-Fi miniport adapters that use WDI, which may see a second OID request if they take too long to complete the previous OID. The following example explains what happens in this situation:

1. The first OID request is passed to the WDI miniport adapter.
2. The NIC does not respond to the OID within the time limit specified by the driver.
3. WDI calls the driver's MINIPORT_WDI_ADAPTER_HANG_DIAGNOSE callback function to collect diagnostic data about the NIC.
4. The first OID is no longer considered to block serialization. This means the WDI miniport adapter can now receive other OID requests, even though the first OID is serialized. However, these other OIDS are also serialized, which means the WDI miniport adapter will not pend more than 2 OIDs simultaneously (the first OID that is still hung and a second OID).

For more information about OID requests in NDIS, see Simplifying your OID request handler on the NDIS blog.

Handling OID Requests In a Miniport Adapter

Article • 12/15/2021

NDIS calls a miniport driver's *MiniportOidRequest* function to submit an OID request to query or set information in the driver. NDIS calls the *MiniportOidRequest* function either on its own behalf or on behalf of an overlying driver that called the **NdisOidRequest** or **NdisFOidRequest** function.

NDIS passes *MiniportOidRequest* a pointer to an **NDIS_OID_REQUEST** structure that contains the request information. The request structure contains an OID_Xxx identifier that indicates the type of request and other members to define the request data.

The **Timeout** member specifies a time-out, in seconds, for the request. NDIS can reset the driver or cancel the request if the time-out expires before the driver completes the request.

The **RequestId** member specifies an optional identifier for the request. Miniport drivers can set the **RequestId** member of a status indication to the value obtained from the **RequestId** member of an associated OID request. Typically, miniport drivers can ignore this member. If a driver must set this member, the reference page for the particular OID provides the required values. For more information about status indications, see Adapter Status Indications.

A miniport driver that successfully handles an OID set request must set the **SupportedRevision** member in the **NDIS_OID_REQUEST** structure upon return from the OID set request. The **SupportedRevision** member notifies the initiator of the request of the revision that the driver supported. For example, a miniport driver can create an Xxx_REVISION_2 structure, supply values that are appropriate for an Xxx_REVISION_1 structure, and fill the rest of the structure with zeros. The miniport driver would report Xxx_REVISION_1 in the **SupportedRevision** member. In this case, a protocol driver that can support an Xxx_REVISION_2 will use Xxx_REVISION_1 information that the miniport driver supported. For more information about version information in NDIS structures, see Specifying NDIS Version Information.

A miniport driver can complete an OID request synchronously by returning a success or failure status.

A miniport driver can complete an OID request asynchronously by returning NDIS_STATUS_PENDING. In this case, the miniport driver must call the **NdisMOidRequestComplete** function to complete the operation.

If *MiniportOidRequest* returns NDIS_STATUS_PENDING, NDIS will not call *MiniportOidRequest* with another request for the adapter until the pending request is completed.

NDIS can call a miniport driver's *MiniportCancelOidRequest* function to cancel an OID request.

Miniport Adapter Direct OID Requests

Article • 12/15/2021

To support the direct OID request path, miniport drivers provide *MiniportXxx* function entry points in the **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** structure and NDIS provides **NdisM*Xxx*** functions for miniport drivers.

The *direct OID request interface* is similar to the standard OID request interface. For example, the **NdisMDirectOidRequestComplete** and *MiniportDirectOidRequest* functions are similar to the **NdisMOidRequestComplete** and *MiniportOidRequest* functions.

Note NDIS 6.1 supports specific OIDs for use with the direct OID request interface. OIDs that existed before NDIS 6.1 and some NDIS 6.1 OIDs are not supported. To determine if an OID can be used in the direct OIDs interface, see the OID reference page.

Miniport drivers must be able to handle direct OID requests that are not serialized. Unlike the standard OID request interface, NDIS does not serialize direct OID requests with other requests that are sent with the direct OID interface or with the standard OID request interface. Also, miniport drivers must be able to handle direct OID requests at IRQL <= DISPATCH_LEVEL.

To support the direct OIDs request interface, use the documentation for the standard OID request interface. The following table shows the relationship between the functions in the direct OID request interface and the standard OID request interface.

Direct OID function	Standard OID function
MiniportDirectOidRequest	*MiniportOidRequest*
MiniportCancelDirectOidRequest	*MiniportCancelOidRequest*
NdisMDirectOidRequestComplete	**NdisMOidRequestComplete**

Miniport Adapter Synchronous OID Requests

Article • 12/15/2021

To support the Synchronous OID request path, miniport drivers provide a *MiniportSynchronousOidRequest* function entry point in the **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** structure when they call the **NdisMRegisterMiniportDriver** function.

For miniport drivers, the *Synchronous OID request interface* differs from the Regular and Direct OID request interfaces in that miniport drivers do not have to register an asynchronous *complete* callback function. This is because of the synchronous nature of the path. For more info about the differences between Regular, Direct, and Synchronous OIDs in general, see Synchronous OID Request Interface in NDIS 6.80.

ⓘ **Note**

NDIS 6.80 supports specific OIDs for use with the Synchronous OID request interface. OIDs that existed before NDIS 6.80 and some NDIS 6.80 OIDs are not supported. To determine if an OID can be used in the Synchronous OID request interface, see the OID reference page.

To support the Synchronous OID request interface, use the documentation for the standard OID request interface. The following table shows the relationship between the functions in the Synchronous OID request interface and the standard OID request interface.

Synchronous OID function	Standard OID function
MiniportSynchronousOidRequest	*MiniportOidRequest*

Miniport Adapter Status Indications

Article • 12/15/2021

Miniport drivers call the NdisMIndicateStatusEx function to report a change in the status of a miniport adapter. The miniport driver passes **NdisMIndicateStatusEx** a pointer to an NDIS_STATUS_INDICATION structure that contains the status information.

The status indication includes information to identify the type of status and a reason for the status change.

The miniport driver should set the **SourceHandle** member to the handle that NDIS passed to the *MiniportAdapterHandle* parameter of the *MiniportInitializeEx* function. If the status indication is associated with an OID request, the miniport driver can set the **DestinationHandle** and **RequestId** members so that NDIS can provide the status indication to a specific protocol binding.

Miniport Adapter Device PnP Event Notifications

Article • 12/15/2021

NDIS calls a miniport driver's *MiniportDevicePnPEventNotify* function to notify the driver of Plug and Play (PnP) events.

NDIS provides an event code that describes the PnP event. The code can indicate that the adapter has been unexpectedly removed from the system or that the power profile of the host system has changed.

If the event code indicates that the power profile has changed, NDIS also indicates the type of change. Either the system is running on battery power or the system is running on AC power.

The miniport driver should adjust the adapter settings accordingly.

Miniport Adapter Check-for-Hang and Reset Operations

Article • 12/15/2021

Overview

> ⚠ **Warning**
>
> Check-for-Hang (CFH) and Reset operations are discouraged for all NDIS 6.83 and later drivers. For more information, see **Check-for-Hang and Reset operations in NDIS 6.83 and later**.

NDIS calls an NDIS miniport driver's *MiniportCheckForHangEx* function to check the operational state of an NDIS adapter that represents a network interface card (NIC). *MiniportCheckForHangEx* checks the internal state of the adapter and returns **TRUE** if it detects that the adapter is not operating correctly.

By default, NDIS calls *MiniportCheckForHangEx* approximately every 2 seconds. If *MiniportCheckForHangEx* returns **TRUE**, NDIS calls the NDIS miniport driver's *MiniportResetEx* function. If the default time-out value of 2 seconds is too small, your miniport driver can set a different value at initialization time as follows:

1. Set the **CheckForHangTimeInSeconds** member of the **NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES** structure to a nonzero value.
2. Pass the **NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES** structure in the *MiniportAttributes* parameter of the **NdisMSetMiniportAttributes** function.

For more information about setting driver attributes, see Initializing an Adapter. The value of **CheckForHangTimeInSeconds** should be greater than the initialize time of your miniport driver. However, if your driver takes longer than **CheckForHangTimeInSeconds** seconds to initialize, this time-out expires, causing NDIS to call your driver's *MiniportCheckForHangEx* function. If *MiniportCheckForHangEx* returns **TRUE**, NDIS will then call your driver's *MiniportResetEx* function. For this reason, you should synchronize your driver's *MiniportCheckForHangEx* function with driver initialization so that *MiniportCheckForHangEx* will not return **TRUE** if the driver has not finished initializing.

If your miniport driver does not complete an OID request within two successive calls to *MiniportCheckForHangEx*, NDIS can call the driver's *MiniportResetEx* function. For some

OID requests, NDIS calls *MiniportResetEx* if the driver does not complete the request within four successive calls to *MiniportCheckForHangEx*.

The reset operation does not affect miniport adapter operational states. Also, the state of the adapter might change while a reset operation is in progress. For example, NDIS might call a driver's *MiniportPause* function when there is a reset operation in progress. In this case, the driver can complete either the reset or the pause operation in any order while following the normal requirements for each operation.

For a reset operation, the driver can fail transmit request packets or it can keep them queued and complete them later. However, you should note that an overlying driver cannot complete a pause operation while its transmit packets are pending.

A miniport driver can complete a reset request synchronously by returning a success or failure status. The driver can complete a reset request asynchronously by returning **NDIS_STATUS_PENDING**. In this case, the driver must call **NdisMResetComplete** to complete the operation.

Check-for-Hang and Reset operations in NDIS 6.83 and later

In versions of NDIS before 6.83, Check-for-Hang (CFH) and Reset operations were discouraged for Always On, Always Connected (AOAC) systems due to battery life issues. However, drivers could still use CFH on other non-AOAC Windows systems by implementing the optional *MiniportCheckForHangEx* and *MiniportResetEx* callback functions.

Starting in NDIS 6.83, these callback functions are discouraged on **all** Windows systems regardless of power capabilities. Although it is not a logo test violation to use CFH in NDIS 6.83 and later, NDIS drivers should use the following table for guidance about its usage.

Caller	Recommendation	Notes
Drivers targeting AOAC systems	Must not implement	Causes battery life issues due to periodic check-for-hang activity
Drivers targeting Windows Server systems	Must not implement	Causes issues when the CPU is stressed

Caller	Recommendation	Notes
Virtual (software-only) miniport drivers	Must not implement	Reset not possible without hardware
Other new NDIS 6.83 and later drivers	Should not implement	
Other existing NDIS 6.82 and earlier code	Not required to change, but should consider removing Check-for-Hang and Reset in future rework

Miniport Driver Hardware Reset

Miniport Driver Reset and Halt Functions

Miniport Adapter Shutdown

Article • 12/15/2021

An NDIS miniport driver must register a *MiniportShutdownEx* function during miniport driver initialization.

NDIS calls an NDIS miniport driver's *MiniportShutdownEx* function when the system is shutting down. *MiniportShutdownEx* restores the hardware to a known state.

The *ShutdownAction* parameter that NDIS passed to *MiniportShutdownEx* informs the miniport driver of the reason for the shutdown.

The shutdown handler can be called as a result of a user operation, in which case it runs at IRQL = PASSIVE_LEVEL. It can also be called as a result of an unrecoverable system error, in which case it can be running at any IRQL.

MiniportShutdownEx should call no **Ndis*Xxx*** functions. The miniport driver can call functions for reading and writing I/O ports or disabling the DMA engine to return the hardware to a known state.

Unlike *MiniportHaltEx*, *MiniportShutdownEx* should not release any allocated resources. *MiniportShutdownEx* should just stop the NIC.

NDIS Management Information and OIDs

Article • 03/14/2023

Each miniport driver contains its own *management information base (MIB)*, which is an information block in which the driver stores dynamic configuration information and statistical information that a management entity can query or set. An Ethernet multicast address list is an example of configuration information. The number of broadcast packets received is an example of statistical information. Each information element within the MIB is referred to as an *object*. To refer to each such managed object, NDIS defines an *object identifier (OID)*. Therefore, if a management entity wants to query or set a particular managed object, it must provide the specific OID for that object.

The MIB tracks three classes of objects:

- Objects that are general to all NDIS miniport drivers.
- Objects that are specific to all NDIS miniport drivers for a given medium type, such as Ethernet.
- Objects that are specific to a particular vendor implementation.

The *general* and mandatory *media-specific* OIDs are documented in the Network Reference section of the WDK documentation. The implementation-specific OIDs for a particular network interface card (NIC) driver should be listed and described in the documentation that accompanies a given miniport driver.

Objects are classified as *operational characteristics* (for example, multicast address list) or *statistics* (for example, broadcast packets received), and they are also classified as *mandatory* or *optional*. All operational characteristics objects for general or media-specific classes are mandatory, but only some statistics objects are mandatory. All implementation-specific objects are classified as mandatory.

For more information about OID classifications, see NDIS OIDs.

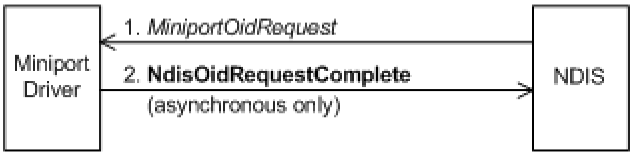
Querying a Connectionless Miniport Driver

Article • 12/15/2021

To query OIDs that a connectionless miniport driver maintains, a bound protocol calls NdisOidRequest and passes an NDIS_OID_REQUEST structure that specifies the object (OID) that is being queried and that points to a buffer into which NDIS eventually writes the requested information.

If NDIS does not respond for the miniport driver, the call to **NdisOidRequest** causes NDIS to call the miniport driver's *MiniportOidRequest* function, which returns the requested information to NDIS. *MiniportOidRequest* can complete synchronously or asynchronously with a call to NdisMOidRequestComplete.

NDIS can also call a miniport driver's *MiniportOidRequest* function on its own behalf--for example, after the miniport driver's *MiniportInitializeEx* function has returned NDIS_STATUS_SUCCESS--to query the miniport driver's capabilities, status, or statistics. The following diagram illustrates querying a connectionless miniport driver.



NDIS responds to many OID requests on behalf of the miniport driver. The miniport driver reports many of its OID values during initialization and in status indications. For more information about OID values that are reported in attributes, see NDIS_MINIPORT_ADAPTER_ATTRIBUTES and the related attributes structures.

When *MiniportOidRequest* is called with OID_GEN_MAC_OPTIONS, it must return a bitmask that specifies the optional operations that the miniport driver performs. The set of flags includes:

- NDIS_MAC_OPTION_COPY_LOOKAHEAD_DATA. This flag indicates to a protocol driver that it can access indicated data by any means. If a miniport driver indicates data out of on-board shared memory, it must not set this flag.

- NDIS_MAC_OPTION_NO_LOOPBACK. If this flag is set, the miniport driver does not loopback a packet that is passed to *MiniportSendNetBufferLists(Packets)* that is directed to a receiver on the same computer and that the miniport driver expects NDIS to perform the loopback. If NDIS performs the loopback of a packet, the packet is not passed down to the miniport driver. A miniport driver always sets this flag unless a NIC performs hardware loopbacks.

- NDIS_MAC_OPTION_RECEIVE_SERIALIZED. If this flag is set, the miniport driver does not indicate any newly received packet up until the previously received packet has been fully processed, including transferring the data. Most miniport drivers, except those that indicate up packets by calling **NdisMIndicateReceiveNetBufferLists**, set this flag.

A miniport driver must never use the flag NDIS_MAC_OPTION_RESERVED, which is reserved for NDIS internal use.

MiniportOidRequest is also queried with a media-specific OID to determine the NIC's current address. For instance, the miniport driver for a NIC of type 802.3 will be queried with OID_802_3_CURRENT_ADDRESS.

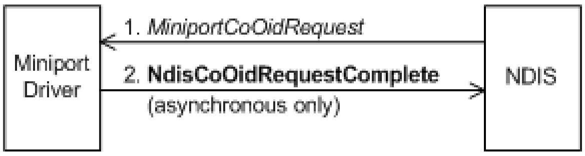
The miniport drivers for certain media types will receive additional OIDs that are media-specific. For example, a miniport driver whose NIC is of type 802.3 is queried with OID_802.3_MAXIMUM_LIST_SIZE. For more information, see General Objects.

Querying a Connection-Oriented Miniport Driver

Article • 12/15/2021

To query information objects that a connection-oriented miniport driver maintains, a bound protocol calls **NdisCoOidRequest** and passes an **NDIS_OID_REQUEST** structure that specifies the object (OID) that is being queried and that provides a buffer into which NDIS eventually writes the requested information. The call to **NdisCoOidRequest** causes NDIS to call the miniport driver's *MiniportCoOidRequest* function, which returns the requested information to NDIS. *MiniportCoOidRequest* can complete synchronously or asynchronously with a call to **NdisCoOidRequestComplete**.

NDIS can also call a miniport driver's *MiniportCoOidRequest* function on its own behalf—for example, after the miniport driver's *MiniportInitializeEx* function has returned NDIS_STATUS_SUCCESS—to query the miniport driver's capabilities, status, or statistics. The following diagram illustrates querying a connection-oriented miniport driver.



A connection-oriented miniport driver must be able to provide information about a global basis for all virtual connections (VCs) for a particular NIC and also on a per-VC basis. For example, if a non-**NULL** *NdisVcHandle* is supplied to *MiniportCoOidRequest* for a query of OID_GEN_CO_RCV_CRC_ERROR, the miniport driver returns the number of CRC errors that were encountered in all receives on the specified VC. For the same request with a **NULL** *NdisVcHandle*, the miniport driver returns the total number of CRC errors that are encountered for all incoming receives through a NIC.

The following list contains the set of mandatory general operational OIDs for connection-oriented miniport drivers:

OID_GEN_CO_SUPPORTED_LIST

OID_GEN_CO_HARDWARE_STATUS

OID_GEN_CO_MEDIA_SUPPORTED

OID_GEN_CO_MEDIA_IN_USE

OID_GEN_CO_LINK_SPEED

OID_GEN_CO_VENDOR_ID

OID_GEN_CO_VENDOR_DESCRIPTION

OID_GEN_CO_VENDOR_DRIVER_VERSION

OID_GEN_CO_DRIVER_VERSION

OID_GEN_CO_MAC_OPTIONS

OID_GEN_CO_MEDIA_CONNECT_STATUS

OID_GEN_CO_MINIMUM_LINK_SPEED

The miniport driver's *MiniportCoOidRequest* function must be prepared to respond to queries or sets, as appropriate, to any of the preceding OIDs.

When *MiniportCoOidRequest* is called with OID_GEN_CO_MAC_OPTIONS, it must return a bitmask that specifies the optional operations that the miniport driver performs. The set of flags includes:

- NDIS_MAC_OPTION_NO_LOOPBACK. If this flag is set, the miniport driver does not loopback a packet that is passed to **MiniportCoSendNetBufferLists** that is directed to a receiver on the same computer and that the miniport driver expects NDIS to perform the loopback. If NDIS performs the loopback of a packet, the packet is not passed down to the miniport driver. A miniport driver always sets this flag unless a NIC performs hardware loopbacks.

- NDIS_MAC_ETOX_INDICATION. If this flag is set, the miniport driver indicates that a send is complete only after the NIC transmits the packet.

A miniport driver must never use the NDIS_MAC_OPTION_RESERVED flag, which is reserved for NDIS internal use.

MiniportCoOidRequest will also be queried with a media-specific OID to determine the NIC's current address.

For more information, see OIDs for Connection-Oriented Call Managers and Clients and General Objects.

Querying a Miniport Driver Directly From User Mode

Article • 12/15/2021

An application can use **IOCTL_NDIS_QUERY_GLOBAL_STATS** to directly query information from a miniport driver's NIC. In this operation, the application can use any query OID that the miniport driver supports.

Querying 64-Bit Statistics OIDs

Article • 12/15/2021

All miniport drivers that are 1 Gigabyte per second (Gbps) and faster must support 64-bit counters for certain statistics OIDs. All 100 Megabytes per second (Mbps) and faster miniport drivers should support 64-bit counters for such OIDs. For more information about statistics OIDs for connectionless miniport drivers, see General Statistics. For more information about such OIDs for connection-oriented miniport drivers, see General Statistics for Connection-Oriented Miniport Drivers.

A requester that queries a statistics OID sets NDIS_OID_REQUEST **InformationBufferLength** to 4 (bytes) to indicate a 32-bit statistics request or to 8 (bytes) to indicate a 64-bit statistics request. In its response, the miniport driver sets NDIS_OID_REQUEST **BytesNeeded** to the size of the statistics value that the miniport driver supports (4 for 32-bits or 8 for 64-bits). The miniport driver sets NDIS_OID_REQUEST **BytesWritten** to the smaller of the **InformationBufferLength** value and the size of statistics that the miniport driver supports.

The following sections describe how a miniport driver that supports 64-bit statistics OIDs responds to queries of such OIDs.

64-bit query of a 64-bit value

NDIS_OID_REQUEST **InformationBufferLength** is greater than or equal to 8.

The miniport driver:

- Returns the 64-bit value in the information buffer.
- Sets NDIS_OID_REQUEST **BytesWritten** to 8.
- Returns NDIS_STATUS_SUCCESS from its *MiniportOidRequest* or **MiniportCoOidRequest** function.

32-bit query of a 64-bit value

NDIS_OID_REQUEST **InformationBufferLength** is greater to or equal to 4 and less than 8.

The miniport driver:

- Returns, in the information buffer, the lower 32 bits of the 64-bit value.

- Sets NDIS_OID_REQUEST **BytesWritten** to 4.
- Sets NDIS_OID_REQUEST **BytesNeeded** to 8.
- Returns NDIS_STATUS_SUCCESS from its *MiniportOidRequest* or **MiniportCoOidRequest** function.

Invalid-length query of a 64-bit value

NDIS_OID_REQUEST **InformationBufferLength** is less than 4.

The miniport driver:

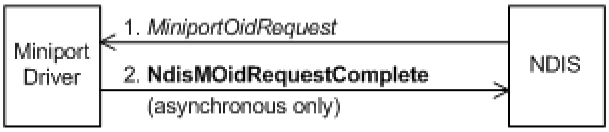
- Does not return any value in the information buffer.
- Sets NDIS_OID_REQUEST **BytesWritten** to 0.
- Sets NDIS_OID_REQUEST **BytesNeeded** to 8.
- Returns NDIS_STATUS_INVALID_LENGTH from its *MiniportOidRequest* or **MiniportCoOidRequest** function.

Setting Information for a Connectionless Miniport Driver

Article • 12/15/2021

To set an OID that a connectionless miniport driver maintains, a bound protocol calls NdisOidRequest and passes an NDIS_OID_REQUEST structure that specifies the object (OID) that is being queried and that points to a buffer that contains the value to which the object should be set. The call to **NdisOidRequest** causes NDIS to call the miniport driver's *MiniportOidRequest* function, which sets the object with the supplied value.

The call to *MiniportOidRequest* can complete synchronously or asynchronously. To complete the call asynchronously, the miniport driver calls NdisMOidRequestComplete. The following diagram illustrates setting information in a connectionless miniport driver (per binding).

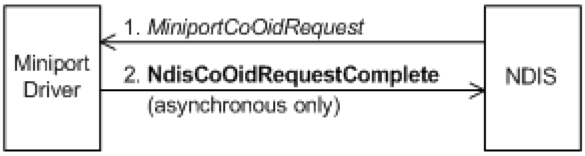


Setting Information for a Connection-Oriented Miniport Driver

Article • 12/15/2021

To set an OID that a connection-oriented miniport driver maintains, a bound protocol calls NdisCoOidRequest and passes an NDIS_OID_REQUEST structure that specifies the object (OID) that is being queried and that points to a buffer that contains the value to which the object should be set. The call to **NdisCoOidRequest** causes NDIS to call the miniport driver's MiniportCoOidRequest function, which sets the object with the supplied value.

The call to **NdisCoOidRequest** can complete synchronously or asynchronously. To complete the call asynchronously, a miniport driver calls NdisCoOidRequestComplete. The following diagram illustrates setting information in a connection-oriented miniport driver.



Occasions for Setting Miniport Driver Information

Article • 12/15/2021

The *MiniportOidRequest* function in a connectionless miniport driver and the **MiniportCoOidRequest** function in a connection-oriented miniport driver are called during initialization. These functions can also be called:

- During a hardware reset,
- If a protocol calls **NdisCloseAdapterEx**.

MiniportOidRequest or *MiniportCoOidRequest* is called during hardware reset operation. In this case, *MiniportOidRequest* or *MiniportCoOidRequest* is called to reset the miniport driver to its initial state with respect to its addresses.

NDIS calls *MiniportOidRequest* or *MiniportCoOidRequest* when a miniport driver's NIC is closed by a protocol's **NdisCloseAdapterEx** call. Such a miniport driver will be requested to update its addressing information.

Reporting Hardware Status

Article • 12/15/2021

A connectionless miniport driver indicates changes in hardware status to upper layers by calling NdisMIndicateStatusEx. A connection-oriented miniport driver indicates changes by calling NdisMCoIndicateStatusEx.

NdisM(Co)IndicateStatusEx takes both a general status code and a buffer that contains media-specific information that further defines the reason for the status change. NDIS reports this status change to bound protocol drivers. NDIS does not interpret or otherwise intercept the status code.

The miniport driver can make one or more such calls. However, unlike earlier versions of NDIS, the miniport driver does not indicate that it has finished sending status. The protocol driver or configuration manager can log the status or take corrective action, as appropriate.

NdisMCoIndicateStatusEx takes any valid NDIS_STATUS_*Xxx* value.

The miniport driver is responsible for indicating status codes that make sense to a protocol or higher level driver. A protocol driver ignores any status values in which it is not interested or that do not make sense in the context of its operations.

A miniport driver cannot indicate status in the context of its *MiniportInitializeEx*, *MiniportInterrupt*, *MiniportHaltEx*, or *MiniportShutdownEx* function.

A miniport driver can also be interrogated by an upper layer driver or by NDIS about the miniport driver's hardware status. When the *MiniportOidRequest* function of a connectionless miniport driver or the MiniportCoOidRequest function of a connection-oriented miniport driver receives OID_GEN_HARDWARE_STATUS, it responds with any of the applicable status values that are defined in NDIS_HARDWARE_STATUS. These status values include:

- NdisHardwareStatusReady
- NdisHardwareStatusInitializing
- NdisHardwareStatusReset
- NdisHardwareStatusClosing
- NdisHardwareStatusNotReady

The miniport driver can be queried so that NDIS can synchronize operations between layers of NDIS drivers--for example, by determining whether a NIC is ready to accept packets.

Indicating Connection Status

Article • 12/15/2021

A miniport driver calls NdisMIndicateStatusEx or NdisMCoIndicateStatusEx to indicate a change in the media connection status. The miniport driver passes one of the following status indications to **NdisM(Co)IndicateStatus**:

NDIS_STATUS_MEDIA_CONNECT
Indicates a media connection status change from disconnected to connected. A media connect status change occurs when a disconnected adapter makes a network connection. For example, the adapter connects when it comes within range (for a wireless adapter) or the user connects the network cable.

NDIS_STATUS_MEDIA_DISCONNECT
Indicates a media connection status change from connected to disconnected. A media disconnect status change occurs when a connected adapter loses a network connection. For example, the adapter loses the connection because it is out of range (for a wireless adapter) or the user unplugs the network cable.

Unless specified otherwise, miniport drivers should indicate media connection status changes within two seconds after detecting the status change.

A miniport driver can check the media connection status while performing certain operations (see the following list). If the status is the same after the operation is complete as it was before the operation started,the miniport driver does not have to report any status changes that might have occurred during the operation.

The following list describes additional requirements for indicating media connection status changes for miniport drivers:

Resetting
NDIS calls *MiniportResetEx* to reset a miniport driver. The miniport driver can complete the reset either synchronously or asynchronously.

If the media connection status is different after resetting, the driver should indicate the status within two seconds after completing the reset.

A miniport driver should not complete the reset operation until it has determined the media connection status.

Halting
A miniport driver must not indicate any media connection status changes when NDIS calls *MiniportHaltEx*.

Initializing
NDIS calls a miniport driver's *MiniportInitializeEx* function to initialize an adapter. During the adapter initialization, the miniport driver must follow these guidelines:

- If the miniport driver does not indicate the media connection status after returning from *MiniportInitializeEx*, NDIS uses the value of the **MediaConnectState** member of the **NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES** structure to determine the media connection status. The miniport driver provides NDIS with this structure when the driver calls **NdisMSetMiniportAttributes** from its *MiniportInitializeEx* function.

  Note If the **MediaConnectState** member is set to MediaConnectStateUnknown, NDIS will proceed as if the adapter is disconnected.

- If an adapter is connected after NDIS calls *MiniportInitializeEx*, the miniport driver can indicate NDIS_STATUS_MEDIA_CONNECT within 5 seconds after it returns from *MiniportInitializeEx*.

- If an adapter is disconnected after NDIS calls *MiniportInitializeEx*, the miniport driver should indicate NDIS_STATUS_MEDIA_DISCONNECT within 2 seconds after it returns from *MiniportInitializeEx*.

- While initializing, the miniport driver should process OID_GEN_MEDIA_CONNECT_STATUS or OID_GEN_CO_MEDIA_CONNECT_STATUS requests asynchronously. The miniport driver should not complete such requests until after it has determined the connection status.

- Determination of the media connection status should not delay initialization. If necessary, the miniport driver should initiate the process to determine the connection status within *MiniportInitializeEx*, and complete the process at a later time. For example, the miniport driver could set a timer to poll the adapter for the connection status.

- A deserialized miniport driver can indicate a media disconnect during initialization, but a serialized miniport driver should not.

Sleeping
A miniport driver enters a network sleep state when it receives an OID_PNP_SET_POWER request to set a device power state of D1, D2, or D3.

A miniport driver must not indicate any media connection status changes when it enters a sleep state or while it is in a sleeping state.

Waking
A miniport driver wakes from a sleep state when it receives an OID_PNP_SET_POWER request to set the device power state to D0.

If the adapter's media connection status after waking is the same as the status was prior to sleeping, the miniport driver should not indicate a media connection status change. If the connection status changed, the miniport driver should indicate the new connection status within two seconds after waking.

While waking, the miniport driver should process OID_GEN_MEDIA_CONNECT_STATUS or OID_GEN_CO_MEDIA_CONNECT_STATUS requests asynchronously. The miniport driver should not complete such requests until after it has determined the connection status.

NDIS Support for WMI

Article • 03/14/2023

Through NDIS, clients of Windows Management Instrumentation (WMI) can obtain and set information that NDIS and NDIS drivers service. WMI clients can also register to receive status updates.

NDIS automatically registers miniport adapters, named virtual connections (VCs), and a set of globally unique identifiers (GUIDs) for each miniport adapter with WMI. For more information about these GUIDs, see Standard Miniport Driver OIDs Registered with WMI. Miniport drivers can also provide support for custom object identifiers (OIDs) and custom status indications, as the Customized OIDs and Status Indications topic describes.

NDIS does not provide WMI support for protocol drivers. A protocol driver, or an intermediate driver, can create a device object for itself and register directly with WMI. For more information about registering directly with WMI, see Registering as a WMI Data Provider.

For more information about the WMI architecture, see Windows Management Instrumentation.

This section includes:

Registration and Deregistration of NDIS Miniport Drivers with WMI

Mapping of GUIDs to OIDs and Miniport Driver Status

Support for Named VCs

NDIS-Supported WMI Operations

Standard WMI OIDs and Status Indications

Customized OIDs and Status Indications

NDIS WMI GUIDs

Registration and Deregistration of NDIS Miniport Drivers with WMI

Article • 03/14/2023

NDIS automatically registers each miniport adapter with WMI. A miniport driver does not have to explicitly register with WMI, because NDIS automatically registers for the associated miniport adapter after the miniport driver returns from the *MiniportInitializeEx* function.

After NDIS registers a miniport adapter as a data provider with WMI, WMI clients can send it query and set requests and register to receive status indications.

Before NDIS calls the miniport driver's *MiniportHaltEx* function, NDIS automatically deregisters the miniport adapter with WMI so that WMI will no longer send WMI requests to the miniport driver.

For each miniport adapter that NDIS registers with WMI, NDIS registers GUIDs that correspond to particular OIDs or status indications. NDIS registers GUIDs for a miniport adapter's supported set of standard OIDs and status indications. For more information about these standard GUIDs, see Standard Miniport Driver OIDs Registered with WMI and Standard Miniport Driver Status Registered with WMI.

NDIS can also register custom GUIDs for custom OIDs and status indications. If the miniport driver supports custom OIDs, it must provide the associated custom GUIDs. For more information about customized OIDs and status indications, see Customized OIDs and Status Indications.

For connection-oriented miniport drivers, NDIS also registers any named virtual connections (VCs). WMI clients can work only with VCs that a stand-alone call manager, or connection-oriented client, has named with the **NdisCoAssignInstanceName** function. For more information about NDIS WMI support for named VCs, see Support for Named VCs.

Mapping of GUIDs to OIDs and Miniport Driver Status

Article • 12/15/2021

When WMI sends a WMI request to a miniport adapter (that is, when WMI sends an I/O request packet [IRP] to a functional device object that NDIS created), NDIS intercepts the request. NDIS does not forward the request to the miniport driver if NDIS already has the information that it requires to service the request. Otherwise, NDIS maps the WMI GUID to an OID and then queries or sets the OID.

If the miniport driver is a connectionless miniport driver, NDIS can call the miniport driver's *MiniportOidRequest* function to handle the OID request. If the miniport driver is a connection-oriented miniport driver, NDIS can call the miniport driver's **MiniportCoOidRequest** function to handle the OID request. NDIS returns the results of the query or set request to WMI.

Miniport drivers generate status indications with the **NdisMIndicateStatusEx** or **NdisMCoIndicateStatusEx** function. If a WMI client registers for a WMI event and a miniport driver generates an associated status indication, NDIS maps that status indication to a WMI GUID and passes a WMI event indication to WMI. WMI then passes the WMI event indication to all of the WMI clients that have registered for the WMI event.

Support for Named VCs

Article • 12/15/2021

NDIS allows WMI clients to query and set information on a per-virtual connection (VC) basis for connection-oriented miniport adapters. WMI clients can also enumerate VCs. Before a WMI client can query or set information that is associated with a particular VC, a stand-alone call manager or connection-oriented client must name the VC by calling the **NdisCoAssignInstanceName** function.

After a stand-alone call manager or connection-oriented client initiates the setup of a VC by calling the **NdisCoCreateVC** function, the stand-alone call manager or connection-oriented client can name the VC with **NdisCoAssignInstanceName**. NDIS assigns the VC an instance name and registers the instance name with WMI. WMI clients can then enumerate the VC and query or set OIDs that are relative to the VC.

A miniport call manager (MCM) cannot use **NdisCoAssignInstanceName** to name its VCs. Instead, an MCM should create a custom GUID and OID for the VC and register the GUID-to-OID mapping with NDIS. For more information about registering custom OIDs, see Customized OIDs and Status Indications.

NDIS-Supported WMI Operations

Article • 03/14/2023

NDIS supports the following WMI operations:

- Enumerate adapter and enumerate virtual connection (VC).

  NDIS registers global GUIDs (GUID_NDIS_ENUMERATE_ADAPTER_EX and GUID_NDIS_ENUMERATE_VC) with WMI that enable WMI clients to enumerate all miniport adapters (that is, miniport driver instances) and all named VCs. Because NDIS track all of the loaded miniport drivers and all of the named VCs, NDIS does not query miniport drivers for such information.

- QUERY SINGLE INSTANCE and SET SINGLE INSTANCE

  Through NDIS, a WMI client can query or set a single instance of a data block, which corresponds to a single OID. For a query, NDIS returns all of the information that is associated with an adapter or VC. A WMI client cannot query or set a data item that is within an OID. For example, a query of the GUID_NDIS_GEN_CO_LINK_SPEED GUID returns both the outbound and inbound speed. A WMI client cannot query only the outbound speed or only the inbound speed.

- QUERY ALL DATA

  NDIS satisfies a QUERY ALL DATA request on a particular GUID by obtaining the appropriate data and returning the combined data for all of the instances of the GUID to WMI. For example, in response to a QUERY ALL DATA request on GUID_NDIS_ENUMERATE_ADAPTER_EX, NDIS returns a list of all of the loaded miniport drivers to WMI. For a QUERY ALL DATA on the GUID that maps to OID_GEN_CO_XMIT_PDUS_OK, NDIS queries that OID for each VC on each connection-oriented miniport driver and returns the combined data to WMI. Because the overhead for a QUERY ALL DATA request might be very high, WMI clients should use a QUERY ALL DATA request only to enumerate adapters and VCs. After determining the adapter or VC interest, the client can then query individual GUID instances.

- EVENT NOTIFICATION

  WMI clients can register with NDIS to be notified for a particular status indication. When such a status indication occurs, NDIS passes the status information with the appropriate GUID to WMI for delivery to the clients as a WMI event.

- EXECUTE METHOD

  Through NDIS, a WMI client can run a method that is associated with a data block, which corresponds to a single OID. WMI clients provide the information that NDIS requires to run the method. Method requests can be associated with miniport adapters, NDIS ports, or VCs. NDIS returns the resulting information after the method is successfully run.

Standard Miniport Driver OIDs Registered with WMI

Article • 12/15/2021

NDIS registers WMI GUIDs with WMI for miniport adapters. To obtain the list of OIDs that a miniport adapter supports, NDIS issues an OID_GEN_SUPPORTED_LIST query to the associated miniport driver. The miniport driver must provide the list of all of the OIDs that the miniport adapter supports. This list must contain all of the mandatory OIDs and should contain optional and custom OIDs, if any.

NDIS maps the supported OIDs to WMI GUIDs and registers the GUIDs with WMI. NDIS translates WMI GUID requests to OID requests, if necessary, for the registered OIDs.

NDIS drivers can also register custom GUIDs with WMI. For more information about custom GUIDs, see Customized OIDs and Status Indications.

NDIS also translates status indications to WMI events. For more information about translating status indications to WMI events, see Standard Miniport Driver Status Registered with WMI.

Standard Miniport Driver Status Indications Registered with WMI

Article • 12/15/2021

NDIS automatically registers GUIDs with WMI for the NDIS status indications that miniport drivers indicate with the **NdisMIndicateStatusEx** or **NdisMCoIndicateStatusEx** function. For a list of general status indications, see Status Indications.

If a WMI client registers with WMI to receive an NDIS WMI event, NDIS translates the corresponding NDIS status indication to the WMI event and reports the event to all of the WMI clients that registered for the event.

NDIS drivers can also generate custom status indications. For more information about custom status indications and WMI, see Customized OIDs and Status Indications.

Customized OIDs and Status Indications

Article • 12/15/2021

You can create a custom OID that NDIS maps to a custom GUID that you create. NDIS registers the custom GUID with WMI for the miniport driver so that WMI clients can query or set the associated information.

To provide a custom status indication, NDIS miniport drivers must use the NDIS_STATUS_MEDIA_SPECIFIC_INDICATION_EX status indication. The WMI clients must use the data that is included with the WMI event to identify the custom event. NDIS does not register custom GUIDs for status indications.

To obtain a miniport adapter's custom OIDs and the associated WMI GUIDs, NDIS issues OID requests to the miniport driver after the miniport driver has completed initialization. NDIS issues an OID_GEN_SUPPORTED_LIST query to obtain the list of the OIDs that the miniport driver supports. The miniport driver includes both custom OIDs and standard OIDs in its response. To obtain the GUIDs that are associated with the custom OIDs, NDIS issues an OID_GEN_SUPPORTED_GUIDS query to connectionless miniport drivers or an OID_GEN_CO_SUPPORTED_GUIDS query to connection-oriented miniport drivers.

The query to OID_GEN_SUPPORTED_GUIDS or OID_GEN_CO_SUPPORTED_GUIDS returns an array of NDIS_GUID structures to NDIS. Each NDIS_GUID structure maps a custom GUID to a custom OID.

To support custom OIDs and status indications, you must fill in NDIS_GUID structures. You must also create a managed object format (MOF) file that describes the GUID and build this file with the miniport driver.

This section includes:

Filling in an NDIS_GUID Structure

Including a MOF File

Filling in an NDIS_GUID Structure

Article • 03/14/2023

An NDIS_GUID structure is defined as follows:

```C++
typedef struct _NDIS_GUID {
  GUID  Guid;
  union {
    NDIS_OID  Oid;
    NDIS_STATUS  Status;
  };
  ULONG  Size;
  ULONG  Flags;
} NDIS_GUID, *PNDIS_GUID;
```

To obtain a GUID for the **Guid** member of the structure, you can run the Uuidgen.exe application. For more information about this application, see Generating Interface UUIDs.

The **Oid** or **Status** member is a ULONG that is an OID code. NDIS 6.0 does not map custom status indications to WMI GUIDs.

If the NDIS_GUID structure maps an OID that returns an array of data items, the **Size** member specifies the size, in bytes, of each data item in the array. If the data is not an array, the **Size** member specifies the size of the data. If the size of the data items is variable, or if the OID does not return data, the **Size** member must be -1.

A bitwise OR of the following values for the **Flags** member indicates the type of data that is associated with the GUID:

fNDIS_GUID_TO_OID
When this flag is set, the NDIS_GUID structure maps a GUID to an OID.

fNDIS_GUID_TO_STATUS
Reserved for NDIS. Miniport drivers should not use this flag.

fNDIS_GUID_ANSI_STRING
When this flag is set, a null-terminated ANSI string is supplied for the GUID.

fNDIS_GUID_UNICODE_STRING
When this flag is set, a Unicode string is supplied for the GUID.

fNDIS_GUID_ARRAY
When this flag is set, an array of data items is supplied for the GUID. The specified **Size** value indicates the length of each data item in the array.

fNDIS_GUID_ALLOW_READ
When this flag is set, all users are allowed to use this GUID to obtain information.

fNDIS_GUID_ALLOW_WRITE
When this flag is set, all users are allowed to use this GUID to set information.

Note By default, custom WMI GUIDs that a miniport driver supplies are accessible only to users with administrator privileges. A user with administrator privileges can always read or write to a custom GUID if the miniport driver supports the read or write operation for that GUID. You can set the fNDIS_GUID_ALLOW_READ and fNDIS_GUID_ALLOW_WRITE flags to allow all users to access a custom GUID.

Note that for all custom GUIDs that a driver registers, the driver must set fNDIS_GUID_TO_OID. Miniport drivers should never set fNDIS_GUID_TO_STATUS. All of the other flags can be combined by using a bitwise OR operation.

Including a MOF File

Article • 12/15/2021

You must include a description of all of the custom GUIDs that map to a miniport driver's custom OIDs in a managed object format (MOF) file that must be compiled and included in the miniport driver's resource (*.rc) file.

The MOF source file must be of type MOFDATA and must have an extension of .mof. You must compile the MOF source file into a binary file with Mofcomp.exe and must check this file with Wmimofck.exe.

You must insert the following line in the miniport driver's resource file (*.rc) to include the MOF binary:

Text

```
NdisMofResource MOFDATA filename.bmf
```

FileName represents the file name of the MOF source file.

GUID_NDIS_STATUS_LINK_STATE

Article • 03/14/2023

The GUID_NDIS_STATUS_LINK_STATE event GUID indicates that there has been a change in the link state of a miniport adapter. This WMI GUID is supported in NDIS 6.0 and later versions.

Miniport drivers use the NDIS_STATUS_LINK_STATE status indication to notify NDIS and overlying drivers that there has been a change in link state.

When a miniport driver indicates a link state change, NDIS translates the status indication to a WMI GUID_NDIS_STATUS_LINK_STATE event for WMI clients.

The data buffer that NDIS provides with the GUID contains an NDIS_WMI_EVENT_HEADER structure that is followed by an NDIS_LINK_STATE structure. The **NDIS_LINK_STATE** structure specifies the physical state of the medium.

For more information about link status, see OID_GEN_LINK_STATE and NDIS_STATUS_LINK_STATE.

GUID_NDIS_STATUS_OPER_STATUS

Article • 03/14/2023

The GUID_NDIS_STATUS_OPER_STATUS event GUID indicates the current operational state of an NDIS network interface. This WMI GUID is supported in NDIS 6.0 and later versions.

NDIS generates an NDIS_STATUS_OPER_STATUS status indication to report the current operational state of an NDIS network interface.

When NDIS indicates a change in the current operational state of an NDIS network interface, NDIS also translates the status indication to a WMI GUID_NDIS_STATUS_OPER_STATUS event for WMI clients.

The data buffer that NDIS provides with the GUID contains an NDIS_WMI_EVENT_HEADER structure that is followed by an NDIS_OPER_STATE structure. For a list of the possible values, see NDIS_STATUS_OPER_STATUS.

GUID_NDIS_STATUS_NETWORK_CHANGE

Article • 03/14/2023

The GUID_NDIS_STATUS_NETWORK_CHANGE event GUID indicates that the layer-three addresses must be renegotiated. This WMI GUID is supported in NDIS 6.0 and later versions.

NDIS or a miniport driver can generate an NDIS_STATUS_NETWORK_CHANGE status indication to report a change in network status.

When miniport drivers or NDIS indicate a change in the network status, NDIS translates the status indication to a WMI GUID_NDIS_STATUS_NETWORK_CHANGE event for WMI clients.

The data buffer that NDIS provides with this GUID contains an NDIS_WMI_EVENT_HEADER structure that is followed by an NDIS_NETWORK_CHANGE_TYPE-typed value. For a list of the possible values, see NDIS_STATUS_NETWORK_CHANGE.

GUID_NDIS_STATUS_PACKET_FILTER

Article • 03/14/2023

The GUID_NDIS_STATUS_PACKET_FILTER event GUID indicates that there has been a change in the packet filter for miniport adapter. This WMI GUID is supported in NDIS 6.0 and later versions.

NDIS generates the NDIS_STATUS_PACKET_FILTER status indication to notify overlying drivers that there might be a change in the packet filter configuration.

NDIS translates the status indication to a WMI GUID_NDIS_STATUS_PACKET_FILTER event for WMI clients.

The data buffer that NDIS provides with the GUID contains an NDIS_WMI_EVENT_HEADER structure that is followed by a ULONG value. For more information about packet filter status and the possible values, see OID_GEN_CURRENT_PACKET_FILTER.

GUID_NDIS_STATUS_MEDIA_SPECIFIC_INDICATION_EX

Article • 03/14/2023

The GUID_NDIS_STATUS_MEDIA_SPECIFIC_INDICATION_EX event GUID indicates a media-specific status. This WMI GUID is supported in NDIS 6.0 and later versions.

When a miniport driver indicates media-specific status, NDIS translates the status indication to a WMI GUID_NDIS_STATUS_MEDIA_SPECIFIC_INDICATION_EX indication for WMI clients.

Miniport drivers make media-specific status indications by calling the NdisMIndicateStatusEx function with the **StatusCode** member of the NDIS_STATUS_INDICATION structure that the *StatusIndication* parameter points to set to NDIS_STATUS_MEDIA_SPECIFIC_INDICATION_EX. The **StatusBuffer** member of this structure points to a driver-allocated buffer that contains data in a format that is specific to the status indication that is identified in **StatusCode**.

Depending on the type of media-specific indication, the GUID header could be followed by data that is specific to the media-specific indication. The data buffer that NDIS provides with this GUID contains an NDIS_WMI_EVENT_HEADER structure that is followed by the media-specific data, if any.

GUID_NDIS_GEN_LINK_STATE

Article • 03/14/2023

WMI clients can use the GUID_NDIS_GEN_LINK_STATE method GUID to determine the current link state. This WMI GUID is supported in NDIS 6.0 and later versions.

NDIS handles this GUID and miniport drivers do not receive an OID query.

When a WMI client issues a GUID_NDIS_GEN_LINK_STATE WMI method request, NDIS returns the current link state for the miniport adapter or NDIS port.

The WMI method identifier should be NDIS_WMI_DEFAULT_METHOD_ID, and the WMI input buffer should contain an NDIS_WMI_METHOD_HEADER structure.

The data buffer that NDIS returns with this GUID contains an NDIS_LINK_STATE structure.

Miniport drivers supply the link state during initialization and provide updates with status indications. WMI clients can use the GUID_NDIS_GEN_LINK_STATE GUID to receive updates when the link state changes.

For more information about link status, see OID_GEN_LINK_STATE and NDIS_STATUS_LINK_STATE.

GUID_NDIS_GEN_STATISTICS

Article • 03/14/2023

WMI clients can use the GUID_NDIS_GEN_STATISTICS method GUID to obtain miniport adapter statistics. This WMI GUID is supported in NDIS 6.0 and later versions.

When a WMI client issues a GUID_NDIS_GEN_STATISTICS WMI method request, NDIS returns the current statistics for the miniport adapter or NDIS port. The WMI method identifier should be NDIS_WMI_DEFAULT_METHOD_ID, and the WMI input buffer should contain an NDIS_WMI_METHOD_HEADER structure.

NDIS uses the OID_GEN_STATISTICS OID to obtain the statistics for a miniport adapter. This OID is mandatory for miniport drivers that support NDIS 6.0 and later versions. The statistics counters are unsigned 64-bit values. The miniport driver returns the statistics in an NDIS_STATISTICS_INFO structure.

The data buffer that NDIS returns with the GUID contains an NDIS_STATISTICS_INFO structure.

GUID_NDIS_STATUS_PORT_STATE

Article • 03/14/2023

The GUID_NDIS_STATUS_PORT_STATE event GUID indicates a change in the state of an NDIS port. This WMI GUID is supported in NDIS 6.0 and later versions.

Miniport drivers that support NDIS ports use the NDIS_STATUS_PORT_STATE status indication to indicate changes in the state of an NDIS port.

When a miniport driver indicates a port state change, NDIS translates the status indication to a WMI GUID_NDIS_STATUS_PORT_STATE event for WMI clients.

The data buffer that NDIS provides with this GUID contains an NDIS_WMI_EVENT_HEADER structure that is followed by an NDIS_PORT_STATE structure.

For more information about the port state, see OID_GEN_PORT_STATE.

GUID_NDIS_GEN_PORT_STATE

Article • 03/14/2023

WMI clients can use the GUID_NDIS_GEN_PORT_STATE method GUID to obtain the state of an NDIS port. This WMI GUID is supported in NDIS 6.0 and later versions.

GUID_NDIS_GEN_PORT_STATE requires a WMI method request to return the state of an NDIS port. The WMI method identifier should be NDIS_WMI_DEFAULT_METHOD_ID, and the WMI input buffer should contain an NDIS_WMI_METHOD_HEADER structure.

NDIS handles this GUID, and miniport drivers do not receive an OID query.

The data buffer that NDIS returns with the GUID contains an NDIS_PORT_STATE structure.

For more information about the port state, see OID_GEN_PORT_STATE.

GUID_NDIS_GEN_ENUMERATE_PORTS

Article • 03/14/2023

WMI clients can use the GUID_NDIS_GEN_ENUMERATE_PORTS method GUID to obtain list of the ports that are associated with a miniport adapter. This WMI GUID is supported in NDIS 6.0 and later versions.

NDIS handles this request, and miniport drivers do not receive an OID query.

GUID_NDIS_GEN_ENUMERATE_PORTS requires a WMI method request to enumerate the ports. The WMI method identifier should be NDIS_WMI_DEFAULT_METHOD_ID. The WMI input buffer should contain an NDIS_WMI_METHOD_HEADER structure that identifies the NDIS network interface name for the miniport adapter in the **NetLuid** member and that specifies zero for the **PortNumber** member. WMI clients can obtain the **NetLuid** value of the adapter with the GUID_NDIS_ENUMERATE_ADAPTERS_EX method GUID.

The data buffer that NDIS returns with the GUID contains an NDIS_PORT_ARRAY structure. The **NumberOfPorts** member of NDIS_PORT_ARRAY contains the number of active ports that are associated with the miniport adapter. The **Ports** member of NDIS_PORT_ARRAY contains a list of pointers to NDIS_PORT_CHARACTERISTICS structures. Each NDIS_PORT_CHARACTERISTICS structure defines the characteristics of a single NDIS port.

For more information about enumerating ports, see OID_GEN_ENUMERATE_PORTS.

GUID_NDIS_GEN_PORT_AUTHENTICATION_PARAMETERS

Article • 03/14/2023

WMI clients can use the GUID_NDIS_GEN_PORT_AUTHENTICATION_PARAMETERS set GUID to set the port authentication parameters for an NDIS port. This WMI GUID is supported in NDIS 6.0 and later versions.

NDIS translates this GUID to the OID_GEN_PORT_AUTHENTICATION_PARAMETERS OID to set the current authentication configuration of an NDIS port. Miniport drivers that support NDIS ports must support this OID.

The WMI input buffer specifies an NDIS_WMI_SET_HEADER structure that is followed by an NDIS_PORT_AUTHENTICATION_PARAMETERS structure.

For more information about port parameters, see OID_GEN_PORT_AUTHENTICATION_PARAMETERS.

GUID_NDIS_GEN_LINK_PARAMETERS

Article • 03/14/2023

WMI clients can use the GUID_NDIS_GEN_LINK_PARAMETERS set GUID to set the link parameters for a miniport adapter. This WMI GUID is supported in NDIS 6.0 and later versions.

NDIS translates this GUID to the OID_GEN_LINK_PARAMETERS OID to set the current link parameters of a miniport adapter. This OID is mandatory for miniport drivers that support NDIS 6.0 and later versions.

The WMI input buffer specifies the data that NDIS should set. The input buffer contains an NDIS_WMI_SET_HEADER structure that is followed by an NDIS_LINK_PARAMETERS structure.

GUID_NDIS_ENUMERATE_ADAPTERS_EX

Article • 03/14/2023

WMI clients can use the GUID_NDIS_ENUMERATE_ADAPTERS_EX GUID to obtain an enumeration of all of the miniport adapters on the computer. This WMI GUID is supported in NDIS 6.0 and later versions. Because NDIS tracks all of the loaded miniport adapters, NDIS does not query miniport drivers for this information.

WMI clients can use this GUID to find a device name and the associated value in the **NetLuid** member of the NDIS_WMI_ENUM_ADAPTER structure. WMI clients can use the **NetLuid** value of the adapter in subsequent GUID requests.

The data buffer that NDIS returns with the GUID contains array of NDIS_WMI_ENUM_ADAPTER structures.

GUID_NDIS_GEN_INTERRUPT_MODERATION

Article • 03/14/2023

WMI clients can use the GUID_NDIS_GEN_INTERRUPT_MODERATION method GUID to obtain the interrupt moderation parameters that are associated with the specified port of a miniport adapter.

This GUID requires a WMI method request to return the interrupt moderation parameters. The WMI method identifier should be NDIS_WMI_DEFAULT_METHOD_ID, and the WMI input buffer should contain an NDIS_WMI_METHOD_HEADER structure.

NDIS translates this GUID to an OID_GEN_INTERRUPT_MODERATION query request for the associated miniport adapter. This OID is mandatory for miniport drivers that support NDIS 6.0 and later versions.

The data buffer that NDIS returns with the GUID contains an NDIS_INTERRUPT_MODERATION_PARAMETERS structure.

For more information about the port state, see OID_GEN_INTERRUPT_MODERATION.

GUID_NDIS_GEN_INTERRUPT_MODERATION_PARAMETERS

Article • 03/14/2023

WMI clients can use the GUID_NDIS_GEN_PORT_PARAMETERS set GUID to set the interrupt moderation configuration for a miniport adapter. This WMI GUID is supported in NDIS 6.0 and later versions.

NDIS translates this GUID to the OID_GEN_INTERRUPT_MODERATION OID to set the current configuration. All NDIS miniport drivers must support this OID.

The WMI input buffer contains an NDIS_WMI_SET_HEADER structure that is followed by an NDIS_INTERRUPT_MODERATION_PARAMETERS structure.

For more information about port parameters, see OID_GEN_INTERRUPT_MODERATION.

GUID_NDIS_TCP_OFFLOAD_CAPABILITIES

Article • 03/14/2023

WMI clients can use the GUID_NDIS_TCP_OFFLOAD_CAPABILITIES method GUID to obtain the task offload capabilities that are associated with the specified port of a miniport adapter.

This GUID requires a WMI method request to return the offload capabilities of an NDIS port. The WMI method identifier should be NDIS_WMI_DEFAULT_METHOD_ID, and the WMI input buffer should contain an NDIS_WMI_METHOD_HEADER structure.

NDIS handles this GUID, and miniport drivers do not receive an OID query.

The data buffer that NDIS returns with the GUID contains an NDIS_OFFLOAD structure.

For more information about the port state, see OID_TCP_OFFLOAD_CURRENT_CONFIG.

GUID_NDIS_TCP_OFFLOAD_HW_CAPABILITIES

Article • 03/14/2023

WMI clients can use the GUID_NDIS_TCP_OFFLOAD_HW_CAPABILITIES method GUID to obtain the TCP offload capabilities that are supported by the hardware that is associated with the specified port of a miniport adapter.

This GUID requires a WMI method request to return the hardware capabilities of an NDIS port. The WMI method identifier should be NDIS_WMI_DEFAULT_METHOD_ID, and the WMI input buffer should contain an NDIS_WMI_METHOD_HEADER structure.

NDIS handles this GUID, and miniport drivers do not receive an OID query.

The data buffer that NDIS returns with the GUID contains an NDIS_OFFLOAD structure.

For more information about the port state, see OID_TCP_OFFLOAD_HARDWARE_CAPABILITIES.

GUID_NDIS_TCP_OFFLOAD_ADMIN_SETTINGS

Article • 03/14/2023

WMI clients can use the GUID_NDIS_TCP_OFFLOAD_ADMIN_SETTINGS set GUID to set the offload configuration parameters for an NDIS port. This WMI GUID is supported in NDIS 6.0 and later versions.

NDIS translates this GUID to the OID_TCP_OFFLOAD_PARAMETERS OID to set the current configuration of an NDIS port. NDIS miniport drivers that provide any kind of support for task offload must support this OID.

The WMI input buffer contains an NDIS_WMI_SET_HEADER structure that is followed by an NDIS_OFFLOAD_PARAMETERS structure.

For more information about port parameters, see OID_TCP_OFFLOAD_PARAMETERS.

GUID_NDIS_STATUS_OFFLOAD_CAPABILITIES_CHANGE

Article • 03/14/2023

The GUID_NDIS_STATUS_OFFLOAD_CAPABILITIES_CHANGE event GUID indicates that there has been a change in the offload characteristics of an NDIS port or miniport adapter. This WMI GUID is supported in NDIS 6.0 and later versions.

Miniport drivers use the NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG status indication to notify NDIS and overlying drivers that there has been a change in task offload capabilities.

When a miniport driver indicates a task offload change, NDIS translates the status indication to a WMI GUID_NDIS_STATUS_OFFLOAD_CAPABILITIES_CHANGE event for WMI clients.

The data buffer that NDIS provides with the GUID contains an NDIS_WMI_EVENT_HEADER structure that is followed by an NDIS_OFFLOAD structure.

For more information about task offload capabilities, see NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG and OID_TCP_OFFLOAD_CURRENT_CONFIG.

GUID_NDIS_STATUS_OFFLOAD_HW_CAPABILITIES

Article • 03/14/2023

The GUID_NDIS_STATUS_OFFLOAD_HW_CAPABILITIES event GUID indicates that there has been a change in the offload characteristics of the hardware that is associated with an NDIS port or miniport adapter. The hardware change typically reflects adding or deleting hardware that is associated with an MUX intermediate driver. This WMI GUID is supported in NDIS 6.0 and later versions.

MUX intermediate drivers use the NDIS_STATUS_TASK_OFFLOAD_HARDWARE_CAPABILITIES status indication to notify NDIS and overlying drivers that there has been a change in task offload capabilities.

When the driver indicates a task offload hardware change, NDIS translates the status indication to a WMI GUID_NDIS_STATUS_OFFLOAD_HW_CAPABILITIES event for WMI clients.

The data buffer that NDIS provides with the GUID contains an NDIS_WMI_EVENT_HEADER structure that is followed by an NDIS_OFFLOAD structure.

For more information about task offload capabilities, see NDIS_STATUS_TASK_OFFLOAD_HARDWARE_CAPABILITIES and OID_TCP_OFFLOAD_HARDWARE_CAPABILITIES.

Overview of NDIS MSI-X

Article • 03/14/2023

Message-signaled interrupts (MSIs) provide an alternative to traditional line-based interrupts that network devices and their miniport drivers can use. Starting with Windows Vista, the operating system supports two types of MSIs: PCI V2.2 MSI and PCI V3.0 MSI-X.

Miniport drivers that support MSI-X can specify an *interrupt affinity*, which is a subset of central processing units (CPUs) that the drivers' message interrupt service routines run on. You can specify the interrupt affinity for each MSI-X message--for example, you can specify interrupt affinities on computers with Non-Uniform Memory Access (NUMA) architecture in terms of the "nearness" of their device to certain CPUs.

MSI-X support can provide significant performance benefits, especially for network interface cards (NICs) that support receive side scaling (RSS). For more information about receive side scaling, see Receive Side Scaling.

For more information about line-based interrupts, see Managing Interrupts.

Handling an MSI Interrupt

Synchronizing with an MSI Interrupt

Changing the CPU Affinity of MSI-X Table Entries

MSI-X Initialization

Article • 12/15/2021

To support MSI-X, MSI initialization requires a pre-registration phase in which the miniport driver establishes a function that filters resource-requirements. This function can change the interrupt affinity for each MSI-X message or remove message interrupt resources if the driver will register for line-based interrupts in the *MiniportInitializeEx* function.

The pre-registration phase occurs before NDIS calls the *MiniportInitializeEx* function. As with line-based interrupts, miniport drivers also register MSI interrupts while initializing miniport adapters in *MiniportInitializeEx*.

This section includes:

MSI-X Pre-Registration

MSI-X Resource Filtering

Registering and Deregistering an MSI Interrupt

MSI-X Pre-Registration

Article • 12/15/2021

To support changing interrupt affinities for MSI-X or to remove message interrupt resources, a miniport driver must establish a resource-requirements filter function. This pre-registration step occurs before NDIS calls the *MiniportInitializeEx* function.

To establish a resource-requirements filter function, the miniport driver must provide a *MiniportSetOptions* function. When the miniport driver calls the **NdisMRegisterMiniportDriver** function from the **DriverEntry** routine, the driver passes the entry point for *MiniportSetOptions* in the **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** structure. NDIS calls the *MiniportSetOptions* function in the context of **NdisMRegisterMiniportDriver**.

From *MiniportSetOptions*, the miniport driver calls the **NdisSetOptionalHandlers** function and specifies an **NDIS_MINIPORT_PNP_CHARACTERISTICS** structure. This structure defines the entry points for the *MiniportAddDevice*, *MiniportRemoveDevice*, *MiniportStartDevice*, and *MiniportFilterResourceRequirements* functions.

When NDIS receives an add-device request from the Plug and Play (PnP) manager, NDIS calls the miniport driver's *MiniportAddDevice* function. The handle that NDIS passes to *MiniportAddDevice* in the *MiniportAdapterHandle* parameter is the handle that NDIS later passes to the *MiniportInitializeEx* function.

In *MiniportAddDevice*, the driver initializes an **NDIS_MINIPORT_ADD_DEVICE_REGISTRATION_ATTRIBUTES** structure and passes this structure to the **NdisMSetMiniportAttributes** function. The NDIS_MINIPORT_ADD_DEVICE_REGISTRATION_ATTRIBUTES structure contains the **MiniportAddDeviceContext** member that is a handle to a miniport driver-allocated context area for the device. NDIS later provides this context handle to the *MiniportRemoveDevice*, *MiniportFilterResourceRequirements*, *MiniportStartDevice*, and *MiniportInitializeEx* functions. For *MiniportInitializeEx*, the context handle is passed in the **MiniportAddDeviceContext** member of the **NDIS_MINIPORT_INIT_PARAMETERS** structure that the *MiniportInitParameters* parameter points to.

After NDIS calls *MiniportAddDevice* and *MiniportAddDevice* returns NDIS_STATUS_SUCCESS, NDIS calls the *MiniportFilterResourceRequirements* function every time that it receives the **IRP_MN_FILTER_RESOURCE_REQUIREMENTS** I/O request packet (IRP). *MiniportFilterResourceRequirements* can change the interrupt affinity for each MSI-X message, add message interrupt resources, or remove message interrupt resources if the driver will register for line-based interrupts in the *MiniportInitializeEx* function. For more information about establishing an interrupt affinity policy, see MSI-X Resource Filtering.

When NDIS receives a remove-device request from the PnP manager, NDIS calls the miniport driver's *MiniportRemoveDevice* function. The *MiniportRemoveDevice* function should undo the operations that the *MiniportAddDevice* function performed.

MSI-X Resource Filtering

Article • 12/15/2021

Miniport drivers must register a resource-requirements filter function if they support MSI-X and will change the interrupt affinity for each MSI-X message or will remove message interrupt resources.

NDIS calls the *MiniportFilterResourceRequirements* function after NDIS receives the **IRP_MN_FILTER_RESOURCE_REQUIREMENTS** I/O request packet (IRP) for a network interface card (NIC). NDIS calls *MiniportFilterResourceRequirements* after the underlying function drivers in the device stack have completed the IRP.

NDIS will call *MiniportFilterResourceRequirements* after the *MiniportAddDevice* function returns NDIS_STATUS_SUCCESS. NDIS may call *MiniportFilterResourceRequirements* again at any time before calling *MiniportRemoveDevice*. NDIS may call *MiniportFilterResourceRequirements* while the miniport is running. While the miniport may modify the resource list as described below, the miniport should not immediately attempt to use the new resources. NDIS will eventually halt and re-initialize the miniport with the new resources; only then should the miniport attempt to use the new resources.

IRP_MN_FILTER_RESOURCE_REQUIREMENTS provides a resource list as an **IO_RESOURCE_REQUIREMENTS_LIST** structure at **Irp->IoStatus.Information**. The resources in the list are described by **IO_RESOURCE_DESCRIPTOR** structures.

A miniport driver can modify the interrupt affinity policy for each resource of type **CmResourceTypeInterrupt** that describes an MSI-X message. If an affinity policy requests targeting for a specific set of processors, the miniport driver also sets a **KAFFINITY** mask at **Interrupt.TargetedProcessors** in the IO_RESOURCE_DESCRIPTOR structure.

A miniport driver can remove all resources of type **CmResourceTypeInterrupt** that are message interrupt resources. The driver can then register for line-based interrupts in the *MiniportInitializeEx* function. If the miniport driver does not remove these message interrupt resources, the operating system will fail if the driver tries to register line-based interrupts in *MiniportInitializeEx*.

An NDIS 6.1 or later miniport driver can add message interrupt resources to the resources list. For example on a computer with eight CPUs, if the NIC can generate four MSI-X messages and if the operating system enables the four message interrupts, the operating system initializes four message table entries in the device's MSI-X configuration space and puts four message interrupt resources in the resources list. In this case, because the miniport driver requires more message interrupt resources, it can allocate four more message interrupt resources to the resources list and set the affinity of each MSI-X message to a CPU. If the operating system can provide more message interrupt resources, the miniport adapter receives eight message interrupt resources when it is started. In this case, the messages have numbers from 0 through 7.

Each message interrupt resource in the list is assigned a message number later that corresponds to the order it shows in the list. For example, the first message interrupt resources in the list is assigned to message 0, the second one is assigned to message 1, and so on.

To assign an MSI-X table entry to a CPU at run time, the miniport driver can call the **NdisMConfigMSIXTableEntry** function, which maps a table entry to an MSI-X message that already has the affinity set to the CPU. For more information about configuration operations for MSI-X table entries, see Changing the CPU Affinity of MSI-X Table Entries.

To allocate memory for a new resource-requirements list, use the **NdisAllocateMemoryWithTagPriority** function. You can free the memory for the old resources-requirement list with the **NdisFreeMemory** function.

Miniport drivers should not modify other resources, such as **CmResourceTypeMemory** and **CmResourceTypePort** resources. Miniport drivers should avoid adding a new resource to the resource list. However, NDIS 6.1 and later miniport drivers can add more message interrupt resources. If the miniport driver adds more message interrupt resources, it must not remove them from the *MiniportStartDevice* function.

For more information about adding and removing resources, see **IRP_MN_FILTER_RESOURCE_REQUIREMENTS**.

Registering and Deregistering an MSI Interrupt

Article • 12/15/2021

To register for MSI support, a miniport driver calls the NdisMRegisterInterruptEx function to register an MSI interrupt. The driver allocates and initializes an NDIS_MINIPORT_INTERRUPT_CHARACTERISTICS structure to specify the interrupt characteristics and function entry points. The driver must set the **MsiSupported** member of the NDIS_MINIPORT_INTERRUPT_CHARACTERISTICS structure to **TRUE**. The driver then passes the structure to **NdisMRegisterInterruptEx**.

You must define the following functions to support MSI interrupts:

- *MiniportMessageInterrupt*
- *MiniportMessageInterruptDpc*
- *MiniportDisableMessageInterrupt*
- *MiniportEnableMessageInterrupt*

The miniport driver should provide entry points for the line-based interrupt functions (which are shown in the following list), even if the driver supports the MSI entry points. If NDIS does not grant an MSI interrupt, it can grant a normal interrupt as a fallback condition.

The line-interrupt functions include the following:

- *MiniportInterrupt*
- *MiniportInterruptDPC*
- *MiniportDisableInterruptEx*
- *MiniportEnableInterruptEx*

Drivers should call the NdisMDeregisterInterruptEx function to release resources that were previously allocated with **NdisMRegisterInterruptEx**.

Handling an MSI Interrupt

Article • 12/15/2021

NDIS calls the *MiniportMessageInterrupt* function when a network interface card (NIC) generates an interrupt. The *MessageId* parameter in this function identifies the MSI-X message.

MiniportMessageInterrupt should always return **TRUE** after processing the interrupt because message interrupts are not shared.

A miniport driver should do as little work as possible in its *MiniportMessageInterrupt* function. The driver should defer I/O operations to the *MiniportMessageInterruptDpc* function, which NDIS calls to complete the deferred processing of an interrupt.

To queue additional deferred procedure calls (DPCs) after *MiniportMessageInterrupt* returns, the miniport driver sets the bits of the *TargetProcessors* parameter of the *MiniportMessageInterrupt* function. To request additional DPCs from *MiniportMessageInterrupt* or *MiniportMessageInterruptDPC*, the miniport driver can call the **NdisMQueueDpc** function.

The miniport driver can call **NdisMQueueDpc** to request additional DPCs for other processors.

NDIS 6.1 and later versions guarantees that DPCs for different messages that are scheduled for the same CPU are queued separately. For example, if a miniport driver schedules two DPCs at the same time on CPU 1 (one DPC for message 0 and the other DPC for message 1), two DPCs are queued for CPU 1 (one DPC with message 0 and the other DPC with message 1).

NDIS also guarantees that DPCs for the same message that are scheduled on different CPUs are queued separately. For example, if a miniport driver schedules two DPCs (one DPC on CPU 0 for message 0 and one DPC on CPU 1 for message 0), two separate DPCs are queued on CPU 0 and CPU 1, both for message 0.

Synchronizing with an MSI Interrupt

Article • 12/15/2021

If a miniport driver's *MiniportMessageInterrupt* function shares resources, such as network interface card (NIC) registers or state variables, with another *MiniportXxx* function that runs at a lower IRQL, the other *MiniportXxx* function must call the **NdisMSynchronizeWithInterruptEx** function. This call ensures that the miniport driver's **MiniportSynchronizeMessageInterrupt** function accesses the shared resources in a synchronized and multiprocessor-safe manner.

Changing the CPU Affinity of MSI-X Table Entries

Article • 12/15/2021

NDIS 6.1 and later miniport drivers that support MSI-X can call the **NdisMConfigMSIXTableEntry** function to mask, unmask, or map MSI-X table entries to device-assigned MSI-X messages. Miniport drivers that support RSS use **NdisMConfigMSIXTableEntry** to change the CPU affinity of MSI-X table entries at run time.

NdisMConfigMSIXTableEntry is a wrapper around the GUID_MSIX_TABLE_CONFIG_INTERFACE query. Miniport drivers can call **NdisMConfigMSIXTableEntry** after NDIS calls the *MiniportInitializeEx* function and before the drivers return from the *MiniportHaltEx* function.

A miniport driver that assigns an MSI-X table entry for each RSS queue and has fewer queues than the number of RSS processors can add additional MSI-X message resources in the *MiniportFilterResourceRequirements* function. For more information about how to modify assigned resources for a device, see MSI-X Resource Filtering.

The miniport driver can set the CPU affinity of MSI-X interrupt resources so that the device has at least one MSI-X message for each RSS processor. Note that the PCI bus driver initially maps the *n* MSI-X table entries (where *n* is the number of MSI-X table entries that the NIC hardware reported to the bus) to the first *n* MSI-X messages in modified resources. After NDIS calls *MiniportInitializeEx*, when the miniport driver changes the target processor of a particular MSI-X table entry, the driver calls **NdisMConfigMSIXTableEntry** to map that table entry to an MSI-X message that already has the affinity set to the desired processor.

NDIS Scatter/Gather DMA

Article • 03/14/2023

> ⊗ **Caution**
>
> For Arm and Arm64 processors, we strongly recommend that NDIS driver writers use WDF DMA or WDM DMA instead of NDIS Scatter/Gather DMA.
>
> For more information about WDF DMA, see **Handling DMA Operations in KMDF Drivers**.
>
> For more information about WDM DMA, see the DMA-related child topics of **Managing Input/Output for Drivers**.

NDIS miniport drivers can use the Scatter/Gather DMA (SGDMA) method to transfer data between a NIC and system memory. A successful DMA transfer requires the physical address of the data to be in an address range that the NIC supports. HAL provides a mechanism for drivers to obtain the physical address list for an MDL chain and, if necessary, will double-buffer the data to a physical address range.

In NDIS versions prior to NDIS 6.0, SGDMA support in miniport drivers and NDIS is limited in some respects, and in particular does not work well in a multipacket send scenario. The NDIS 6.0 SGDMA support overcomes these limitations while providing a simple interface for miniport drivers.

History of NDIS SGDMA

In NDIS versions prior to NDIS 6.0, NDIS obtains a scatter gather (SG) list for each packet before sending the packet to the miniport driver. NDIS also handles the case where the original attempt to get the SG list fails due to excessive fragmentation. In this case, NDIS double-buffers the packet to a contiguous buffer and tries again. HAL can also double-buffer the data to a physical address that the NIC supports if, for example, the physical address of the data is above the 32-bit maximum and the NIC does not support 64-bit DMA.

To avoid a deadlock situation, NDIS obtains a SG list for a packet, and sends one packet at a time. If NDIS attempts to map all the packets before sending them to the miniport driver, the system could run out resources. In this case, NDIS would be waiting for map registers to become available while some map registers are locked down for the packets that have not been sent. Locked down packets cannot be reused.

This approach to SGDMA support has the following limitations:

- Because the packet is mapped before it gets to the miniport driver, the driver cannot optimize for small packets or packets that are too fragmented. The miniport driver cannot double buffer the packet to a known physical address.
- There is no guarantee that the physical address array that NDIS passed to the miniport driver maps to the virtual address of the original data. Therefore, if the driver changes the data at the virtual address in the MDL chain before sending it, the modifications made to the data are not reflected in the data in the physical addresses. In this case, the NIC sends the unmodified data.
- NDIS is limited to sending one packet at a time to avoid a deadlock due to resource issues. This is not as efficient as sending multiple packets.
- Because NDIS cannot determine the transmit capabilities of miniport drivers, it cannot preallocate the storage for an SG list buffer. Therefore, NDIS must allocate the necessary storage at run time. This is not as efficient as preallocating the storage.
- HAL functions that allocate an SG list should be called at IRQL = DISPATCH_LEVEL. NDIS does not have the current IRQL information, so it has to set the IRQL to DISPATCH_LEVEL even if it is already at DISPATCH_LEVEL. This is not efficient if the IRQL is already at DISPATCH_LEVEL.

Benefits of NDIS SGDMA Support

In the NDIS 6.0 and later SGDMA interface, NDIS does not map the data buffer before sending it down to the miniport driver. Instead, NDIS provides an interface for the driver to map the network data.

This approach yields the following benefits:

- Since NDIS provides the interface to HAL for mapping the network data, NDIS shields miniport drivers from the complexity and details of the mapping process.
- Miniport drivers have access to the data before it is mapped. Therefore, any changes made to the original data are reflected in the data represented by the SG list even if NDIS or HAL double-buffers the data.
- Miniport drivers can optimize the transmission of small or highly fragmented packets by copying them to a preallocated buffer with a known physical address. This approach avoids mapping that is not required and therefore improves system performance.

- NDIS can send multiple buffers to the miniport driver safely. This results in fewer calls to miniport drivers and therefore improves system performance.
- Miniport drivers can preallocate the memory for an SG list as part of the transmit descriptor blocks. Therefore, NDIS or miniport drivers are not required to allocate memory for SG lists at run time.
- Because miniport drivers can be running at IRQL = DISPATCH_LEVEL, miniport drivers can avoid unnecessary calls to raise the IRQL to DISPATCH_LEVEL. For example, because completing a send happens in the context of an interrupt DPC, miniport drivers can free the SG list without raising the IRQL.

Registering and Deregistering DMA Channels

An NDIS miniport driver calls the **NdisMRegisterScatterGatherDma** function from its *MiniportInitializeEx* function to register a DMA channel with NDIS.

The miniport driver passes a DMA description to **NdisMRegisterScatterGatherDma** in the *DmaDescription* parameter. **NdisMRegisterScatterGatherDma** returns a size for the buffer that should be large enough to hold the scatter/gather list. Miniport drivers should use this size to preallocate the storage for scatter/gather lists.

The miniport driver also passes **NdisMRegisterScatterGatherDma** the entry points for the *MiniportXxx* functions that NDIS calls to process the scatter/gather list. NDIS calls the miniport driver's *MiniportProcessSGList* function after HAL has built the scatter/gather list for a buffer. **NdisMRegisterScatterGatherDma** supplies a handle in the *pNdisMiniportDmaHandle* parameter, which the miniport driver must use in subsequent calls to NDIS scatter/gather DMA functions.

An NDIS miniport driver calls the **NdisMDeregisterScatterGatherDma** function from its *MiniportHaltEx* function to release scatter/gather DMA resources.

Allocating and Freeing Scatter/Gather Lists

An NDIS miniport driver calls the **NdisMAllocateNetBufferSGList** function in its *MiniportSendNetBufferLists* function. The miniport driver calls **NdisMAllocateNetBufferSGList** once for each **NET_BUFFER** structure that it must map. After the resources become available and HAL has the SG list ready, NDIS calls the driver's *MiniportProcessSGList* function. NDIS can call *MiniportProcessSGList* before or after the miniport driver's call to **NdisMAllocateNetBufferSGList** returns.

To improve system performance, the scatter/gather list is generated from the network data starting at the beginning of the MDL that is specified at the **CurrentMdl** member of the associated NET_BUFFER_DATA structure. The start of the network data in the SG list is offset from the beginning of the SG list by the value specified in the **CurrentMdlOffset** member of the associated **NET_BUFFER_DATA** structure.

While handling a DPC for a send-complete interrupt, and after the miniport driver does not need the SG list any more, the miniport driver should call the NdisMFreeNetBufferSGList function to free the SG list.

Note Do not call NdisMFreeNetBufferSGList while the driver or hardware is still accessing the memory that is described by the NET_BUFFER structure that is associated with the scatter/gather list.

Before accessing received data, miniport drivers must call NdisMFreeNetBufferSGList to flush the memory cache.

Exporting a MiniportDevicePnPEventNotify Function

Article • 12/15/2021

NDIS calls a miniport driver's *MiniportDevicePnPEventNotify* function to notify the miniport driver of the following Plug and Play (PnP) events:

- The surprise removal of a NIC that the miniport driver controls.

- A change in the system's power source.

If a miniport driver does not export a *MiniportDevicePnPEventNotify* function, NDIS cannot notify the driver of these PnP events.

All NDIS 6.0 and later miniport drivers *must* export a *MiniportDevicePnPEventNotify* function. In addition, all miniport drivers that have a WDM lower edge *should* export a *MiniportDevicePnPEventNotify* function.

Handling the Surprise Removal of a NIC

Article • 12/15/2021

A surprise removal occurs when a user removes a network interface card (NIC) from a running system without notifying the system beforehand through the user interface (UI).

Miniport drivers for Windows Vista and later versions of the operating system should be able to handle surprise removals. In particular, NDIS miniport drivers with a Windows Driver Model (WDM) lower edge should be able to handle such events. If an NDIS-WDM miniport driver does not handle a surprise removal, any pending IRPs that the miniport driver sent to the underlying bus driver before the surprise removal cannot be completed.

For Windows Vista and later versions, a miniport driver (such as a miniport driver with a WDM lower edge) that does not control hardware directly should set the NDIS_MINIPORT_ATTRIBUTES_SURPRISE_REMOVE_OK attribute flag when calling **NdisMSetMiniportAttributes**. Setting this flag prevents a warning from being displayed when a user performs a surprise removal of a NIC. A miniport driver that cannot handle a surprise removal should not set this flag.

A miniport driver that supports surprise removal should itself attempt to detect a surprise removal during normal operations--outside of the context of *MiniportDevicePnPEventNotify*. After a NIC is removed, an attempt to read a NIC's I/O ports typically results in return values that have all bits set to one. If a miniport driver reads such a value, it should check for the presence of the hardware with a more conclusive test. For example, the miniport driver could write a value to an I/O port and then try to read the value from that port. The miniport driver could also check for valid values in the NIC's I/O registers. Detecting a surprise removal in such a way prevents the miniport driver from hanging in an infinite loop when it attempts to read a removed NIC's registers in an interrupt DPC.. A miniport driver that stops responding in this way stops NDIS from calling the driver's *MiniportDevicePnPEventNotify* function.

Handling a Change in the System's Power Source

Article • 12/15/2021

The system can change from battery power to AC power or vice versa.

After initializing a miniport driver, NDIS calls a miniport driver's *MiniportDevicePnPEventNotify* function to notify the miniport driver of the system's power source. The miniport driver can use this information to adjust the power consumption of a NIC. For example, the miniport driver for a wireless LAN (WLAN) device could reduce power consumption if the system is running on battery power or increase power consumption if the system is running on AC power.

Overview of NDIS Processing of Plug and Play Events

Article • 03/14/2023

The function drivers for a network interface card (NIC) are implemented as an NDIS and miniport driver pair. When a NIC is added to the system, NDIS creates the functional device object (FDO) for the NIC. NDIS then subsequently handles all IRPs, including Plug and Play (PnP) and power management IRPs, that are passed to this FDO. The miniport driver for the NIC provides the operational interface for the NIC.`

The following sections describe how NDIS processes PnP IRPs on behalf of a NIC:

Adding a NIC

Starting a NIC

Stopping a NIC

Removing a NIC

Processing the Surprise Removal of a NIC

Adding a NIC

Article • 12/15/2021

The following description starts with the loading of the miniport driver and describes how a NIC is added. For the initial processing that the PnP manager performs when a NIC is added to a running system, see steps 1-11 of Adding a PnP Device to a Running System.

1. If the miniport driver for the NIC is not already loaded, the PnP manager loads the driver and then calls the miniport driver's **DriverEntry** function. If the driver is already loaded, processing continues with step 4.

2. From its **DriverEntry** function, the miniport driver registers as a miniport drivers and performs other drivers initialization. For more information about registering as a miniport driver, see Initializing a Miniport Driver.

3. NDIS fills in the following entries in the driver object for the miniport driver:

   - The entry point for the *AddDevice* routine.
   - The *DispatchXxx* entry points for handling IRPs.
   - The entry point for the *Unload* routine.

4. The PnP manager calls NDIS's *AddDevice* routine. NDIS's *AddDevice* routine creates a functional device object (FDO) for the newly added NIC and attaches this FDO to the device stack for the NIC.

5. NDIS reads information from the registry to obtain configuration information for the NIC. This information includes binding information and the hardware attributes of the NIC.

6. The PnP manager assigns resources to the NIC, if necessary.

Starting a NIC

Article • 12/15/2021

The following steps describe how NDIS participates in the starting of a NIC:

1. The PnP manager issues an **IRP_MN_START_DEVICE** request. This IRP contains information that informs NDIS about the resources that the PnP manager has allocated for the NIC.

2. NDIS sets an **IoCompletion** routine and passes the IRP_MN_START_DEVICE request down the device stack to the next lowest driver, which is typically the bus driver. When the bus driver receives the IRP_MN_START_DEVICE request, the bus driver performs its start operations on the device and passes the completed IRP_MN_START_DEVICE request back up the device stack.

3. When NDIS receives the completed IRP_MN_START_DEVICE request (that is, when NDIS's **DispatchPnP** routine gains control after all lower drivers have finished with the IRP), NDIS calls the miniport driver's *MiniportInitializeEx* function.

4. If the *MiniportInitializeEx* function returns NDIS_STATUS_SUCCESS, NDIS schedules an event to call the *ProtocolBindAdapterEx* function of all protocol drivers that are supposed to bind to the adapter, as indicated by the binding information in the registry. Note that the miniport driver has no information about bindings.

5. NDIS completes the IRP_MN_START_DEVICE request.

Stopping a NIC

Article • 12/15/2021

The PnP manager stops a NIC so that it can reconfigure or rebalance the hardware resources that it assigned to the NIC. The following steps describe how NDIS participates in the stopping of a NIC:

1. The PnP manager issues an **IRP_MN_QUERY_STOP_DEVICE** request.

2. When NDIS receives this IRP, it calls the *FilterNetPnPEvent* function of the lowest filter driver that is attached to the NIC in the driver stack. In this call, NDIS specifies an event code of **NetEventQueryRemoveDevice**.

   Note NDIS performs this step only for filter drivers that advertise an entry point for the *FilterNetPnPEvent* function. A filter driver advertises this entry point when it calls the **NdisFRegisterFilterDriver** function.

3. Within the context of the call to its *FilterNetPnPEvent* function, the filter driver must call **NdisFNetPnPEvent** to forward the **NetEventQueryRemoveDevice** event up to the next filter driver in the driver stack. This causes NDIS to call that filter driver's *FilterNetPnPEvent* function with an event code of **NetEventQueryRemoveDevice**.

   Note NDIS performs this step only for the next filter driver in the driver stack that advertises an entry point for the *FilterNetPnPEvent* function.

4. Each filter driver in the driver stack repeats the previous step until the highest filter driver in the stack has forwarded the **NetEventQueryRemoveDevice** event.

   When this happens, NDIS calls the *ProtocolNetPnPEvent* function of all protocol drivers that are bound to the NIC. In this call, NDIS specifies an event code of **NetEventQueryRemoveDevice**.

5. If a protocol driver fails the **NetEventQueryRemoveDevice** event by returning a failure code from *ProtocolNetPnPEvent*, NDIS or the PnP manager might ignore the failure and subsequently succeed the IRP_MN_QUERY_STOP_DEVICE request. A protocol driver must, therefore, be prepared to handle the removal of the NIC even though the protocol driver failed the **NetEventQueryRemoveDevice** event.

6. The PnP manager issues an **IRP_MN_STOP_DEVICE** request to stop the device or an **IRP_MN_CANCEL_STOP_DEVICE** request to cancel the pending stop.

7. If the PnP manager issues an IRP_MN_CANCEL_STOP_DEVICE request, NDIS calls the *FilterNetPnPEvent* function of the lowest filter driver that is attached to the NIC in the driver stack. In this call, NDIS specifies an event code of **NetEventCancelRemoveDevice**.

   Note NDIS performs this step only for filter drivers that advertise an entry point for the *FilterNetPnPEvent* function.

8. Within the context of the call to its *FilterNetPnPEvent* function, the filter driver must call **NdisFNetPnPEvent** to forward the **NetEventCancelRemoveDevice** event up to the next filter driver in the driver stack. This causes NDIS to call that filter driver's *FilterNetPnPEvent* function with an event code of **NetEventCancelRemoveDevice**.

   Note NDIS performs this step only for the next filter driver in the driver stack that advertises an entry point for the *FilterNetPnPEvent* function.

9. Each filter driver in the driver stack repeats the previous step until the highest filter driver in the stack has forwarded the **NetEventCancelRemoveDevice** event.

   When this happens, NDIS calls the *ProtocolNetPnPEvent* function of all protocol drivers that are bound to the NIC. In this call, NDIS specifies an event code of **NetEventCancelRemoveDevice**.

10. If the PnP manager issues an IRP_MN_STOP_DEVICE request, NDIS performs these steps:

    a. It pauses all protocol drivers that are bound to the NIC.

    b. It pauses all filter drivers that are attached to the NIC.

    c. It pauses the miniport driver for the NIC.

    d. It calls the *ProtocolUnbindAdapterEx* function of all protocol drivers that are bound to the NIC.

    e. It calls the *FilterDetach* function of all filter modules that are attached to the NIC.

11. After all protocol and filter drivers are unbound and detached from the NIC, NDIS calls the miniport driver's *MiniportHaltEx* function. NDIS sets the *HaltAction* parameter of *MiniportHaltEx* to **NdisHaltDeviceStopped**.

12. When processing an IRP_MN_STOP_DEVICE request, NDIS does not destroy the functional device object (FDO) that it created for the NIC when the *AddDevice*

routine was called. NDIS destroys the device object only after receiving an **IRP_MN_REMOVE_DEVICE** request for the NIC.

If the PnP manager issues an IRP_MN_START_DEVICE to restart the NIC, NDIS will reuse the FDO that was previously created for the NIC. NDIS will then restart the NIC. For more information on this procedure, see Starting a NIC.

Removing a NIC

Article • 12/15/2021

The following steps describe how NDIS participates in the removal of a NIC:

1. The PnP manager issues an IRP_MN_QUERY_REMOVE_DEVICE request to query whether the NIC can be removed without disrupting the computer.

2. When NDIS receives this IRP, it calls the *FilterNetPnPEvent* function of the lowest filter driver that is attached to the NIC in the driver stack. In this call, NDIS specifies an event code of **NetEventQueryRemoveDevice**.

   Note NDIS performs this step only for filter drivers that advertise an entry point for the *FilterNetPnPEvent* function. A filter driver advertises this entry point when it calls the **NdisFRegisterFilterDriver** function.

3. Within the context of the call to its *FilterNetPnPEvent* function, the filter driver must call **NdisFNetPnPEvent** to forward the **NetEventQueryRemoveDevice** event up to the next filter driver in the driver stack. This causes NDIS to call that filter driver's *FilterNetPnPEvent* function with an event code of **NetEventQueryRemoveDevice**.

   Note NDIS performs this step only for the next filter driver in the driver stack that advertises an entry point for the *FilterNetPnPEvent* function.

4. Each filter driver in the driver stack repeats the previous step until the highest filter driver in the stack has forwarded the **NetEventQueryRemoveDevice** event.

   When this happens, NDIS calls the *ProtocolNetPnPEvent* function of all protocol drivers that are bound to the NIC. In this call, NDIS specifies an event code of **NetEventQueryRemoveDevice**.

5. If a protocol driver fails the **NetEventQueryRemoveDevice** event by returning a failure code NDIS_STATUS_FAILURE from *ProtocolNetPnPEvent*, NDIS or the PnP manager might ignore the failure and subsequently succeed the IRP_MN_QUERY_REMOVE_DEVICE request. A protocol driver must, therefore, be prepared to handle the removal of the NIC even though the protocol driver failed the **NetEventQueryRemoveDevice** event.

6. The PnP manager issues an IRP_MN_REMOVE_DEVICE request to remove the software representation (device objects, and so on) for the NIC or an IRP_MN_CANCEL_REMOVE_DEVICE request to cancel the pending removal. Note

that an IRP_MN_REMOVE_DEVICE request is not always preceded by an IRP_MN_QUERY_REMOVE_DEVICE request.

7. If the PnP manager issues an IRP_MN_CANCEL_REMOVE_DEVICE request, NDIS calls the *FilterNetPnPEvent* function of the lowest filter driver that is attached to the NIC in the driver stack. In this call, NDIS specifies an event code of **NetEventCancelRemoveDevice**.

   Note NDIS performs this step only for filter drivers that advertise an entry point for the *FilterNetPnPEvent* function.

8. Within the context of the call to its *FilterNetPnPEvent* function, the filter driver must call **NdisFNetPnPEvent** to forward the **NetEventCancelRemoveDevice** event up to the next filter driver in the driver stack. This causes NDIS to call that filter driver's *FilterNetPnPEvent* function with an event code of **NetEventCancelRemoveDevice**.

   Note NDIS performs this step only for the next filter driver in the driver stack that advertises an entry point for the *FilterNetPnPEvent* function.

9. Each filter driver in the driver stack repeats the previous step until the highest filter driver in the stack has forwarded the **NetEventCancelRemoveDevice** event.

   When this happens, NDIS calls the *ProtocolNetPnPEvent* function of all protocol drivers that are bound to the NIC. In this call, NDIS specifies an event code of **NetEventCancelRemoveDevice**. This event code ends the removal sequence.

10. If the PnP manager issues an IRP_MN_REMOVE_DEVICE request, NDIS performs these steps:

    a. It pauses all protocol drivers that are bound to the NIC.

    b. It pauses all filter drivers that are attached to the NIC.

    c. It pauses the miniport driver for the NIC.

    d. It calls the *ProtocolUnbindAdapterEx* function of all protocol drivers that are bound to the NIC.

    e. It calls the *FilterDetach* function of all filter modules that are attached to the NIC.

11. If the miniport driver was successfully initialized, NDIS calls the miniport driver's *MiniportHaltEx* function. NDIS sets the *HaltAction* parameter of *MiniportHaltEx* to **NdisHaltDeviceDisabled**.

12. NDIS sends the IRP_MN_REMOVE_DEVICE request to the next lower device object in the stack.

13. When NDIS receives the completed IRP_MN_REMOVE_DEVICE request from the next lower device object in the stack, NDIS destroys the functional device object (FDO) that it created for the NIC.

Processing the Surprise Removal of a NIC (Windows Vista)

Article • 12/15/2021

The following steps describe how NDIS participates in the surprise removal of a NIC in Windows Vista and Windows Server 2008:

1. The PnP manager issues an **IRP_MN_SURPRISE_REMOVAL** request to the device stack for the NIC.

2. When NDIS receives this IRP, it calls the *FilterNetPnPEvent* function of the lowest filter driver that is attached to the NIC in the driver stack. In this call, NDIS specifies an event code of **NetEventQueryRemoveDevice**.

   Note NDIS performs this step only for filter drivers that advertise an entry point for the *FilterNetPnPEvent* function. A filter driver advertise this entry point when it calls the **NdisFRegisterFilterDriver** function.

3. Within the context of the call to its *FilterNetPnPEvent* function, the filter driver must call **NdisFNetPnPEvent** to forward the **NetEventQueryRemoveDevice** event up to the next filter driver in the driver stack. This causes NDIS to call that filter driver's *FilterNetPnPEvent* function with an event code of **NetEventQueryRemoveDevice.**.

   Note NDIS performs this step only for the next filter driver in the driver stack that advertises an entry point for the *FilterNetPnPEvent* function.

4. Each filter driver in the driver stack repeats the previous step until the highest filter driver in the stack has forwarded the **NetEventQueryRemoveDevice.** event.

   When this happens, NDIS calls the *ProtocolNetPnPEvent* function of all protocol drivers that are bound to the NIC. In this call, NDIS specifies an event code of **NetEventQueryRemoveDevice.**.

5. If the miniport driver was successfully initialized, NDIS calls the *MiniportDevicePnPEventNotify* function with an event code of **NdisDevicePnPEventSurpriseRemoved**. The miniport driver should note that the device has been physically removed. If the miniport driver is an NDIS-WDM driver, it should cancel any pending IRPs that it sent down to the underlying bus driver. If the miniport driver was not successfully initialized, processing continues.

6. NDIS sends the IRP_MN_SURPRISE_REMOVAL request to the next-lower device object in the stack. After receiving the returned IRP_MN_SURPRISE_REMOVAL request from the next-lower device object in the stack, NDIS completes the IRP_MN_SURPRISE_REMOVAL request.

7. The PnP manager issues an **IRP_MN_REMOVE_DEVICE** request to remove the software representation (device objects, and so forth) for the NIC.

8. NDIS performs the following steps:

   a. It pauses all protocol drivers that are bound to the NIC.

   b. It pauses all filter drivers that are attached to the NIC.

   c. It pauses the miniport driver for the NIC.

   d. It calls the *ProtocolUnbindAdapterEx* function of all protocol drivers that are bound to the NIC.

   e. It calls the *FilterDetach* function of all filter modules that are attached to the NIC.

9. After all protocol and filter drivers are unbound and detached from the NIC, NDIS calls the miniport driver's *MiniportHaltEx* function. NDIS sets the *HaltAction* parameter of *MiniportHaltEx* to **NdisHaltDeviceSurpriseRemoved**.

10. NDIS sends the IRP_MN_REMOVE_DEVICE request to the next lower device object in the stack.

11. When NDIS receives the completed IRP_MN_REMOVE_DEVICE request from the next lower device object in the stack, NDIS destroys the functional device object (FDO) that it created for the NIC.

Processing the Surprise Removal of a NIC (Windows 7 and Later Versions)

Article • 12/15/2021

In Windows 7 and Windows Server 2008 R2 and later, NDIS may participate in the surprise removal of a network interface card (NIC) differently than it had in previous versions of Windows. NDIS performs a revised surprise removal procedure if *any* of the following conditions are true:

- The operating system is Windows 8 / Windows Server 2012 or later.
- The operating system is Windows 7, and the hotfix for KB2471472 has been installed.
- The operating system is Windows 7, and the network adapter is a mobile broadband (MBB) device.

If none of these conditions are met, NDIS participates in the surprise removal process as it did in previous versions of Windows. For more information about this procedure, see Processing the Surprise Removal of a NIC (Windows Vista).

The following steps describe the revised way in which NDIS participates in the surprise removal of a NIC:

1. The PnP manager issues an **IRP_MN_SURPRISE_REMOVAL** request to the device stack for the NIC.

2. When NDIS receives this IRP, it calls the *FilterNetPnPEvent* function of the lowest filter driver that is attached to the NIC in the driver stack. In this call, NDIS specifies an event code of **NetEventQueryRemoveDevice**.

   Note NDIS performs this step only for filter drivers that advertise an entry point for the *FilterNetPnPEvent* function. A filter driver advertise this entry point when it calls the **NdisFRegisterFilterDriver** function.

3. Within the context of the call to its *FilterNetPnPEvent* function, the filter driver must call **NdisFNetPnPEvent** to forward the **NetEventQueryRemoveDevice** event up to the next filter driver in the driver stack. This causes NDIS to call that filter driver's *FilterNetPnPEvent* function with an event code of **NetEventQueryRemoveDevice**.

   Note NDIS performs this step only for the next filter driver in the driver stack that advertises an entry point for the *FilterNetPnPEvent* function.

4. Each filter driver in the driver stack repeats the previous step until the highest filter driver in the stack has forwarded the **NetEventQueryRemoveDevice** event.

   When this happens, NDIS calls the *ProtocolNetPnPEvent* function of all protocol drivers that are bound to the NIC. In this call, NDIS specifies an event code of **NetEventQueryRemoveDevice**.

5. NDIS calls the *MiniportDevicePnPEventNotify* function with an event code of **NdisDevicePnPEventSurpriseRemoved**. The miniport driver should note that the device has been physically removed. If the miniport driver is an NDIS-WDM driver, it should cancel any pending IRPs that it sent down to the underlying bus driver.

6. NDIS performs the following steps:

   a. It pauses all protocol drivers that are bound to the NIC.

   b. It pauses all filter drivers that are attached to the NIC.

   c. It pauses the miniport driver for the NIC.

   d. It calls the *ProtocolUnbindAdapterEx* function of all protocol drivers that are bound to the NIC.

   e. It calls the *FilterDetach* function of all filter modules that are attached to the NIC.

7. After all protocol and filter drivers are unbound and detached from the NIC, NDIS calls the miniport driver's *MiniportHaltEx* function. NDIS sets the *HaltAction* parameter of *MiniportHaltEx* to **NdisHaltDeviceSurpriseRemoved**.

8. NDIS sends the IRP_MN_SURPRISE_REMOVAL request to the next-lower device object in the stack. After receiving the returned IRP_MN_SURPRISE_REMOVAL request from the next-lower device object in the stack, NDIS completes the IRP_MN_SURPRISE_REMOVAL request.

9. The PnP manager issues an **IRP_MN_REMOVE_DEVICE** request to remove the software representation (device objects, and so forth) for the NIC.

10. NDIS sends the IRP_MN_REMOVE_DEVICE request to the next lower device object in the stack.

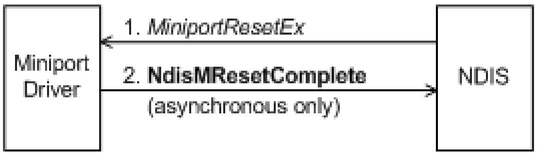
11. When NDIS receives the completed IRP_MN_REMOVE_DEVICE request from the next lower device object in the stack, NDIS destroys the functional device object (FDO) that it created for the NIC.

Miniport Driver Hardware Reset

Article • 12/15/2021

A miniport driver must register a *MiniportResetEx* function with **NdisMRegisterMiniportDriver**.

MiniportResetEx can complete synchronously or asynchronously with a call to **NdisMResetComplete**(see the following figure).



MiniportResetEx should:

- Disable further interrupts.
- Clear out the data that is associated with any sends in progress. For example, on a ring buffer for a bus-master direct memory access (DMA) device, the pointers to send buffers should be cleared. Deserialized and connection-oriented miniport drivers must return NDIS_STATUS_REQUEST_ABORTED for any queued send requests.
- Restore the hardware state and the miniport driver's internal state to the state that existed before the reset operation.

The miniport driver is responsible for restoring the hardware state of the device except for multicast addresses, packet filters, task offload settings, and wake up patterns. These setting are restored by either the miniport driver or NDIS. The miniport driver determines who is responsible for restoring these settings by returning a Boolean value in the *AddressingReset* parameter.

If the miniport driver returns **FALSE** in the *AddressingReset* parameter, the miniport driver restores its multicast addresses, packet filters, task offload settings, and wake up patterns to their initial state. If the miniport driver returns **TRUE** in *AddressingReset*, NDIS calls a connectionless miniport driver's *MiniportOidRequest* function or a connection-oriented miniport driver's **MiniportCoOidRequest** function to set the following configuration settings:

- The network packet filter through a set request of OID_GEN_CURRENT_PACKET_FILTER.
- The multicast address list through a set request of OID_802_3_MULTICAST_LIST.

- Task offload encapsulation settings through a set request of OID_OFFLOAD_ENCAPSULATION.
- Power management wake-up patterns through a set request of OID_PNP_ADD_WAKE_UP_PATTERN. **Note** Starting with NDIS 6.20, wake-up patterns set through OID_PM_ADD_WOL_PATTERN must be restored by the miniport driver.

Miniport Driver Reset and Halt Functions

Miniport Driver Halt Handler

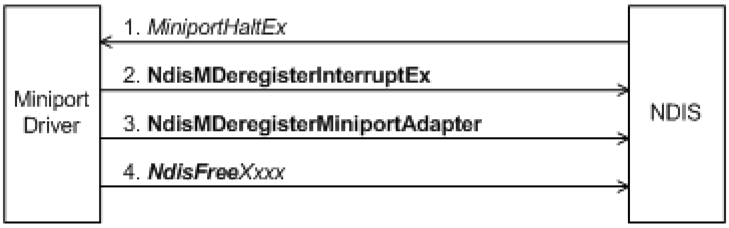
Article • 12/15/2021

An NDIS miniport driver must supply a *MiniportHaltEx* function to **NdisMRegisterMiniportDriver**.

MiniportHaltEx should undo everything that *MiniportInitializeEx* did. For example, the NDIS miniport driver might:

- Free ports. (For more information, see Freeing an NDIS Port.)
- Release all of the hardware resources that *MiniportInitializeEx* claimed.
- Free interrupt resources by calling **NdisMDeregisterInterruptEx**.
- Free any memory that *MiniportInitializeEx* allocated.
- Stop the NIC, unless the *MiniportShutdownEx* function has already restored the NIC to its initial state.

The following diagram illustrates unloading a miniport driver.



Miniport Driver
1. MiniportHaltEx
2. NdisMDeregisterInterruptEx
3. NdisMDeregisterMiniportAdapter
4. NdisFreeXxxx
NDIS

MiniportHaltEx should complete the operations that are necessary to unload the driver before returning. If the miniport driver has any outstanding receive indications (that is, received network data that it has indicated up to NDIS but which NDIS has not yet returned), *MiniportHaltEx* must not return until such data is returned to the miniport driver's *MiniportReturnNetBufferLists* function.

The preceding figure shows a set of calls that could be made by a *MiniportHaltEx* function. These calls are only a subset of the calls that could be made. The actual set of calls depends on previous actions of the miniport driver. The miniport driver can make these same calls in *MiniportInitializeEx* if it cannot successfully initialize the network adapter because of hardware problems or because it cannot acquire a resource that it needs. In such a case, *MiniportInitializeEx* should unload the driver by undoing its previous actions. Otherwise, *MiniportHaltEx* will undo the actions of *MiniportInitializeEx*.

The following list describes the calls that are required to reverse certain actions that the miniport driver might take:

- If the miniport driver registered an interrupt, it should call NdisMDeregisterInterruptEx.

- If the miniport driver set up a timer or timers, it should call NdisCancelTimerObject for each timer that it created. If a call to **NdisCancelTimerObject** fails, the timer might have already fired. In this case, the miniport driver should wait for the timer handler to complete before returning from *MiniportHaltEx*.

- If the miniport driver allocated any memory with NdisAllocateMemoryWithTagPriority, it should call NdisFreeMemory to free that memory.

- If the miniport driver allocated any memory with NdisMAllocateSharedMemory, or NdisMAllocateSharedMemoryAsyncEx, it should call NdisMFreeSharedMemory to free that memory.

- If the miniport driver allocated and initialized storage for a pool of packet descriptors with NdisAllocateNetBufferPool, it should call NdisFreeNetBufferPool to free that storage.

- If the miniport driver allocated or reserved any hardware resources, these should be returned. For example, if the miniport driver mapped an I/O port range on a NIC, it should release the ports by calling NdisMDeregisterIoPortRange.

Overview of Miniport Drivers with a WDM Lower Interface

Article • 12/15/2021

A miniport driver with a Microsoft Windows Driver Model (WDM) lower interface is also known as an *NDIS-WDM miniport driver*. This type of miniport driver:

- Uses a WDM lower edge.
- Can call both NDIS and non-NDIS functions. However, whenever possible, the miniport driver should call NDIS functions.
- Can initialize a miniport instance that is used to control devices that are attached to a particular bus and that communicates with those devices over that bus.

For example, a miniport driver that controls devices on either Universal Serial Bus (USB) or IEEE 1394 (Firewire) buses must expose a standard NDIS miniport driver interface at its upper edge and use the class interface for the particular bus at its lower edge. Such a miniport driver communicates with devices that are attached to the bus by sending I/O request packets (IRPs) to the bus.

The following topics describe how to implement a miniport driver that uses a WDM lower edge:

Miniport Driver with a WDM Lower Edge

Registering Miniport Driver Functions for WDM Lower Edge

Initializing a Miniport Driver with a WDM Lower Edge

Miniport Driver with a WDM Lower Edge

Article • 12/15/2021

A miniport driver with a WDM lower edge (an NDIS-WDM miniport driver) follows the WDM rule that specifies that a WDM header file must be included in the driver's source files. An NDIS-WDM miniport driver requires a WDM header file to call kernel-mode routines on its lower edge. Typically, NDIS miniport drivers should just call functions that NDIS provides. This restriction is shown by the way NDIS wraps around NDIS miniport drivers in the figure in the NDIS Drivers section. Although typical NDIS miniport drivers are not called WDM drivers, they indirectly follow WDM rules because NDIS itself follows WDM rules.

The following diagram shows an NDIS-WDM miniport driver that interfaces with the USB driver stack by using a WDM lower edge.

An NDIS-WDM miniport driver that interfaces with the USB driver stack.

USB Client Drivers
Other vendor-supplied USB client drivers.

USB Class Interface
USB Routines and I/O requests that USB client drivers can use to interface with the USB driver stack.

USB Driver Stack

Driver stack for USB devices. For more information, see USB Driver Stack Architecture.

Registering Miniport Driver Functions for WDM Lower Edge

Article • 12/15/2021

A miniport driver that has a WDM lower edge must call the NdisMRegisterMiniportDriver function in its **DriverEntry** routine to register certain entry-point functions with the NDIS library. These entry-point functions compose the miniport driver's upper edge and are described in Initializing a Miniport Driver. However, a miniport driver that has a WDM lower edge is not required to set up certain entry-point functions. For example, the following entry-point functions are not set up for the following reasons:

- *MiniportInterrupt*, *MiniportInterruptDPC*, *MiniportEnableInterruptEx*, and *MiniportDisableInterruptEx*

  Because the miniport driver does not receive interrupts from a physical network interface card (NIC), it does not require these entry-point routines. The driver for the particular bus receives interrupts when packets arrive on the bus that are intended for the miniport driver. The bus driver then notifies the miniport driver.

- *MiniportSharedMemoryAllocateComplete*

  Because the miniport driver does not allocate shared memory, a completion entry-point routine is not specified.

- *MiniportCheckForHangEx*

  The miniport driver can rely on NDIS to determine if its miniport instance has stopped responding, based on sends and requests that time out, so this routine is not typically required.

Initializing a Miniport Driver with a WDM Lower Edge

Article • 12/15/2021

After a miniport driver has been loaded by the operating system, NDIS calls the miniport driver's *MiniportInitializeEx* function to initialize a miniport instance that the miniport driver manages. To communicate through a miniport instance that has a WDM lower edge, the miniport driver must retrieve specific information to set up its communications.

During initialization of this miniport instance, the miniport driver must call the **NdisMGetDeviceProperty** function to retrieve device objects that are required to set up communication with the miniport instance through a WDM interface. In this call, the miniport driver passes the handle to the miniport instance in the *MiniportAdapterHandle* parameter and buffers that receive pointers to **DEVICE_OBJECT** structures. The miniport driver uses the retrieved pointer to the next-device object (*NextDeviceObject* parameter) to create and submit IRPs. For more information, see Handling IRPs.

A miniport driver with a WDM lower edge must be a deserialized miniport driver. A deserialized miniport driver manages its own queue of send and receive requests internally whenever it has insufficient resources to handle these requests immediately; if a miniport driver is not deserialized, NDIS manages this queue. An NDIS-WDM miniport driver must be deserialized because it sends and receives packets outside of the context of NDIS calls. During initialization of a miniport instance, an NDIS-WDM miniport driver must specify the deserialized feature. All NDIS 6.0 and later miniport drivers are deserialized.

Note that an NDIS-WDM miniport driver cannot be an intermediate driver (a driver that exposes a miniport driver interface at the top and a protocol driver interface at the bottom).

Issuing Commands to Communicate with Devices

Article • 12/15/2021

A miniport driver with a WDM lower edge that controls devices on a bus issues commands to the bus interface to communicate with those devices. For more information, see Handling IRPs and the documentation for the particular bus-driver interface.

Implementation Tips and Requirements for WDM Lower Edge

Article • 12/15/2021

This topic describes tips and requirements for implementing an NDIS-WDM miniport driver. An NDIS-WDM miniport driver can call both NDIS and non-NDIS functions. These non-NDIS functions include, for example, WDM-kernel-mode support routines and functions for a particular bus-driver interface.

When implementing an NDIS-WDM miniport driver, keep the following in mind:

- Building an NDIS-WDM miniport driver requires that the NDIS_WDM flag is defined before the Ndis.h header file is included. Defining the NDIS_WDM flag ensures that Ndis.h automatically includes the appropriate WDM header file. The NDIS_WDM flag should be either embedded at the start of the miniport driver's source code or set in the miniport driver's Sources file. An NDIS-WDM miniport driver requires a WDM header file to call kernel-mode routines such as **IoCallDriver** and **IoAllocateIrp**.

- Function calls for a particular bus-driver interface require the header files for that bus driver.

- Including NDIS and non-NDIS headers in the same source file is not recommended because they might not be compatible. That is, separate source files should be created for code that calls NDIS functions and for code that calls non-NDIS functions.

- An NDIS-WDM miniport driver should call appropriate NDIS functions to allocate and release resources unless the NDIS-WDM miniport driver allocates and releases resources in one of the following scenarios:
  - A resource, typically a memory resource, is allocated by the NDIS-WDM miniport driver and is later released by a non-NDIS entity such as a bus-driver interface,
  - A resource, typically a memory resource, is allocated by a non-NDIS entity and is later released by the NDIS-WDM miniport driver.

  For the preceding scenarios, the NDIS-WDM miniport driver should call the appropriate WDM routines to allocate or release resources for the non-NDIS entity.

Compile Flags for WDM Lower Edge

Article • 12/15/2021

You must include the following compile flags in the Sources file for an NDIS-WDM miniport driver to build the NDIS-WDM miniport driver:

- -DNDIS_WDM=1

  Directs NDIS to include the appropriate WDM header file.

Alternatively, you can embed compile flags at the start of the miniport driver's source code before the Ndis.h header file is included.

Power Management for WDM Lower Edge

Article • 12/15/2021

NDIS handles all Plug and Play (PnP) and power management IRPs for NDIS-WDM miniport drivers. Therefore, NDIS-WDM miniport drivers should respond to PnP and power management OIDs, based on device capabilities, as described in Power Management for NDIS Miniport Drivers.

Installing NDIS-WDM Miniport Drivers

Article • 03/14/2023

When you implement the installation mechanism for an NDIS-WDM miniport driver, you should keep the following items in mind:

- Create an information (INF) file for a **Net** class of network component as described in Creating Network INF Files.

- Include Plug and Play (PnP) identifiers (ID) of devices as is typically done for any **Net** class of network component; however, make these IDs specific to the bus type to which the devices are attached.

Overview of WAN Miniport Drivers

Article • 09/27/2024

This section describes CoNDIS WAN miniport drivers, CoNDIS WAN call managers, CoNDIS WAN miniport call managers (MCMs), and the environments in which they operate. These WAN drivers support the Remote Access Service (RAS) and the Point-to-Point Protocol (PPP) over such media as ISDN, Frame Relay, or Switched 56.

This section includes the following topics:

Choosing a WAN Driver Model

Overview of the WAN Architecture

Implementing CoNDIS WAN Miniport Drivers

CoNDIS WAN Operations That Support Telephonic Services

WAN Packet Framing

WAN Miniport Driver Build Parameters

WAN Driver Models

Article • 12/15/2021

Microsoft Windows 2000 and later operating systems support two WAN driver models: NDIS WAN and CoNDIS WAN.

NDIS WAN miniport drivers are built on the NDIS model for connectionless miniport drivers. NDIS WAN miniport drivers are not supported for NDIS version 5.0 and later drivers. New drivers should be based on the CoNDIS WAN driver architecture.

CoNDIS WAN drivers are built on the connection-oriented NDIS (CoNDIS) driver model.

CoNDIS WAN miniport drivers and miniport call managers (MCMs) can:

- Call the same NDIS functions that non-WAN connection-oriented miniport drivers call.
- Export the same set of *MiniportXxx* functions that non-WAN connection-oriented miniport drivers export.
- Provide additional WAN-specific capabilities.

For more information about CoNDIS drivers, see Connection-Oriented NDIS.

If you are writing a new WAN driver, we recommend that you use the CoNDIS WAN model.

Microsoft will continue to support existing NDIS WAN miniport drivers. You do not have to write CoNDIS drivers for old hardware.

The following topics describe the primary advantages of using the CoNDIS WAN model:

CoNDIS WAN Is More Flexible

CoNDIS WAN Is Less Complex

Other Benefits of CoNDIS WAN

Other NDIS Features Available to CoNDIS WAN Drivers

CoNDIS WAN Is More Flexible

Article • 03/14/2023

In the CoNDIS model, major functions (such as call management and data transfer) are compartmentalized into discrete components or subcomponents. This organization enables you to use system-supplied and third-party components and update functionality more easily.

The CoNDIS model provides four types of drivers:

- Connection-oriented client drivers
- Call managers
- Connection-oriented miniport drivers
- Integrated miniport call managers (MCMs)

For more information about CoNDIS drivers, see Connection-Oriented NDIS.

The separation of call manager and miniport driver components enables you to update the miniport driver to support new hardware while the call manager remains unchanged. In many cases, the call manager might require upgrades only to correct defects.

The separation of architectural components remains clearly defined in an MCM. The call manager subcomponent of the MCM handles the signaling aspects of connections, and the CoNDIS WAN miniport driver subcomponent handles the NIC hardware.

You can use a system-supplied call manager. If the system does not provide a call manager for your media type (as with, for example, ISDN), you can write one or possibly obtain one from a third party.

The Microsoft Windows operating system includes a PPP CoNDIS client, and CoNDIS WAN miniport drivers are available for many devices. You can write CoNDIS WAN clients to extend the system to support other protocol drivers in addition to PPP.

The CoNDIS WAN model is not restricted to PPP data. You can implement a custom WAN client driver and miniport driver to handle, for example, raw data streaming or proprietary encryption.

CoNDIS WAN Is Less Complex

Article • 03/14/2023

CoNDIS defines objects that correspond to each of the logical entities that are involved in a connection. These entities include address families (AFs), virtual connections (VCs), service access points (SAPs), and parties.

In the CoNDIS environment, the system handles many of the complex TAPI requirements. Therefore, a CoNDIS WAN miniport driver or MCM does not have to handle as many TAPI OIDs as an NDIS WAN miniport driver. In addition, the CoNDIS WAN miniport driver or MCM is not required to handle the following status indications:

- NDIS_STATUS_TAPI_INDICATION
- NDIS_STATUS_WAN_LINE_UP
- NDIS_STATUS_WAN_LINE_DOWN

The separation of the call manager and miniport driver functions enables you to implement two simple drivers. The simplified drivers should be easier to maintain and debug than one large and complex driver.

Other Benefits of CoNDIS WAN

Article • 03/14/2023

In addition to flexibility and simplicity, the CoNDIS WAN model provides the following benefits:

- CoNDIS WAN miniport drivers support multipacket send and receive operations.
- When a CoNDIS miniport driver indicates a receive packet, a bound protocol can defer processing of the packet. When an NDIS WAN miniport driver indicates a receive packet, a bound protocol must copy the data immediately.
- CoNDIS WAN supports multipoint calls. For more information about making multipoint calls, see Making a Call.
- CoNDIS WAN supports quality of service (QoS). CoNDIS WAN drivers use the **NET_BUFFER** structure. For more information about CoNDIS QoS, see Client-Initiated Request to Change Call Parameters.
- Only CoNDIS WAN will support future NDIS enhancements that apply to WAN drivers.

Other NDIS Features Available to CoNDIS WAN Drivers

Article • 03/14/2023

CoNDIS WAN miniport drivers or MCMs can take advantage of the following functionality:

- Plug and Play (PnP) event notification for miniport drivers
- 64-bit statistical counters
- Canceling send packets
- Registering a *MiniportShutdownEx* function
- New miniport driver attributes
- Safe functions

Overview of the WAN Architecture

Article • 12/15/2021

The WAN architecture consists primarily of the components that interface directly to WAN miniport drivers. However, the WAN architecture is best introduced within the broader context of the RAS architecture. The RAS architecture includes some components that are essential for a high-level understanding of the WAN architecture but are otherwise out of the scope of the Microsoft Windows Driver Kit (WDK) and the Windows Driver Development Kit (DDK).

The following topics describe an overview of the RAS architecture, the major WAN system components, and the primary implementation differences between the CoNDIS WAN and NDIS WAN models:

RAS Architecture Overview

NDISWAN Overview

WAN Driver Bindings and Connections

NDISTAPI Overview

NDPROXY Overview

RAS Architecture Overview

Article • 12/06/2022

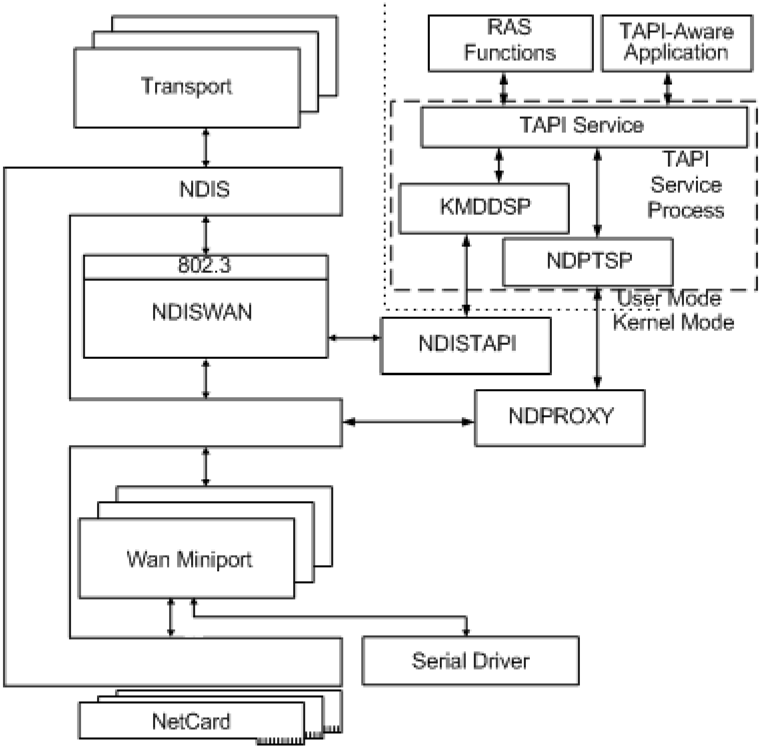
The Remote Access Service (RAS) enables remote workstations to establish a dial-up connection to a LAN and access resources on the LAN as if the remote workstation were on the LAN. WAN miniport drivers provide the interface between RAS and wide area network (WAN) cards such as ISDN, X.25, and Switched 56 adapters.

The primary system-supplied components of the RAS architecture include the following:

- NDISWAN
- TAPI service
- NDPROXY
- NDISTAPI

Developers provide TAPI-aware applications and WAN miniport drivers. CoNDIS WAN developers can also provide WAN client protocol drivers, a miniport call manager (MCM), or a separate call manager.

The following figure shows the RAS architecture.



The following sections briefly describe the components in the RAS architecture.

RAS and TAPI Components

The components on the right side of the preceding figure implement TAPI-related call management operations, such as setting up and tearing down calls and connections. The details of these operations depend on the WAN model (NDIS WAN or CoNDIS WAN).

RAS Functions

User-mode applications call RAS functions to make RAS connections with remote computers. After a RAS connection is established, such applications can connect to network services by using standard network interfaces such as Microsoft Windows Sockets, NetBIOS, Named Pipes, or RPC.

TAPI-Aware Applications

TAPI-aware applications, which are capable of telephony communication, run in both application and service processes. Service providers communicate with specific devices. TAPI-aware applications communicate through the TAPI interface (Tapi32.dll) with their service providers. These service providers run in the TAPI service process.

TAPI Service

The TAPI service (Tapisrv.exe) process presents the Telephony Service Provider Interface (TSPI) of service providers to TAPI-aware applications. These service providers are DLLs that run in the context of the TAPI service process.

The operating system supplies service providers that NDIS WAN or CoNDIS WAN miniport drivers use to communicate with user-mode applications. The service provider for NDIS WAN miniport drivers is KMDDSP. The service provider for CoNDIS WAN miniport drivers (and MCMs) is NDPTSP.

KMDDSP

KMDDSP (Kmddsp.tsp) is a service provider DLL that runs in the context of the TAPI service process. KMDDSP provides a TSPI interface that the TAPI service presents to TAPI-aware applications so that NDISTAPI can communicate with user-mode applications.

KMDDSP works with NDISTAPI to convert user-mode requests to corresponding TAPI OIDs (OID_TAPI_*Xxx*). For more information about TAPI OIDs, see TAPI Objects.

NDPTSP

NDPTSP (Ndptsp.tsp) is a service provider DLL that runs in the context of the TAPI service process. NDPTSP provides a TSPI interface that the TAPI service presents to TAPI-aware applications so that NDPROXY can communicate with user-mode applications.

NDPTSP works with NDPROXY to convert user-mode requests to TAPI connection-oriented OIDs (OID_CO_TAPI_*Xxx*). For more information about TAPI connection-oriented OIDs, see TAPI Extensions for Connection-Oriented NDIS.

NDISTAPI

NDISTAPI (Ndistapi.sys) receives TAPI requests from KMDDSP and then calls **NdisOidRequest** to route the corresponding TAPI OIDs to NDIS WAN miniport drivers. For more information about NDISTAPI, see NDISTAPI Overview.

NDPROXY

NDPROXY (Ndproxy.sys) communicates with TAPI through the TSPI interface that NDPTSP provides. NDPROXY communicates through NDIS with NDISWAN and CoNDIS WAN miniport drivers, MCMs, and call managers.

For more information about NDPROXY, see NDPROXY Overview.

Driver Stack

WAN Transports

The RAS system component provides transports such as PPP Authentication (PAP, CHAP) and network configuration protocol drivers (IPCP, IPXCP, NBFCP, LCP, and so on). A WAN miniport driver (or MCM) implements only PPP media-specific framing.

NDISWAN

NDISWAN (Ndiswan.sys) is an NDIS intermediate driver. NDISWAN binds to NDIS protocol drivers at its upper edge and WAN miniport drivers at its lower edge.

NDISWAN provides PPP protocol/link framing, compression/decompression, and encryption/decryption. NDISWAN interfaces with both NDIS WAN and CoNDIS WAN miniport drivers.

For more information about NDISWAN, see NDISWAN Overview.

Serial Driver

The serial driver component is a standard device driver for internal serial ports or multiport serial cards. The asynchronous WAN miniport driver included with Microsoft Windows 2000 and later uses the internal serial driver for modem communications. Any driver that exports the same functions as the serial driver can interface with the built-in asynchronous WAN miniport driver.

Note X.25 vendors can implement serial driver emulators for an X.25 interface card. In this case, each virtual circuit on the X.25 card appears as a serial port with an X.25 packet assembler/disassembler (PAD) attached to it. The connection interface must correctly emulate serial signals such as DTR, DCD, CTS, RTS, and DSR. X.25 vendors who implement a serial driver emulator for their X.25 card must also make an entry for their PAD in the Pad.inf file. This file contains the command/response script required to make a connection through the X.25 PAD.

WAN Miniport Driver

A WAN miniport driver provides the interface between NDISWAN and WAN NICs.

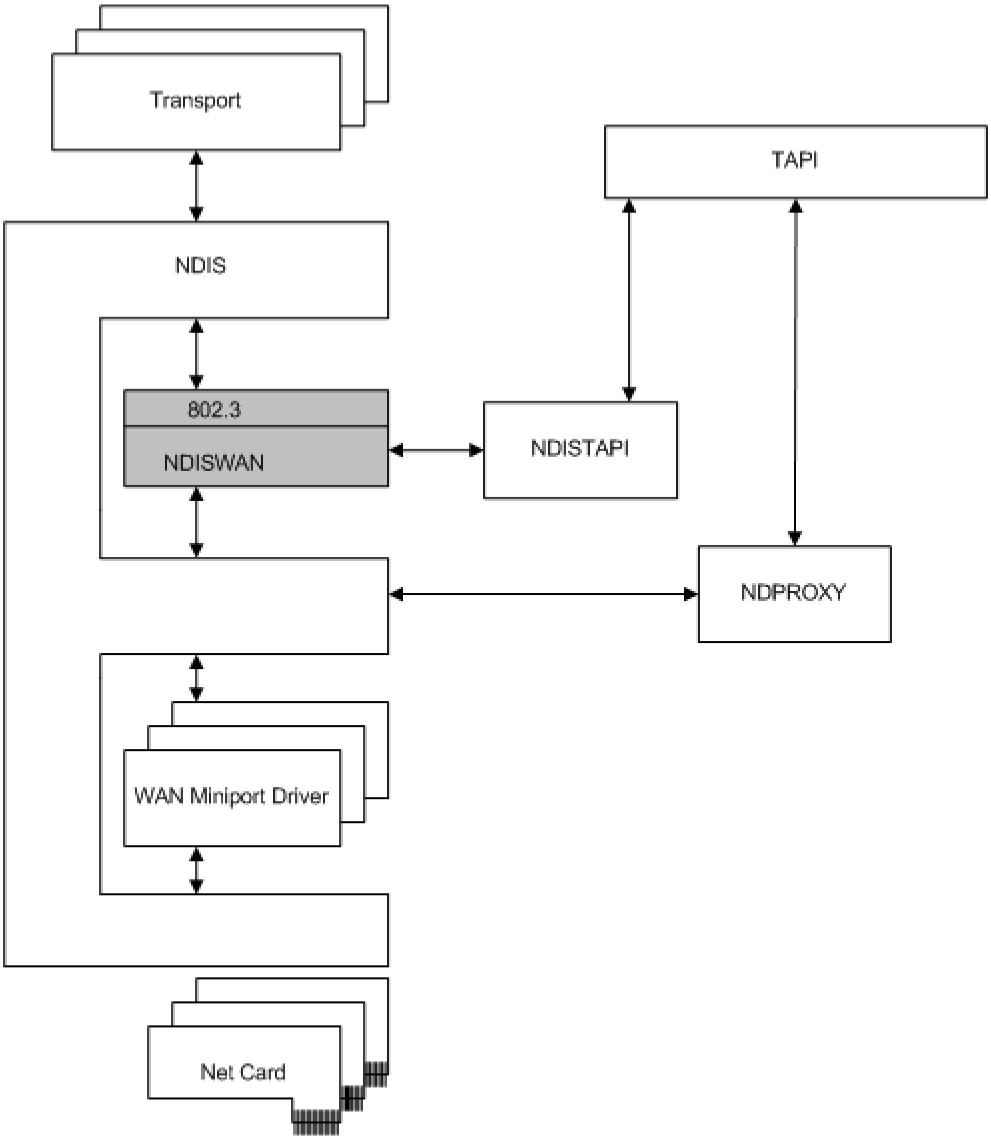
A WAN miniport driver can be implemented as an NDIS WAN miniport driver or a CoNDIS WAN miniport driver. For more information about choosing the miniport driver model that is most appropriate for your application, see Choosing a WAN Driver Model.

NDISWAN Overview

Article • 03/14/2023

NDISWAN is a system-supplied NDIS intermediate driver that provides functionality such as data compression, encryption, loopback, and simple PPP framing that is used by WAN miniport drivers. WAN miniport drivers are therefore required to implement only those features that are specific to the medium (for example, Q931 signaling is required for ISDN).

The following figure shows how NDISWAN interfaces with other components in the RAS architecture.



To overlying protocol drivers, NDISWAN presents both NDIS and CoNDIS miniport driver interfaces. To underlying WAN miniport drivers, NDISWAN presents both NDIS and CoNDIS protocol interfaces that include some WAN-specific elements.

In a CoNDIS environment, the WAN miniport driver can be a connection-oriented miniport driver or an integrated miniport call manager (MCM).

NDISWAN provides the following functionality:

- **Packet conversion**

  NDISWAN converts send packets that are passed to it by protocol drivers from LAN to PPP format. NDISWAN performs the reverse conversion for receive packets passed to it by WAN miniport drivers. NDISWAN uses simple HDLC framing. Most of the media-specific framing must be done by the miniport driver. For more information about WAN packet framing, see WAN Packet Framing.

- **Packet processing**

  Send packets include configuration options for header compression, data compression, and encryption. NDISWAN applies these operations in that order on send packets. NDISWAN applies these options in the reverse order on receive packets. If NDISWAN determines that a configuration option such as compression or encryption is enabled, NDISWAN sends an OID to inform the underlying WAN miniport driver.

- **Simplified binding for drivers**

  NDISWAN simplifies the bindings between protocol drivers and WAN miniport drivers. For more information about WAN driver bindings, see WAN Driver Bindings and Connections.

- **Data forwarding**

  In an NDIS WAN environment, NDISWAN examines the header of the descriptor of a send packet and determines over which link the packet will be sent. NDISWAN copies the packet into a contiguous buffer and forwards it to the underlying miniport driver. In a CoNDIS WAN environment, NDISWAN forwards packets based on the packet's associated virtual connection (VC). For more information about WAN driver links and connections, see WAN Driver Bindings and Connections.

WAN Driver Bindings and Connections

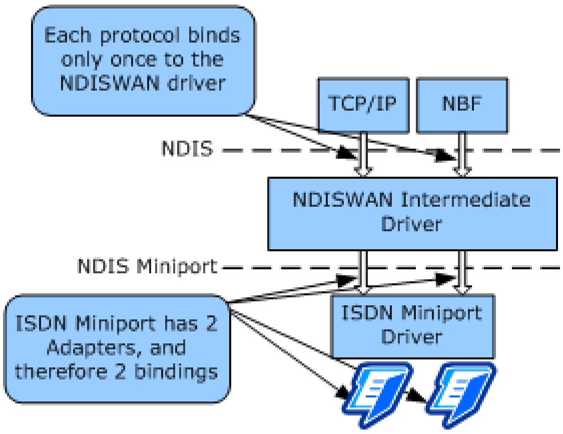
Article • 12/15/2021

This topic provides an overview of bindings and connections between NDISWAN, overlying protocol drivers, and the underlying WAN miniport drivers.

Bindings

NDISWAN binds to one or more WAN miniport drivers and one or more protocol drivers bind to NDISWAN.

The following figure illustrates the binding relationships between WAN client protocol drivers, NDISWAN, and WAN miniport drivers.



Each protocol binds only once to the NDISWAN driver
TCP/IP
NBF
NDIS
NDISWAN Intermediate Driver
NDIS Miniport
ISDN Miniport has 2 Adapters, and therefore 2 bindings
ISDN Miniport Driver

Protocol drivers bind once to NDISWAN and do not bind to WAN miniport drivers. This type of binding saves memory and simplifies WAN miniport drivers. Because there are typically several protocol drivers in a given system and there could be more than one WAN miniport driver, the reduction in the number of bindings saves memory. That is, each protocol does not have to bind to each WAN miniport driver. Also, because protocol drivers can rely on only having a single WAN binding, these protocol drivers can be simplified.

Connections

NDIS WAN and CoNDIS WAN miniport drivers implement different models for connections:

- An NDIS WAN miniport driver uses links to send and receive data. Links are logical, point-to-point bidirectional communication channels. There can be many links per NIC. Links are dynamically established and torn down. The link speed and quality of the link can vary for each connection. However, the padding and link parameters must be the same for all links that a NIC supports. For example, if an NDIS WAN miniport driver specifies a 20-byte header padding and 4-byte tail padding, this padding must remain constant for all links that the miniport driver's NIC supports.

- A CoNDIS WAN miniport driver sends and receives data over virtual connections (VCs). There can be many VCs per NIC. While the data transmission speed can vary from VC to VC, the other VC parameters are the same for all VCs that the NIC supports. A CoNDIS WAN miniport driver can specify a maximum frame size for any net packet that the miniport driver can send and receive. If the miniport driver specifies a maximum frame size, that maximum frame size must remain constant for all VCs on that NIC.

Like other miniport drivers, every WAN miniport driver must have at least one NIC for which it allocates and maintains a NIC-specific context area. The NIC-specific context area is simply a way to store, retrieve, and use information about the hardware specifics of the NIC (such as interrupt, bus type, I/O range, and memory) and to maintain the run-time state for connections. A miniport driver should specify one NIC-specific context area for each network card in the system that it supports.

If a particular WAN miniport driver specifies that it does not require PPP address and control-field compression, it is assumed true for all connections on the miniport driver's NIC.

Before a WAN miniport driver can send or receive packets on a wide area network, a connection must be created:

- In an NDIS environment, an application must set up a connection that originates on the sending node or accept a connection that originates on a remote node by making or accepting a call. The setup, supervision, and tear-down of a connection is done through TAPI. TAPI requests and status indications to TAPI all go through NDISTAPI. For more information about TAPI and NDISTAPI, see NDISTAPI Overview.

- In a CoNDIS environment, a VC must be created. The NDPROXY driver creates a VC for an outgoing call that an application originated. Similarly, a call manager (or MCM) initiates the creation of a VC for an incoming call that the call manager indicates to NDISWAN and NDPROXY. The call manager must communicate and sometimes negotiate the parameters for the VC with the remote party. The setup, supervision, and tear-down of a connection is done through TAPI. TAPI requests and status indications to TAPI all go through NDPROXY. For more information about TAPI and NDPROXY, see NDPROXY Overview.

NDISTAPI Overview

Article • 03/14/2023

NDISTAPI is a system-provided driver that interfaces NDISWAN and NDIS WAN miniport drivers to the TAPI services. NDIS WAN miniport drivers are not supported for NDIS 5.0 and later drivers. New drivers should be based on the CoNDIS WAN driver architecture.

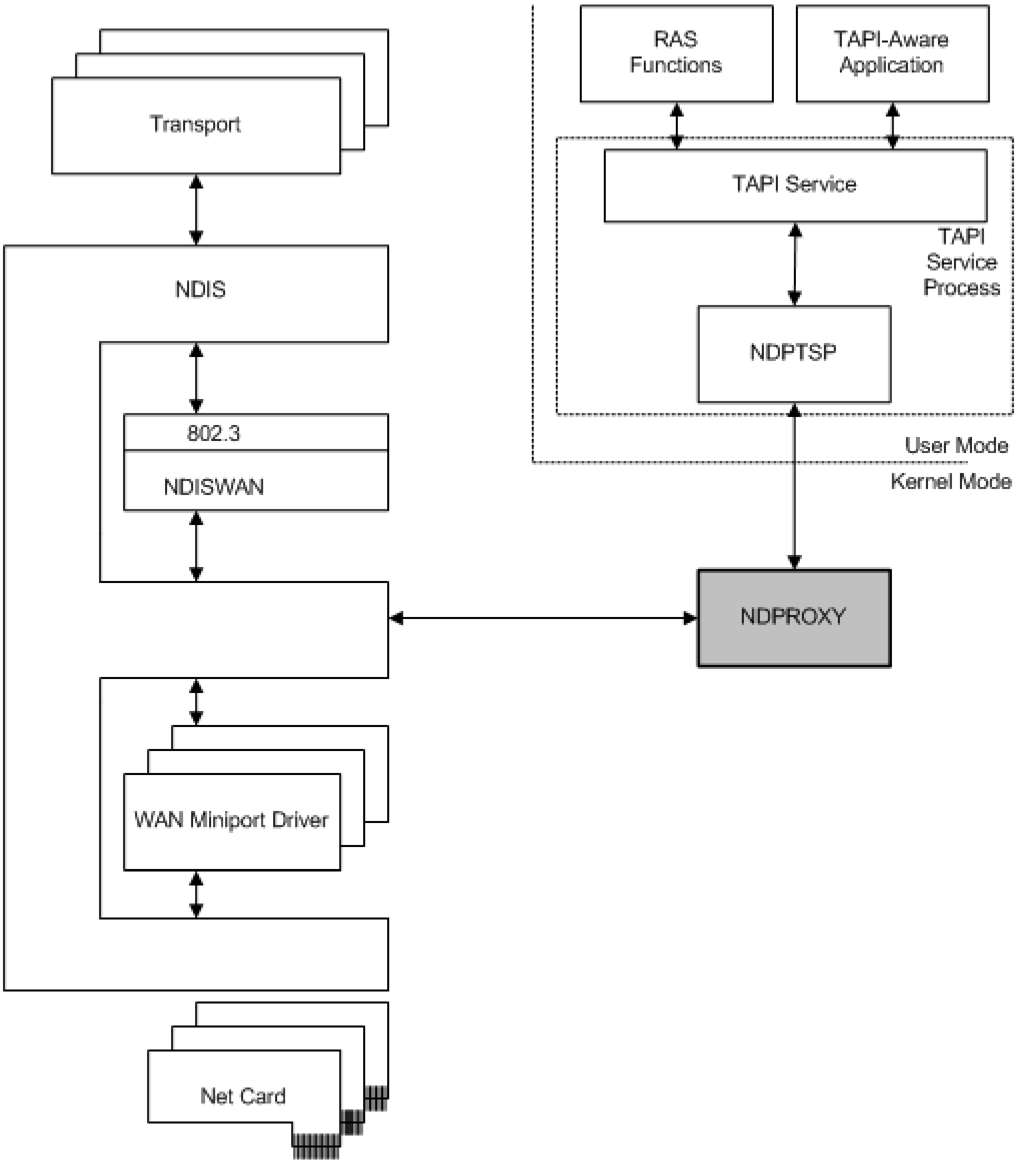
NDPROXY Overview

Article • 12/15/2021

Note If you are reading this page because of the 27 November 2013 Microsoft Security Advisory (2914486) affecting Windows XP and Windows Server 2003, you may find this Trustworthy Computing blog post helpful.

NDPROXY is a system-provided driver that interfaces NDISWAN and CoNDIS WAN drivers (WAN miniport drivers, call managers, and miniport call managers) to the TAPI services. This topic introduces NDPROXY operations that are further documented in CoNDIS WAN Operations that Support Telephonic Services.

The following figure shows how NDPROXY interfaces with other components in the RAS architecture.



NDPROXY provides the kernel-mode component of the service provider interface (SPI) for CoNDIS WAN. TAPI-aware applications make user-mode TAPI requests and the TAPI service routes these requests to NDPTSP. NDPTSP converts the user-mode TAPI service requests to kernel-mode SPI requests and passes the SPI requests to NDPROXY.

NDPROXY communicates through NDIS with the NDISWAN driver and one of the following:

- A miniport driver with a separate call manager
- An integrated miniport call manager (MCM)

The miniport driver interface and call manager interface to NDISWAN and NDPROXY are the same regardless of the configuration.

Note You can use the miniport driver with a separate call manager in situations where multiple hardware platforms need to be supported. In this situation, the same call manager can be used in combination with multiple miniport drivers to simplify development.

The following list summarizes the interfaces that exist between NDPROXY and the other components in the CoNDIS WAN driver stack:

- NDPROXY presents a connection-oriented client interface to CoNDIS WAN miniport drivers and a call manager interface to NDISWAN.
- NDISWAN presents a connection-oriented client interface to NDPROXY, CoNDIS WAN miniport drivers, and MCMs.
- CoNDIS WAN call managers or MCMs present a call manager interface to NDPROXY.
- CoNDIS WAN miniport drivers and MCMs present a CoNDIS miniport driver interface to NDISWAN.

For more information about connection-oriented clients, call managers, miniport drivers, and MCMs, see Connection-Oriented Environment.

NDPROXY calls the **NdisCoOidRequest** function with connection-oriented TAPI OIDs to determine the capabilities of a CoNDIS WAN miniport driver. NDPROXY also registers the TAPI-specific address family, creates virtual connections (VCs), makes and accepts calls, and activates VCs so that data can be sent and received on those VCs. For more information about handling OID requests in the CoNDIS WAN miniport driver, see Handling Queries in a CoNDIS WAN Miniport Driver and Setting CoNDIS WAN Miniport Driver Information.

Implementing CoNDIS WAN Miniport Drivers

Article • 03/14/2023

CoNDIS WAN miniport drivers are the same as other CoNDIS drivers with the exception of features added to support WAN operations. For more information about connection-oriented NDIS, see Connection-Oriented NDIS. For more information about features that support WAN operations, see WAN-Specific Capabilities of CoNDIS WAN Drivers.

The following topics provide information specific to CoNDIS WAN miniport drivers:

Registering CoNDIS WAN Drivers

Registering the WAN Address Family

Handling Queries in a CoNDIS WAN Miniport Driver

Setting CoNDIS WAN Miniport Driver Information

Sending Packets from a CoNDIS WAN Miniport Driver

Indicating Received Data from a CoNDIS WAN Miniport Driver

Indicating CoNDIS WAN Miniport Driver Status

WAN-Specific Capabilities of CoNDIS WAN Drivers

Article • 03/14/2023

CoNDIS WAN drivers differ from a non-WAN CoNDIS drivers as follows:

- CoNDIS WAN drivers that support TAPI services use the CO_ADDRESS_FAMILY_TAPI_PROXY address family.
- CoNDIS WAN drivers support WAN-specific OIDs: OID_WAN_PERMANENT_ADDRESS, OID_WAN_CURRENT_ADDRESS, and OID_WAN_MEDIUM_SUBTYPE.
- CoNDIS WAN miniport drivers support a set of CoNDIS WAN OIDs to set and query operating characteristics. For more information about CoNDIS WAN OIDs, see CoNDIS WAN Objects.
- CoNDIS WAN miniport drivers that provide TAPI services support a set of CoNDIS TAPI OIDs to set and query operating characteristics. For more information about CoNDIS TAPI OIDs, see TAPI Extensions for Connection-Oriented NDIS.
- CoNDIS WAN miniport drivers support a set of WAN-specific status indications that denote changes in the status of a link. For more information about CoNDIS WAN miniport driver status indications, see Indicating CoNDIS WAN Miniport Driver Status.
- CoNDIS WAN miniport drivers keep a WAN-specific set of statistics. The OID_WAN_CO_GET_STATS_INFO OID requests the miniport driver to return the statistics information.
- CoNDIS WAN miniport drivers never attempt to loop back any packets; NDISWAN provides loop-back support.

Registering CoNDIS WAN Drivers

Article • 03/14/2023

A CoNDIS WAN miniport driver or MCM calls **NdisMRegisterMiniportDriver** from its **DriverEntry** function to register its standard *MiniportXxx* functions with NDIS. For more information about registering *MiniportXxx* functions, see Initializing a Miniport Driver.

A CoNDIS WAN call manager is an NDIS protocol driver. As such, a call manager calls **NdisRegisterProtocolDriver** to register its standard *ProtocolXxx* functions. For more information about registering an NDIS protocol driver, see Initializing a Protocol Driver. For information about other differences between call manager initialization and MCM initialization, see Differences in Initialization.

The call to **NdisMRegisterMiniportDriver** provides an NDIS_MINIPORT_DRIVER_CHARACTERISTICS structure from the miniport driver. You must specify the correct NDIS version number. For more information about setting the NDIS version number, see **NDIS_MINIPORT_DRIVER_CHARACTERISTICS**.

CoNDIS WAN drivers must indicate NDIS version 5.0 or later.

NDIS 6.0 and later drivers must register CoNDIS callback functions as follows:

- To register CoNDIS *ProtocolXxx* and *MiniportXxx* functions, all CoNDIS drivers must call the **NdisSetOptionalHandlers** function.

- To register its CoNDIS *MiniportXxx* functions, a miniport driver or miniport call manager (MCM) must call the **NdisSetOptionalHandlers** function from its *MiniportSetOptions* function and pass it an **NDIS_MINIPORT_CO_CHARACTERISTICS** structure. To register call manager *ProtocolXxx* functions, MCMs also provide an **NDIS_CO_CALL_MANAGER_OPTIONAL_HANDLERS** structure.

- To register its CoNDIS *ProtocolXxx* functions, a client or call managers must call the **NdisSetOptionalHandlers** function from its *ProtocolSetOptions* function and must provide an **NDIS_PROTOCOL_CO_CHARACTERISTICS** structure. Clients must also provide an **NDIS_CO_CLIENT_OPTIONAL_HANDLERS** structure and call managers must also provide an **NDIS_CO_CALL_MANAGER_OPTIONAL_HANDLERS** structure.

For more information about CoNDIS driver registration, see CoNDIS Registration.

.

Registering the WAN Address Family

Article • 12/15/2021

This topic describes how to register the TAPI address family from a CoNDIS WAN miniport call manager (MCM) or a separate call manager.

Either type of call manager calls the **NdisCmRegisterAddressFamilyEx** function to register its call manager entry points and the address family type CO_ADDRESS_FAMILY_TAPI_PROXY. By doing so, the driver indicates that it provides TAPI services. For more information about registering an address family in a CoNDIS driver, see Registering and Opening an Address Family.

NDIS notifies NDPROXY of the newly-registered address family. NDPROXY determines that it can use the TAPI services that the call manager provides. NDPROXY opens the TAPI-proxy address family that is associated with the driver and registers NDPROXY's connection-oriented entry points with NDIS. These entry points are used to communicate with the driver.

NDPROXY can enumerate the TAPI capabilities of the miniport driver and later send TAPI requests that are encapsulated in NDIS structures. For details about using CoNDIS extensions for TAPI support, see CoNDIS WAN Operations That Support Telephonic Services.

Handling Queries in a CoNDIS WAN Miniport Driver

Article • 03/14/2023

This topic provides an overview of the requirements for handling queries in a CoNDIS WAN miniport driver. An upper-layer driver calls **NdisCoOidRequest** with a query request to determine WAN-specific capabilities and current status of a CoNDIS WAN miniport driver and the miniport driver's NIC.

After the NDISWAN intermediate driver forwards the query request, NDIS calls the miniport driver's **MiniportCoOidRequest** function. In a CoNDIS WAN miniport driver, this function is the same as in any connection-oriented miniport driver, except that the CoNDIS WAN miniport driver supports CoNDIS WAN Objects.

If the CoNDIS WAN miniport driver completes *MiniportCoOidRequest* asynchronously by returning a status of NDIS_STATUS_PENDING, it must complete the query later by calling **NdisCoOidRequestComplete**.

When NDIS calls *MiniportCoOidRequest*, NDIS passes a pointer to the **NDIS_OID_REQUEST** structure that contains the query OID and a buffer to hold the information retrieved from the miniport driver. The miniport driver controls this buffer until the request completes. If the number of bytes specified in the **InformationBufferLength** member of NDIS_OID_REQUEST is insufficient for the information that the OID requires, the miniport driver should fail the query request and set the **BytesNeeded** member of NDIS_OID_REQUEST to the number of bytes that the OID requires.

No other requests will be submitted to the particular WAN miniport driver until the current query request completes.

The following table summarizes the OIDs used to get or set operational characteristics for CoNDIS WAN miniport drivers.

Name	Optional or Required
OID_WAN_CO_GET_INFO Get information about virtual connections (VCs).	Required
OID_WAN_CO_GET_LINK_INFO Get information about a VC.	Required
OID_WAN_CO_GET_STATS_INFO Get statistics information for a VC.	Optional

A CoNDIS WAN miniport driver can support all of the NDIS General Objects. To learn more about setting information in a CoNDIS miniport driver, see Querying or Setting Information.

Setting CoNDIS WAN Miniport Driver Information

Article • 03/14/2023

This topic provides an overview of the requirements for setting information in a CoNDIS WAN miniport driver. An upper-layer driver calls **NdisCoOidRequest** with a set request to change information that a CoNDIS WAN miniport driver and the miniport driver's NIC maintain.

After the NDISWAN intermediate driver forwards the set request, NDIS calls the WAN miniport driver's **MiniportCoOidRequest** function. In a CoNDIS WAN miniport driver, this function is the same as in any CoNDIS miniport driver, except that the CoNDIS WAN miniport driver supports CoNDIS WAN Objects.

No other requests will be submitted to the CoNDIS WAN miniport driver until the current set request is complete. If the miniport driver does not immediately complete the set request, it returns NDIS_STATUS_PENDING from *MiniportCoOidRequest* and must later call **NdisCoOidRequestComplete** to complete the request.

A CoNDIS WAN miniport driver must recognize and respond properly to the following CoNDIS WAN OIDs.

Name	Optional or Required
OID_WAN_CO_SET_LINK_INFO Set information for a VC.	Required

A CoNDIS WAN miniport driver also supports the NDIS General Objects. To learn more about setting information in a CoNDIS miniport driver, see Querying or Setting Information.

Sending Packets from a CoNDIS WAN Miniport Driver

Article • 03/14/2023

An upper-layer driver calls NdisCoSendNetBufferLists to send network data packets to an underlying CoNDIS WAN miniport driver in a list of NET_BUFFER_LIST structures. The NDISWAN intermediate driver forwards those NET_BUFFER_LIST structures from the upper-layer driver. NDISWAN repackages the structures before sending them. NDISWAN forwards packets in new NET_BUFFER_LIST structures.

The NDISWAN intermediate driver calls NDIS to forward the new NET_BUFFER_LIST structures, NDIS calls the WAN miniport driver's MiniportCoSendNetBufferLists function.

The CoNDIS WAN miniport driver owns both the NET_BUFFER_LIST structures and associated data until the send completes. The miniport driver must later call NdisMSendNetBufferListsComplete to complete the send request.

A completion call does not necessarily indicate that the network datahas been transmitted; however with the exception of intelligent NICs, the network data usually has been transmitted. A completion call does however, indicate that the miniport driver is ready to release ownership of the NET_BUFFER_LIST structures.

After the CoNDIS WAN miniport driver receives NET_BUFFER_LIST structure that contains a network data packet, it should send the packet out on an active virtual connection (VC).

A CoNDIS WAN miniport driver specifies the number of outstanding packets that it can have per VC in the **MaxSendWindow** member of the NDIS_WAN_CO_INFO structure. The miniport driver provides this structure when the miniport driver responds to the OID_WAN_CO_GET_INFO request from the protocol driver. However, the miniport driver can adjust this number dynamically and on a per-VC basis by using the **SendWindow** member in the WAN_CO_LINKPARAMS structure. The miniport driver passes this structure to the NdisMCoIndicateStatusEx function. NDISWAN uses the current **SendWindow** value as its limit on outstanding sends. The miniport driver can set the value of the **SendWindow** member to zero to specify that it cannot handle any outstanding packets. That is, if the **SendWindow** member is set to zero, the send window is shut down and NDISWAN stops sending packets for the particular VC.

Packets that a WAN miniport driver sends contain simple HDLC PPP framing if PPP framing is set. For SLIP or RAS framing, packets contain only the data portion with no framing whatsoever. For more information about WAN packet framing, see WAN Packet Framing.

A WAN miniport driver must not attempt to provide software loopback or promiscuous-mode loopback. Both of these loopback types are fully supported by the NDISWAN driver.

Indicating Received Data from a CoNDIS WAN Miniport Driver

Article • 03/14/2023

The following operations occur when a CoNDIS WAN miniport driver receives a network data packet:

1. The driver removes driver-specific encapsulation from the network data packet, if necessary before calling NdisMCoIndicateReceiveNetBufferLists to indicate the received data in a NET_BUFFER_LIST structure. For example, the driver can remove PPPoE encapsulation. However, the miniport driver should leave encapsulated data, such as PPP header and payload, intact.

2. The driver calls the **NdisMCoIndicateReceiveNetBufferLists** function to indicate to NDISWAN that a packet has arrived.

3. NDISWAN processes the packet and calls NdisMIndicateReceiveNetBufferLists to indicate the arrival of the packet.

4. To forward the packet, NDIS calls the ProtocolReceiveNetBufferLists function of bound overlying protocol drivers.

Indicating CoNDIS WAN Miniport Driver Status

Article • 03/14/2023

A CoNDIS WAN miniport driver calls **NdisMCoIndicateStatusEx** to indicate status changes up to bound protocol drivers. For more information about indicating status from a CoNDIS miniport driver or MCM, see Indicating Miniport Driver Status.

Bound protocol drivers can ignore these status indications. However, processing these indications typically results in improved performance for protocol drivers and the miniport driver.

The NDISWAN intermediate driver forwards status indications to NDIS. NDIS calls the **ProtocolCoStatusEx** functions of bound protocol drivers or a configuration manager. These protocol drivers or configuration manager can log these indications and possibly take corrective action, if necessary.

For a CoNDIS WAN miniport driver, a call to **NdisMCoIndicateStatusEx** is the same as in any CoNDIS miniport driver, except that the CoNDIS WAN miniport driver indicates a WAN-specific status for each virtual connection (VC) on the miniport driver's NIC. The miniport driver calls **NdisMCoIndicateStatusEx** with an explicit VC handle to indicate these changes up to a protocol driver that shares this VC. If the driver specifies a **NULL***NdisVcHandle*, the status pertains to a general change in the state of the NIC.

Each status indication provides two basic pieces of information:

- A status code that specifies the general status. There are a limited number of defined general status codes; this list is subject to future expansion.

- A buffer that contains the status information. This status information can be specific to a NIC, or, for a CoNDIS WAN miniport driver, specific to a VC on a NIC. For example, a buffer might contain the new transmit speed of an X.25 connection, which recently decreased by a factor of two.

The CoNDIS WAN VC status indications are:

- NDIS_STATUS_WAN_CO_LINKPARAMS

  A CoNDIS WAN miniport driver calls **NdisMCoIndicateStatusEx** to indicate that the parameters for a particular VC that is active on the NIC have changed. In this call, the miniport driver passes the handle to the VC in the *NdisVcHandle* parameter, NDIS_STATUS_WAN_CO_LINKPARAMS in the *GeneralStatus* parameter, and a pointer to a **WAN_CO_LINKPARAMS** structure in the *StatusBuffer* parameter. WAN_CO_LINKPARAMS describes new parameters for the VC.

- NDIS_STATUS_WAN_CO_FRAGMENT

  A CoNDIS WAN miniport driver calls **NdisMCoIndicateStatusEx** to indicate that it has received a partial packet from the endpoint of a VC. In this call, the miniport driver passes the handle to the VC in the *NdisVcHandle* parameter, NDIS_STATUS_WAN_CO_FRAGMENT in the *GeneralStatus* parameter, and a pointer to an **NDIS_WAN_CO_FRAGMENT** structure in the *StatusBuffer* parameter. NDIS_WAN_CO_FRAGMENT describes the reason that the partial packet was received.

  After this indication occurs, a connection-oriented client should send frames to the connection-oriented client at the other end of the VC. These frames will notify the opposite endpoint of the partial-packet situation, so that the opposite endpoint is not required to wait for a time-out to occur.

  NDISWAN monitors dropped packets by counting the number of fragment indications on each VC.

CoNDIS WAN Operations that Support Telephonic Services

Article • 03/14/2023

This section describes how CoNDIS WAN miniport drivers implement telephonic services using NDIS functions in a connection-oriented environment. CoNDIS WAN miniport drivers communicate through NDIS with the NDPROXY and NDISWAN drivers. The NDPROXY driver communicates with telephony applications through a telephony service provider. For more information, see the Telephony Application Programming Interface (TAPI).

The following topics describe the NDPROXY driver more fully. These topics also describe how a CoNDIS WAN miniport driver registers and enumerates its TAPI capabilities, how it brings up lines, and how it sets up and closes calls that are initiated by TAPI requests:

NDPROXY Overview

CoNDIS TAPI Registration

CoNDIS TAPI Initialization

Making Outgoing Calls

Accepting Incoming Calls

CoNDIS TAPI Shutdown

Call Manager Requirements for Voice Streaming

Non-WAN-Specific Extensions to Support Telephonic Services Over Connection-Oriented NDIS

These descriptions briefly discuss the concepts embodied in TAPI, but the reader should consult the Windows SDK for details about TAPI. For more information about how TAPI models line devices and how all WAN miniport drivers should maintain the state of their connections, see Line Devices, Addresses, and Calls (NDIS 5.1) and Maintaining State Information (NDIS 5.1).

CoNDIS TAPI Registration

Article • 03/14/2023

This section discusses how a CoNDIS WAN miniport driver indicates that it supports TAPI services and how it sets up TAPI-specific communications with the NDISWAN and NDPROXY drivers.

After a CoNDIS WAN miniport driver has registered its miniport driver entry points for one or more NICs, the following operations cause the NDISWAN and NDPROXY drivers to become associated, in a TAPI-specific way, with those NICs.

- The CoNDIS WAN miniport driver calls the **NdisMCmRegisterAddressFamilyEx** function from within its *MiniportInitializeEx* function to register its call manager entry points and the address family type CO_ADDRESS_FAMILY_TAPI_PROXY. By doing so, the miniport driver advertises that it provides TAPI services.

- NDIS calls NDPROXY's **ProtocolCoAfRegisterNotify** function to notify NDPROXY of the newly registered address family. NDPROXY's *ProtocolCoAfRegisterNotify* examines the address-family data and determines that it can use the TAPI services provided by the call manager that is integrated into the CoNDIS WAN miniport driver. A TAPI-capable CoNDIS WAN miniport driver is an integrated miniport call manager (MCM) driver.

- NDPROXY calls the **NdisClOpenAddressFamilyEx** function to open the TAPI-proxy address family that is associated with the CoNDIS WAN miniport driver. **NdisClOpenAddressFamilyEx** registers NDPROXY's connection-oriented entry points with NDIS. These entry points are used to communicate with a TAPI-capable CoNDIS WAN miniport driver.

- NDPROXY calls **NdisCmRegisterAddressFamilyEx** to register its call manager entry points and the address family type CO_ADDRESS_FAMILY_TAPI. By doing so, NDPROXY advertises that it implements TAPI services.

- NDIS calls NDISWAN's *ProtocolCoAfRegisterNotify* function to notify NDISWAN of the newly registered address family. NDISWAN's *ProtocolCoAfRegisterNotify* examines the address-family data and determines that NDISWAN can use the TAPI services provided by NDPROXY.

- NDISWAN calls the **NdisClOpenAddressFamilyEx** function to open the TAPI address family that is associated with NDPROXY. **NdisClOpenAddressFamilyEx** registers NDISWAN's connection-oriented entry points with NDIS. These entry points are used to communicate with NDPROXY.

- NDISWAN calls the **NdisClRegisterSap** function to inform NDPROXY that NDISWAN can accept incoming calls on a particular Service Access Point (SAP). In this call, NDISWAN passes a **CO_SAP** structure that describes the SAP. NDISWAN sets the **SapType** member of CO_SAP to AF_TAPI_SAP_TYPE to specify that the SAP will be used for TAPI calls. NDISWAN sets the **Sap** member of CO_SAP to a string for a particular TAPI device class. A TAPI application provides this string when the application calls the TAPI **lineGetID** function. NDPROXY should notify NDISWAN about all incoming calls addressed to the SAP.

CoNDIS TAPI Initialization

Article • 03/14/2023

This section discusses how a CoNDIS WAN miniport driver enumerates its TAPI capabilities for applications. These TAPI capabilities consist of:

- Number of line devices the miniport driver supports--line devices include, for example, a modem, a fax board, and an ISDN card.
- Information for specific lines--line information includes, for example, a line identifier and the number of channel addresses (telephone numbers) the line supports for simultaneous transmission of voice and data.
- Information for specific channel addresses on lines of devices--address information includes, for example, the identity of a caller (Caller ID) and the number of active calls possible.

To retrieve information about underlying hardware, NDPROXY issues requests for line and channel-address capabilities. That is, the NDPROXY driver queries the TAPI capabilities of a CoNDIS WAN miniport driver. The NDPROXY driver calls the NdisCoOidRequest function to query the TAPI capabilities of the miniport driver. In this call, NDPROXY passes an NDIS_OID_REQUEST structure. NDPROXY specifies the following in NDIS_OID_REQUEST:

- **NdisRequestQueryInformation** value in the **RequestType** member
- Object identifier (OID) that specifies the TAPI capability to retrieve from the miniport driver in the **Oid** member
- Buffer to hold the TAPI-capability information that is returned in the **InformationBuffer** member

All queries sent to a CoNDIS WAN miniport driver by the NDPROXY driver can be completed either synchronously or asynchronously. If a CoNDIS WAN miniport driver determines that it cannot complete the query immediately, then it can simply return NDIS_STATUS_PENDING and call the NdisMCmOidRequestComplete function from within its *ProtocolCoOidRequest* function when it has completed the query.

After a CoNDIS WAN miniport driver notifies NDPROXY about the registration of a new address family as specified in CoNDIS TAPI Registration, NDPROXY queries the following OIDs to determine the TAPI-specific capabilities of the CoNDIS WAN miniport driver and the miniport driver's NIC.

- NDPROXY queries the miniport driver with OID_CO_TAPI_CM_CAPS to determine the number of lines supported by the miniport driver's device (the device for which it provides TAPI services). This OID also requests the miniport driver to indicate whether these lines have dissimilar line capabilities.

- NDPROXY next queries the miniport driver with OID_CO_TAPI_LINE_CAPS to determine the telephony capabilities for the specified line. This OID also requests the miniport driver to indicate whether addresses on this line have dissimilar address capabilities.
    - If the previous query of OID_CO_TAPI_CM_CAPS indicated that the miniport driver's device supports only one line, or if the device supports multiple lines that have the same line capabilities, NDPROXY has to query OID_CO_TAPI_LINE_CAPS only once to obtain the line capabilities of the device. In this case, the line capabilities returned by the miniport driver apply to all lines on the device.
    - If the device supports multiple lines with dissimilar line capabilities, NDPROXY must query OID_CO_TAPI_LINE_CAPS once for each line to obtain the line capabilities of each line.

- Finally, NDPROXY queries the miniport driver with OID_CO_TAPI_ADDRESS_CAPS to determine the telephony capabilities for a specified address on a specified line.
    - If the previous query of OID_CO_TAPI_LINE_CAPS indicated that the line supports only one address or that all addresses on the line have the same address capabilities, NDPROXY queries OID_CO_TAPI_ADDRESS_CAPS only once to determine the capabilities of all the addresses on the line.
    - If a line supports multiple addresses that have dissimilar capabilities, NDPROXY queries OID_CO_TAPI_ADDRESS_CAPS once for each address on the line.

The NDPROXY driver uses the information obtained with the TAPI enumeration OIDs to do the following:

- Create TAPI parameters for subsequent TAPI calls.

- Determine whether to accept or reject subsequent incoming TAPI calls.

- Register one or more TAPI service access points (SAPs) on which to receive subsequent incoming TAPI calls.

Making Outgoing Calls

Article • 12/15/2021

If an application attempts to make an outgoing call, it must first open a line. A line is opened as a result of an application calling the TAPI **lineOpen** function. To place a telephony call on the previously opened line, the application calls the TAPI **lineMakeCall** function and passes a pointer to the specific destination address. If anything but default call-setup parameters are requested, the application also passes a pointer to a LINECALLPARAMS structure. If the application uses default call-setup parameters, **lineMakeCall** provides those parameters in a LINECALLPARAMS structure. Members of this structure specify how the telephony call should be set up.

These TAPI-function calls cause the NDPROXY driver to first create a virtual connection (VC) with the CoNDIS WAN miniport driver and then to encapsulate TAPI parameters in NDIS structures in order to make the outgoing call. The miniport driver will use these TAPI parameters to set up the outgoing call. The following describes how the outgoing call is connected, set up, and made:

- NDPROXY calls NdisCoCreateVc to initiate the creation of the VC with the miniport driver. After NDPROXY calls **NdisCoCreateVc**, NDIS calls, as a synchronous operation, the *ProtocolCoCreateVc* function of the call manager integrated into the miniport driver. NDIS passes to *ProtocolCoCreateVc* a handle that represents the VC. If the call to **NdisCoCreateVc** is successful, NDIS fills and returns the VC handle. *ProtocolCoCreateVc* performs any necessary allocations of dynamic resources and structures that the miniport call manager (MCM) driver requires to perform subsequent operations on the VC that will later be activated. Such resources include, but are not limited to, memory buffers, data structures, events, and other such similar resources.

- NDPROXY specifies the TAPI parameters for an outgoing call in a CO_AF_TAPI_MAKE_CALL_PARAMETERS structure. NDPROXY fills this structure's members with the following information that was passed in the TAPI **lineMakeCall** function:
  - The destination address in the **DestAddress** member
  - The open-line identifier in the **ulLineID** member
  - The LINECALLPARAMS structure in the **LineCallParams** member

- NDPROXY overlays the CO_AF_TAPI_MAKE_CALL_PARAMETERS structure on the **Parameters** member of a CO_SPECIFIC_PARAMETERS structure and sets the **Length** member of CO_SPECIFIC_PARAMETERS to the size of CO_AF_TAPI_MAKE_CALL_PARAMETERS.

- NDPROXY sets the CO_SPECIFIC_PARAMETERS structure to the **MediaSpecific** member of a CO_MEDIA_PARAMETERS structure.

- NDPROXY sets a pointer to the CO_MEDIA_PARAMETERS structure to the **MediaParameters** member of a CO_CALL_PARAMETERS structure.

- Once NDPROXY encapsulates TAPI parameters, NDPROXY calls the NdisClMakeCall function to initiate the outgoing call. In this function call, NDPROXY passes a pointer to the filled CO_CALL_PARAMETERS structure. NDIS in turn calls the ProtocolCmMakeCall function of the CoNDIS WAN miniport driver's call manager. The miniport driver should examine only the CO_AF_TAPI_MAKE_CALL_PARAMETERS structure embedded in CO_CALL_PARAMETERS. No other call parameters are meaningful in this case. If the miniport driver subsequently activates the VC for the outgoing call, the miniport driver calls the NdisMCmActivateVc function and passes a pointer to the filled CO_CALL_PARAMETERS.

- After the miniport driver has negotiated with the network to establish the telephony-call parameters for the VC and set up a NIC for those call parameters, the miniport driver calls the NdisMCmMakeCallComplete function to indicate that it is ready to make data transfers on the VC. In this call, the miniport driver must pass the handle to the VC and modifications made to telephony-call parameters.

- The miniport driver must modify the **CallMgrParameters** member of the CO_CALL_PARAMETERS structure to specify the quality of service (QoS) of transferring packets, such as the bandwidth. To set this **CallMgrParameters** member, the miniport driver fills members of a CO_CALL_MANAGER_PARAMETERS structure and points this structure to **CallMgrParameters**. For example, to identify the transmit and receive speeds in bytes per second for the VC, the miniport driver must set the **PeakBandwidth** members of the **Transmit** and **Receive** members of CO_CALL_MANAGER_PARAMETERS. The **Transmit** and **Receive** members are FLOWSPEC structures. For more information about the FLOWSPEC structure, see the Microsoft Windows SDK.

- If the miniport driver has modified telephony-call parameters, it must set the **Flags** member in the CO_CALL_PARAMETERS structure with CALL_PARAMETERS_CHANGED. As a result of the **NdisMCmMakeCallComplete** call made by the miniport driver, NDIS calls NDPROXY's *ProtocolClMakeCallComplete* function to complete the asynchronous operations that were initiated with **NdisClMakeCall**.

- After the miniport driver successfully completes the outgoing call, NDPROXY notifies a TAPI application that the call is connected. This TAPI application then calls the TAPI **lineGetID** function to inform NDPROXY to locate the appropriate CoNDIS client. In this **lineGetID** call, the TAPI application supplies a string for a particular TAPI device class to which the application requires a handle. NDPROXY uses this string to locate the CoNDIS client that previously registered a SAP for the particular TAPI device class. If the CoNDIS client is NDISWAN, the string is NDIS. If NDPROXY locates a SAP with a string that matches the string passed by the TAPI application, NDPROXY calls NdisMCmCreateVc to set up a connection endpoint with NDISWAN on which it can dispatch notification of the outgoing call that was made. NDIS in turn calls NDISWAN's *ProtocolCoCreateVc* function and passes a handle that represents the VC.

- After NDPROXY sets up the connection endpoint with NDISWAN, it calls the NdisCmDispatchIncomingCall function to notify NDISWAN about the outgoing call. In this call, NDPROXY passes the encapsulated CO_AF_TAPI_MAKE_CALL_PARAMETERS structure that contains the outgoing call parameters. NDIS in turn calls NDISWAN's *ProtocolClIncomingCall* function, within which NDISWAN either accepts or rejects the requested connection. If NDISWAN changes the call parameters passed to it, it must set the **Flags** member in the CO_CALL_PARAMETERS structure with CALL_PARAMETERS_CHANGED.

- After deciding whether to accept the connection and after possibly changing the call parameters, NDISWAN calls the NdisClIncomingCallComplete function. NDIS in turn calls the miniport driver's *ProtocolCmIncomingCallComplete* function. Depending on whether NDISWAN accepted the outgoing call and whether the miniport driver accepts or rejects NDISWAN's proposed changes to the call parameters, the miniport driver calls either NdisCmDispatchCallConnected or NdisCmDispatchIncomingCloseCall functions. **NdisCmDispatchCallConnected** notifies NDISWAN that data transfers can begin on the VC that NDPROXY created for the outgoing call. **NdisCmDispatchIncomingCloseCall** informs NDISWAN and NDPROXY to tear down the proposed outgoing call.

- After NDISWAN accepts the outgoing call, NDPROXY calls the NdisCoGetTapiCallId function to retrieve a string that identifies NDISWAN's context for the VC. NDPROXY passes this string back to the TAPI application. The TAPI application uses this VC-context string to complete its call to **lineGetID**.

Accepting Incoming Calls

Article • 12/15/2021

Before an application can accept an incoming call, it first must have a line open. A line is opened as a result of an application calling the TAPI **lineOpen** function. This TAPI-function call causes underlying drivers to encapsulate TAPI parameters in NDIS structures in order to prepare to receive an incoming call. After the CoNDIS WAN miniport driver receives an incoming call, the miniport driver must first create a virtual connection (VC) with the NDPROXY driver and then notify NDPROXY of the incoming call. NDPROXY in turn notifies the application through TAPI. The following list describes how the incoming call is set up, connected, and made:

- NDPROXY specifies the TAPI parameters for an incoming connection in a CO_AF_TAPI_SAP structure. NDPROXY fills this structure's members with the following information that was passed in the TAPI **lineOpen** function:
  - Open-line identifier in the **ulLineID** member
  - Address of the incoming connection in the **ulAddressID** member
  - Media mode of the incoming connection's information stream in the **ulMediaModes** member

- NDPROXY overlays the CO_AF_TAPI_SAP structure on the **Sap** member of a CO_SAP structure and sets the **SapLength** member of CO_SAP to the size of CO_AF_TAPI_SAP. NDPROXY must also set the **SapType** member of CO_SAP to AF_TAPI_SAP_TYPE.

- Once NDPROXY encapsulates TAPI parameters, NDPROXY calls the NdisClRegisterSap function to make itself ready to receive incoming calls. In this function call, NDPROXY passes a pointer to the filled CO_SAP structure that specifies the Service Access Point (SAP) on which NDPROXY can receive incoming calls. NDIS forwards the CO_SAP structure to the *ProtocolCmRegisterSap* function of the CoNDIS WAN miniport call manager (MCM) driver. *ProtocolCmRegisterSap* communicates with network control devices or other media-specific agents, as necessary, to register the SAP on the network for NDPROXY. After the miniport driver has registered the SAP, it can accept an incoming-call offer directed to that SAP.

- A CoNDIS WAN miniport driver is alerted to an incoming call by signaling messages from the network. From these signaling messages, the miniport driver extracts the call parameters for the call, including the SAP to which the incoming call is addressed.

- Before indicating an incoming call to NDPROXY, the miniport driver calls the NdisMCmCreateVc function to initiate the creation of a VC with NDPROXY. NDPROXY allocates and initializes resources required for the VC and stores the handle to the VC.

- The CoNDIS WAN miniport driver sets the TAPI parameters for an incoming call in a CO_AF_TAPI_INCOMING_CALL_PARAMETERS structure. The miniport driver fills this structure's members with the following information that was extracted from signaling messages:
  - Line identifier in the **ulLineID** member
  - Address of the incoming call in the **ulAddressID** member
  - CO_TAPI_FLAG_INCOMING_CALL bit in the **ulFlags** member. All other bits of **ulFlags** are reserved and must be set to 0.
  - LINECALLPARAMS structure in the **LineCallInfo** member. Members of LINECALLPARAMS specify TAPI call parameters for an incoming call.

- The miniport driver overlays CO_AF_TAPI_INCOMING_CALL_PARAMETERS on the **Parameters** member of a CO_SPECIFIC_PARAMETERS structure and sets the **Length** member of CO_SPECIFIC_PARAMETERS to the size of CO_AF_TAPI_INCOMING_CALL_PARAMETERS.

- The miniport driver sets the CO_SPECIFIC_PARAMETERS structure to the **MediaSpecific** member of a CO_MEDIA_PARAMETERS structure.

- The miniport driver sets a pointer to the CO_MEDIA_PARAMETERS structure to the **MediaParameters** member of a CO_CALL_PARAMETERS structure.

- The miniport driver must also set the **CallMgrParameters** member of the CO_CALL_PARAMETERS structure to specify the quality of service (QoS) of transferring packets, such as the bandwidth. To set this **CallMgrParameters** member, the miniport driver fills members of a CO_CALL_MANAGER_PARAMETERS structure and points this structure to **CallMgrParameters**. For example, to identify the transmit and receive speeds in bytes per second for the VC, the miniport driver must set the **PeakBandwidth** members of the **Transmit** and **Receive** members of CO_CALL_MANAGER_PARAMETERS. The **Transmit** and **Receive** members are FLOWSPEC structures. For more information about the FLOWSPEC structure, see the Microsoft Windows SDK.

- After the miniport driver encapsulates TAPI parameters and fills the **CallMgrParameters** member of CO_CALL_MANAGER_PARAMETERS, it calls the NdisMCmDispatchIncomingCall function to indicate the incoming call to NDPROXY. In this call, the miniport driver passes the following:

  - A handle that identifies the SAP to which the incoming call is addressed
  - A handle that identifies the VC for the incoming call
  - A pointer to the filled CO_CALL_PARAMETERS structure

- NDPROXY returns NDIS_STATUS_PENDING to the miniport driver so NDPROXY can complete **NdisMCmDispatchIncomingCall** asynchronously.

- After the TAPI application answers the incoming call with the **lineAnswer** function, NDPROXY calls the NdisClIncomingCallComplete function. NDIS in turn calls the miniport driver's *ProtocolCmIncomingCallComplete* function. If NDPROXY returns an NDIS_STATUS_SUCCESS code, it indicates acceptance of the call parameters. If NDPROXY finds the call parameters unacceptable, it can request a change in the call parameters by setting the **Flags** member in the CO_CALL_PARAMETERS structure to CALL_PARAMETERS_CHANGED and by supplying revised call parameters. If NDPROXY accepts the incoming call, the miniport driver should send signaling messages to indicate to the calling entity that the call has been accepted. Otherwise, the miniport driver should send signaling messages to indicate that the call has been rejected. If NDPROXY is requesting a change in call parameters, the miniport driver sends signaling messages to request a change in call parameters.

- The miniport driver activates the VC that the miniport driver created with NDPROXY and must also call the NdisMCmActivateVc function to notify NDPROXY that the miniport driver is ready to transfer packets on the VC.

- If NDPROXY rejects the call, the miniport driver calls the NdisMCmDeactivateVc function to deactivate the VC that the miniport driver created for the incoming call. After the VC is deactivated, the miniport driver calls the NdisMCmDeleteVc function to delete the VC.

- Depending on whether NDPROXY accepted the incoming call and whether the end-to-end connection was successfully established, the miniport driver calls either NdisMCmDispatchCallConnected or NdisMCmDispatchIncomingCloseCall functions. Note that if the remote calling entity tore down the call, it sends signaling messages to indicate that the end-to-end connection was not successfully established. **NdisMCmDispatchCallConnected** notifies NDPROXY that data transfers can begin on the VC that the miniport driver created and activated for the incoming call. **NdisMCmDispatchIncomingCloseCall** informs NDPROXY to tear down the incoming call.

- If NDPROXY is directed to tear down the incoming call, it calls the NdisClCloseCall function to acknowledge that it will neither attempt to send nor expect to receive data on the VC. NDIS in turn calls the miniport driver's *ProtocolCmCloseCall* function. The miniport driver then calls the **NdisMCmDeactivateVc** function to deactivate the VC. After the VC is deactivated, the miniport driver calls the **NdisMCmDeleteVc** function to delete the VC.

- After the TAPI application accepts the incoming call and NDPROXY notifies the application that the call is connected, the application calls the TAPI **lineGetID** function to inform NDPROXY to locate the appropriate CoNDIS client. In this **lineGetID** call, the TAPI application supplies a string for a particular TAPI device class to which the application requires a handle. NDPROXY uses this string to locate the CoNDIS client that previously registered a SAP for the particular TAPI device class. If the CoNDIS client is NDISWAN, the string is NDIS. If NDPROXY locates a SAP with a string that matches the string passed by the TAPI application, NDPROXY calls **NdisMCmCreateVc** to set up a connection endpoint with NDISWAN on which it can dispatch notification of the incoming call. NDIS in turn calls NDISWAN's *ProtocolCoCreateVc* function and passes a handle that represents the VC.

- After NDPROXY sets up the connection endpoint with NDISWAN, it calls the NdisCmDispatchIncomingCall function to notify NDISWAN about the incoming call. In this call, NDPROXY passes the encapsulated CO_AF_TAPI_INCOMING_CALL_PARAMETERS structure that contains the incoming call parameters. NDIS in turn calls NDISWAN's *ProtocolClIncomingCall* function, within which NDISWAN either accepts or rejects the requested connection.

- After deciding whether to accept the connection and after possibly changing the call parameters, NDISWAN calls the **NdisClIncomingCallComplete** function. NDIS in turn calls the miniport driver's *ProtocolCmIncomingCallComplete* function. Depending on whether NDISWAN accepted the incoming call and whether the miniport driver accepts or rejects NDISWAN's proposed changes to the call parameters, the miniport driver calls either **NdisCmDispatchCallConnected** or **NdisCmDispatchIncomingCloseCall** functions. **NdisCmDispatchCallConnected** notifies NDISWAN that data transfers can begin on the VC that the miniport driver created for the incoming call. **NdisCmDispatchIncomingCloseCall** informs NDISWAN and NDPROXY to tear down the incoming call.

- After NDISWAN accepts the incoming call, NDPROXY calls the NdisCoGetTapiCallId function to retrieve a string that identifies NDISWAN's context for the VC. NDPROXY passes this string back to the TAPI application. The TAPI application uses this VC-context string to complete its call to **lineGetID**.

CoNDIS TAPI Shutdown

Article • 03/14/2023

A TAPI session begins after a CoNDIS WAN miniport driver has enumerated its TAPI capabilities to an application. Within a session, one or more lines can be opened and one or more calls can be established. During the time a line is open, many calls can be established and then closed or dropped. During a session, one or more lines can go through transitions from open to closed many times. How a miniport driver handles such transitions is described in this section.

Closing a Call

An in-process call can be closed either by the local node or by the remote node. The call can be closed on the local node, either because the last application with a handle to the call has closed the handle, or perhaps because the miniport driver's *MiniportHaltEx* or *MiniportResetEx* has been called. If the remote node hangs up an in-process call, the miniport driver must inform upper layers to tear down the call.

If an application on the local node closes the call, it must disconnect the call. A call is disconnected as a result of an application calling the TAPI **lineDrop** function. This TAPI-function call causes the NDPROXY driver to call the **NdisClCloseCall** function and to pass a handle that represents the VC for the call. NDIS in turn calls the CoNDIS WAN miniport driver's **ProtocolCmCloseCall** function. The miniport driver should return NDIS_STATUS_PENDING to NDPROXY so the miniport driver can complete **NdisClCloseCall** asynchronously.

The miniport driver's *ProtocolCmCloseCall* must communicate with network control devices to terminate a connection between the local node and a remote node. The miniport driver must then call the **NdisMCmDeactivateVc** function to initiate deactivation of the VC used for the call.

After the miniport driver terminates the connection, its *ProtocolCmCloseCall* can call the **NdisMCmCloseCallComplete** function to complete the call closure.

If the remote node hangs up an in-process call, the miniport driver calls the **NdisCmDispatchIncomingCloseCall** function to inform NDISWAN and NDPROXY to tear down the incoming call.

Closing a Line

A line is closed when the last application with an open handle to the line has closed the handle. A line is closed as a result of an application calling the TAPI **lineClose** function. This TAPI-function call causes the NDPROXY driver to initiate the closure of all calls on that line as described in the preceding section. The miniport driver should drop those calls and clean up their state.

Closing a Session

Session termination can be initiated by either the upper layers or a CoNDIS WAN miniport driver. After the last client process has detached from the higher-level Telephony module, the NDPROXY driver will be informed that it must terminate its session with each of the registered adapters. To do so, the NDPROXY driver calls the NdisClCloseAddressFamily function and passes the handle to the TAPI address family. NDIS in turn calls the miniport driver's ProtocolCmCloseAf function. The miniport driver should terminate any related activities it has in progress on the specified adapter and release any relevant resources. After calling **NdisClCloseAddressFamily**, the client should consider the handle to the TAPI address family invalid.

Driver-initiated session termination can occur if the miniport driver is being unloaded in its *MiniportHaltEx* function. Typically, the miniport driver would complete any outstanding NDPROXY requests and notify NDISWAN that all calls are closing. If the miniport driver were reloaded again later, it would go through the same initialization process described previously.

The CoNDIS WAN miniport driver might also initiate session termination if it underwent some dynamic reconfiguration that necessitated a complete reinitialization of all clients and drivers. For example, if an adapter's line-device modeling (for example, the number of line devices supported) was changed on the fly.

Responding to an OID_CO_TAPI_LINE_CAPS Query

Article • 12/06/2022

In response to an OID_CO_TAPI_LINE_CAPS query, a call manager or MCM returns a CO_TAPI_LINE_CAPS structure that contains a LINE_DEV_CAPS structure. To support voice streaming, a call manager or MCM must specify the following values in the LINE_DEV_CAPS structure:

- **ulMediaModes**

  This field should contain LINEMEDIAMODE_AUTOMATEDVOICE, which maps to TAPIMEDIAMODE_AUDIO in TAPI 3.0.

- **ulAddressTypes**

  This field must be filled in appropriately. For a description of valid values, see the description of **dwAddressTypes**. This field must not be zero.

- **ulGenerateDigitModes**

  This field must be filled in with a bitwise OR of the LINEDIGITMODE_constants that specify the digit modes that can be generated on the line. For a description of the LINEDIGITMODE_constant, see the description of **dwGenerateDigitModes**.

- **ulMonitorDigitModes**

  This field must be filled in with a bitwise OR of the LINEDIGITMODE_constants that specify the digit modes than can be detected on this line. For a description of the LINEDIGITMODE_constants, see the description of **dwMonitorDigitModes**.

Specifying Parameters for an Outgoing Call

Article • 12/15/2021

When making an outgoing call, a call manager or MCM that supports voice streaming must supply the following values in the **CO_CALL_MANAGER_PARAMETERS** structure:

- Maximum transmit SDU size (CallMgrParameters->Transmit.MaxSduSize)

- Maximum receive SDU size (CallMgrParameters->Receive.MaxSduSize)

A call manager or MCM that supports an address family other than CO_ADDRESS_FAMILY_TAPI_PROXY fills in these values when translating TAPI call parameters to NDIS call parameters in response to a query of OID_CO_TAPI_TRANSLATE_TAPI_CALLPARAMS.

A call manager or MCM that supports the CO_ADDRESS_FAMILY_TAPI_PROXY family writes these values to the CO_CALL_MANAGER_PARAMETERS structure in the context of its **ProtocolCmMakeCall** function. Note that the maximum SDU sizes passed to the *ProtocolCmMakeCall* function are incorrect. The *ProtocolCmMakeCall* function must overwrite the incorrect values with correct values.

Specifying Parameters for an Incoming Call

Article • 12/06/2022

When indicating an incoming call with **Ndis(M)CmDispatchIncomingCall**, a call manager or MCM that supports voice streaming must specify the following values in the CO_CALL_MANAGER_PARAMETERS structure:

- Maximum transmit SDU size (CallMgrParameters->Transmit.MaxSduSize)
- Maximum receive SDU size (CallMgrParameters->Receive.MaxSduSize)

In addition, a call manager or an MCM must specify the following values in the LINE_CALL_INFO structure:

- **ulMediaMode**

  This field should contain LINEMEDIAMODE_AUTOMATEDVOICE, which maps to TAPIMEDIAMODE_AUDIO in TAPI 3.0.

- **ulCallerIDFlags**
- **ulCallerIDSize**
- **ulCallerIDOffset**
- **ulCallerIDNameSize**
- **ulCallerIDNameOffset**
- **ulCalledIDFlags**
- **ulCalledIDSize**
- **ulCalledIDOffset**
- **ulCalledIDNameSize**
- **ulCalledDNameOffset**
- **ulCallerIDAddressType**
- **ulCalledIDAddressType**

A call manager or MCM that supports an address family other than CO_ADDRESS_FAMILY_TAPI_PROXY specifies the preceding LINE_CALL_INFO members when responding to an OID_CO_TAPI_TRANSLATE_NDIS_CALLPARAMS query.

A call manager or an MCM that supports the CO_ADDRESS_FAMILY_TAPI_PROXY family specifies the above-listed LINE_CALL_INFO members in the media-specific portion of the CO_CALL_MANAGER_PARAMETERS structure that it supplies to **Ndis(M)CmDispatchIncomingCall**.

Non-WAN-Specific Extensions to Support Telephonic Services Over Connection-Oriented NDIS

Article • 03/14/2023

This topic describes non-WAN-specific extensions for TAPI support over connection-oriented NDIS. These extensions are the NDIS/TAPI translation OIDs. These extensions allow non-WAN-specific call managers and integrated miniport call manager (MCM) drivers to translate TAPI parameters to NDIS parameters or TAPI parameters to NDIS parameters. These extensions allow call managers and MCMs that support ATM, for example, to provide TAPI access over connection-oriented media. For information about WAN-specific extensions for TAPI support over connection-oriented NDIS, see CoNDIS WAN Operations that Support Telephonic Services.

The NDIS/TAPI translation OIDs should not be used for call managers or MCMs that respectively register CO_ADDRESS_FAMILY_TAPI_PROXY with **NdisCmRegisterAddressFamilyEx** or **NdisMCmRegisterAddressFamilyEx**. Instead, such call managers and MCMs, as well as their TAPI clients, should encapsulate TAPI parameters inside connection-oriented structures, as described in CoNDIS WAN Operations that Support Telephonic Services.

The NDIS/TAPI translation OIDs are as follows:

- OID_CO_TAPI_TRANSLATE_TAPI_CALLPARAMS

  This OID requests a call manager or MCM to translate TAPI call parameters supplied by the client to NDIS call parameters. The client typically uses the NDIS call parameters returned by the call manager or MCM as an input (formatted as a **CO_CALL_PARAMETERS** structure) to **NdisClMakeCall**. The client uses **NdisClMakeCall** to initiate a connection-oriented call.

- OID_CO_TAPI_TRANSLATE_NDIS_CALLPARAMS

  This OID requests a call manager or MCM to translate NDIS call parameters for an incoming call (passed in a CO_CALL_PARAMETERS structure to the client's **ProtocolClIncomingCall** function) to TAPI call parameters. The client uses the translated TAPI call parameters returned by the call manager or MCM to determine whether to accept or reject the incoming call.

- OID_CO_TAPI_TRANSLATE_SAP

This OID requests a call manager or MCM to prepare one or more NDIS SAPs from TAPI call parameters that are supplied by the client. The client typically uses an NDIS SAP returned by the call manager or MCM as an input (formatted as a **CO_SAP** structure) to **NdisClRegisterSap**, with which the client registers a SAP on which to receive incoming calls.

WAN Packet Framing Overview

Article • 12/15/2021

This section provides information about WAN packet framing.

The NDISWAN intermediate driver retrieves information about the WAN packet framing performed by a WAN miniport driver from the miniport driver's response to the OID_WAN_MEDIUM_SUBTYPE query information request.

NDISWAN converts an out-going packet from LAN to PPP format. NDISWAN uses simple HDLC framing. Most of the media-specific framing must be done by the miniport driver.

Before sending packets to the WAN miniport driver's send function, NDISWAN does simple PPP HDLC framing. Simple PPP HDLC framing is PPP's HDLC framing without the FCS, bit or byte stuffing, and any beginning or end flags.

The following topics provide additional information about WAN packet framing:

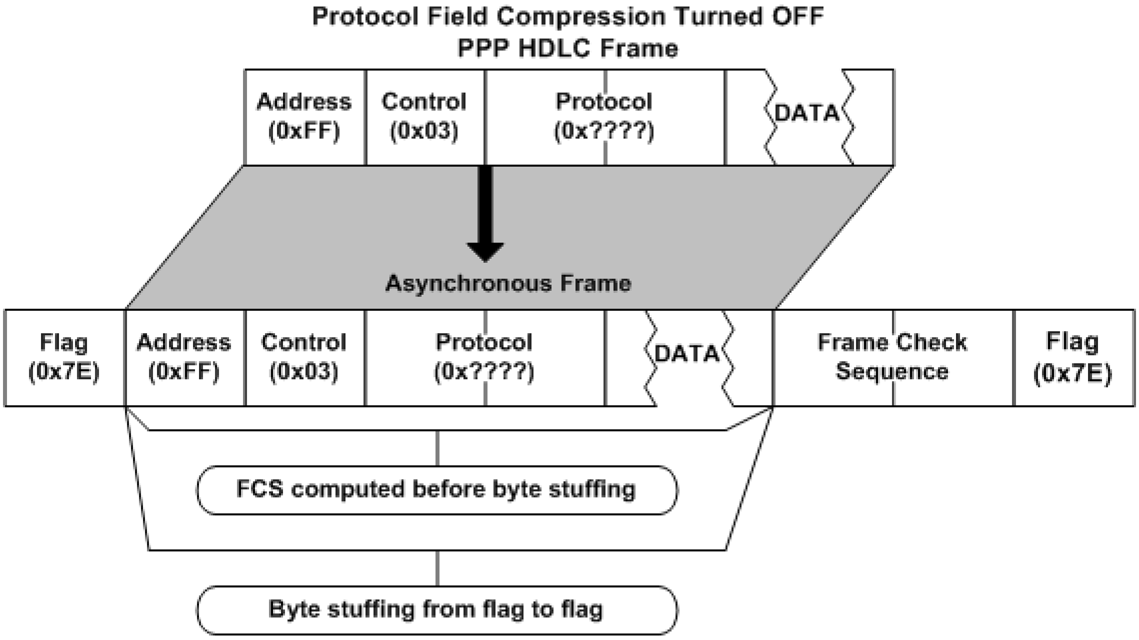
Asynchronous Framing

ISDN and Switched-56K Framing

Asynchronous Framing

Article • 12/15/2021

The following diagram illustrates asynchronous framing with compression turned off.



ISDN and Switched 56K Framing

Article • 12/15/2021

Initially, ISDN B channels (not D channels) should be used. Multiple B channel support is done through NDISWAN's multilink support. Initially, bit-synchronous HDLC framing with NRZ encoding should be used. Transparency should be provided by the driver or ISDN hardware. It is also the responsibility of the ISDN driver or hardware to provide for NRZ encoding, to calculate the FCS to add the PPP end flag (0x7E), and to insert any inter-frame time fill. Switched 56K drivers should frame in the same manner as ISDN.

WAN Miniport Driver Build Parameters

Article • 12/15/2021

This topics provides some information about defining build parameters for NDIS and CoNDIS WAN miniport drivers.

Add the following line to your Sources file before building to identify your driver as a miniport driver.

Text

```
C_DEFINES=/DNDIS_MINIPORT_DRIVER
```

If you are writing an NDIS WAN miniport driver that supports connections through TAPI, you must add the following line to your Sources file before building to identify the TAPI version that your driver supports.

Text

```
C_DEFINES=-DNDIS_TAPI_CURRENT_VERSION=0x00010003
```

If you are writing a CoNDIS WAN miniport driver that is an integrated miniport call manager (MCM) and that supports the CoNDIS address family type CO_ADDRESS_FAMILY_TAPI_PROXY, you must add the following line to your sources file before building to identify the TAPI version that your driver supports.

Text

```
C_DEFINES=-DNDIS_TAPI_CURRENT_VERSION=0x00030000
```

For WAN miniport drivers, the include paths should include Ndiswan.h as well as Ndis.h.

If the WAN miniport driver supports connections through TAPI, the driver should also include Ndistapi.h.

Standardized INF Keywords for Network Devices

Article • 12/15/2021

This section provides information about standardized keywords that appear in the registry and are specified in INF files. NDIS 6.0 and later versions of NDIS support standardized keywords for miniport drivers in network devices.

Standardized keywords provide:

- Standardized user interface properties for end users.
- The ability for both home network users and large-scale enterprises to easily configure networks that include devices from multiple hardware manufacturers.
- The ability to programmatically test for all advanced network device features.

The following standard INF keywords are mandatory for connectionless NDIS 6.0 and later miniport drivers:

- ***IfType**
- ***MediaType**
- ***PhysicalMediaType**

If the mandatory keywords are missing from the driver's INF file, NDIS does not call the miniport driver's *MiniportInitializeEx* function.

Standardized keywords are required for NDIS 6.0 and later miniport drivers if both of the following are true:

- An INF setting must be exposed in the **Advanced** properties page of the user interface.
- The device fully supports the specified properties.

Note Standardized keywords are optional but recommended for NDIS 5.1 and earlier NDIS miniport drivers.

This section specifies the INF keywords that are exposed in the user interface. However, miniport drivers must read the registry settings during initialization to determine the current configuration settings.

Within an INF file, definitions for these keywords are placed with the other definitions for the advanced properties page. For more information about advanced properties, see Specifying Configuration Parameters for the Advanced Properties Page.

All standardized keyword names start with an asterisk (*). This naming convention enables you to easily distinguish standardized names from non-standard names.

There are three types of standardized keyword data that are exposed in the user interface:

Enum
Values that can be selected from a list that appears in a drop down menu in the **Advanced** properties page.

Int
Numerical values that you can edit.

Edit
Text values that you can edit.

The following topics include descriptions for the standardized keywords that are common to all networking technologies:

Enumeration Keywords

Keywords That Can Be Edited

Keywords Not Displayed in the User Interface

In addition, standardized keywords that are specific to networking technologies are described in the following topics:

INF File Settings for Filter Drivers

INF Requirements for NDKPI

MB Miniport Driver INF Requirements

Standardized INF Keywords for Header-Data Split

Standardized INF Keywords for NDIS Quality of Service (QoS)

Standardized INF Keywords for NDIS Selective Suspend

Standardized INF Keywords for NVGRE Task Offload

Standardized INF Keywords for NDIS Packet Timestamping

Standardized INF Keywords for Packet Coalescing

Standardized INF Keywords for Power Management

Standardized INF Keywords for RSC

Standardized INF Keywords for RSS

Standardized INF Keywords for Single Root I/O Virtualization (SR-IOV)

Standardized INF Keywords for Virtual Machine Queue (VMQ)

Enumeration Keywords

Article • 12/15/2021

NDIS 6.0 and later versions of NDIS provide standardized enumeration keywords for miniport drivers of network devices. Enumeration keywords are associated with values that appear as a list in a menu.

The following example shows an INF file definition for an enumeration keyword.

```INF
HKR, Ndi\params\<SubkeyName>, ParamDesc, 0, "%<SubkeyName>%"
HKR, Ndi\params\<SubkeyName>, Type, 0, "enum"
HKR, Ndi\params\<SubkeyName>, Default, 0, "3"
HKR, Ndi\params\<SubkeyName>, Optional, 0, "0"
HKR, Ndi\params\<SubkeyName>\enum, "0", 0, "%Disabled%"
HKR, Ndi\params\<SubkeyName>\enum, "1", 0, "%Tx Enabled%"
HKR, Ndi\params\<SubkeyName>\enum, "2", 0, "%Rx Enabled%"
HKR, Ndi\params\<SubkeyName>\enum, "3", 0, "%Rx & Tx Enabled%"
```

The general enumeration keywords are:

***SpeedDuplex**
Speed and duplex settings that a device supports. The device INF file should list only the settings that the associated device supports. That is, for an Ethernet 10/100 device that can support only full-duplex mode, settings for Gigabit or higher speeds or half duplex should not be listed in the associated INF file.

Speed values that are not specifically defined already with enumerated values of 0 through 10 may be set as a number that is the value directly in Mbps. Direct values must be at least 1,000 Mbps (1 Gbps) and above. Here are a few examples for specifying the speed directly:

SpeedDuplex value	Resulting speed
1,000	1 Gbps
10,000	10 Gbps
25,000	25 Gbps
50,000	50 Gbps
100,000	100 Gbps

***FlowControl**
The ability for the device to enable or disable flow control in the send or receive path.

Note Ethernet devices today support flow control, and the Windows 8 in-box drivers for LAN have flow control enabled by default. When a kernel debugger attaches to one of these LAN adapters, the NIC will start pushing flow control pause frames into the network. Most network switches will react by temporarily taking down the network for all other computers that are connected to the same hub. This is a common development scenario, and the end-user experience is both undesirable and difficult to diagnose.

Note Client and Server defaults are not the same; refer to the table of defaults below.

For this reason, in Windows 8 and later, NDIS will disable flow control automatically when debugging is enabled on the computer (for example, by typing **bcdedit /set debug on** at the command line). When kernel debugging is enabled and the miniport calls NdisReadConfiguration and passes "*FlowControl" for the *Keyword* parameter, NDIS will override the configured value and return zero.

If you need to enable flow control while debugging, NDIS provides the **AllowFlowControlUnderDebugger** registry value to allow you to do that. The **AllowFlowControlUnderDebugger** registry value prevents NDIS from disabling flow control, and allows NICs to keep their configured behavior. It can be found under the following registry key:

HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\NDIS\Parameters

Set this registry value to 0x00000001.

If it does not exist, you can create a value with the name **AllowFlowControlUnderDebugger** and the type **REG_DWORD** and set it to 0x00000001.

***PriorityVLANTag**
A value that indicates whether the device has enabled or disabled the ability to insert the 802.1Q tags for packet priority and virtual LANs (VLANs). This keyword does not indicate whether the device enabled or disabled packet priority or VLAN tags. Instead, it describes the following:

- Whether the device inserts 802.1Q tags during a send operation
- Whether 802.1Q tag information is available in the NET_BUFFER_LIST out-of-band (OOB) information
- Whether the device copies 802.1Q tags to OOB during receive operations

The miniport driver should remove the 802.1Q header from all receive packets regardless of the ***PriorityVLANTag** setting. If the 802.1Q header is left in a packet, other drivers might not be able to parse the packet correctly.

If the Rx flag is enabled on the receive path, the miniport driver should copy the removed 802.1Q header into OOB.

Otherwise, if the Rx flag is disabled, the miniport driver should not copy the removed 802.1Q header into OOB.

If the Tx flag is enabled on the transmit path, the miniport driver should do the following:

- Insert the 802.1Q header into each outgoing packet and fill it up with the data from OOB (if any non-zero data exists in OOB).
- Advertise appropriate **MacOptions** in NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES (**NDIS_MAC_OPTION_8021P_PRIORITY** and **NDIS_MAC_OPTION_8021Q_VLAN**).

Otherwise, if the Tx flag is disabled, then:

- The miniport filter should not honor 802.1Q information in OOB (and therefore not insert any tag).
- The miniport filter should not advertise appropriate **MacOptions** in NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES.

Note If the miniport driver supports NDIS quality of service (QoS), it must also read the ***QOS** keyword value. Based on the ***QOS** keyword value, the ***PriorityVLANTag** keyword values are interpreted differently. For more information, see Standardized INF Keywords for NDIS QoS.

***InterruptModeration**
A value that describes whether the device enabled or disabled interrupt moderation. Interrupt moderation algorithms are device-dependent. The device manufacturer can use non-standardized keywords to support algorithmic settings. For more information about interrupt moderation, see Interrupt Moderation.

***RSS**
A value that describes whether the device enabled or disabled receive side scaling (RSS). For more information about RSS, see Receive Side Scaling.

***HeaderDataSplit**
A value that describes whether the device enabled or disabled header-data split. For more information about header-data split, see Header-Data Split.

The following keywords are associated with connection offload services:

***TCPConnectionOffloadIPv4**

***TCPConnectionOffloadIPv6**

For more information about the connection offload keywords, see Using Registry Values to Enable and Disable Connection Offloading.

The following keywords are associated with task offload services:

***IPChecksumOffloadIPv4**

***TCPChecksumOffloadIPv4**

***TCPChecksumOffloadIPv6**

***UDPChecksumOffloadIPv4**

***UDPChecksumOffloadIPv6**

***LsoV1IPv4**

***LsoV2IPv4**

Note For devices that support both large send offload version 1 (LSOv1) and LSOv2 over IPv4, only the ***LsoV2IPv4** keyword should be used in the INF file and registry values. If, for example, the ***LsoV2IPv4** keyword appears in the INF file and the ***LsoV1IPv4** keyword appears in the registry (or vice versa), the ***LsoV2IPv4** keyword always takes precedence.

***LsoV2IPv6**

***IPsecOffloadV1IPv4**

***IPsecOffloadV2**

***IPsecOffloadV2IPv4**

***TCPUDPChecksumOffloadIPv4**

***TCPUDPChecksumOffloadIPv6**

For more information about the TCP/IP offload keywords, see Using Registry Values to Enable and Disable Task Offloading.

The columns in the table at the end of this topic describe the following attributes for enumeration keywords:

SubkeyName
The name of the keyword that you must specify in the INF file and that appears in the registry.

ParamDesc
The display text that is associated with **SubkeyName**.

Value
The enumeration integer value that is associated with each option in the list. This value is stored in **NDI\params\***SubkeyName*\*Value*.

EnumDesc
The display text that is associated with each value that appears in the menu.

Default
The default value for the menu.

The following table lists all of the keywords and describes the values that a driver must use for the preceding attributes. For more information about a keyword, search for the keyword in the WDK documentation.

SubkeyName	ParamDesc	Value	EnumDesc
***SpeedDuplex**	Speed & Duplex	0 (Default)	Auto Negotiation
		1	10 Mbps Half Duplex
		2	10 Mbps Full Duplex
		3	100 Mbps Half Duplex
		4	100 Mbps Full Duplex
		5	1.0 Gbps Half Duplex
		6	1.0 Gbps Full Duplex
		7	10 Gbps Full Duplex
		8	20 Gbps Full Duplex
		9	40 Gbps Full Duplex
		10	100 Gbps Full Duplex
***FlowControl**	Flow Control	0 (Server Default)	Tx & Rx Disabled
		1	Tx Enabled

SubkeyName	ParamDesc	Value	EnumDesc
		2	Rx Enabled
		3 (Client Default)	Rx & Tx Enabled
		4	Auto Negotiation
***PriorityVLANTag**	Packet Priority & VLAN	0	Packet Priority & VLAN Disabled
		1	Packet Priority Enabled
		2	VLAN Enabled
		3 (Default)	Packet Priority & VLAN Enabled
***InterruptModeration**	Interrupt Moderation	0	Disabled
		1 (Default)	Enabled
***RSS**	Receive Side Scaling	0	Disabled
		1 (Default)	Enabled
***HeaderDataSplit**	Header Data Split	0 (Default)	Disabled
		1	Enabled
***TCPConnectionOffloadIPv4**	TCP Connection Offload (IPv4)	0	Disabled
		1 (Default)	Enabled
***TCPConnectionOffloadIPv6**	TCP Connection Offload (IPv6)	0	Disabled
		1 (Default)	Enabled
***IPChecksumOffloadIPv4**	IPv4 Checksum Offload	0	Disabled
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Rx & Tx Enabled
***TCPChecksumOffloadIPv4**	TCP Checksum Offload (IPv4)	0	Disabled

SubkeyName	ParamDesc	Value	EnumDesc
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Rx & Tx Enabled
***TCPChecksumOffloadIPv6**	TCP Checksum Offload (IPv6)	0	Disabled
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Rx & Tx Enabled
***UDPChecksumOffloadIPv4**	UDP Checksum Offload (IPv4)	0	Disabled
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Rx & Tx Enabled
***UDPChecksumOffloadIPv6**	UDP Checksum Offload (IPv6)	0	Disabled
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Rx & Tx Enabled
***LsoV1IPv4**	Large Send Offload Version 1 (IPv4)	0	Disabled
		1 (Default)	Enabled
***LsoV2IPv4**	Large Send Offload Version 2 (IPv4)	0	Disabled
		1 (Default)	Enabled
***LsoV2IPv6**	Large Send Offload Version 2 (IPv6)	0	Disabled
		1 (Default)	Enabled
***IPsecOffloadV1IPv4**	IPsec Offload Version 1 (IPv4)	0	Disabled

SubkeyName	ParamDesc	Value	EnumDesc
		1	Auth Header Enabled
		2	ESP Enabled
		3 (Default)	Auth Header & ESP Enabled
***IPsecOffloadV2**	IPsec Offload	0	Disabled
		1	Auth Header Enabled
		2	ESP Enabled
		3 (Default)	Auth Header & ESP Enabled
***IPsecOffloadV2IPv4**	IPsec Offload (IPv4 only)	0	Disabled
		1	Auth Header Enabled
		2	ESP Enabled
		3 (Default)	Auth Header & ESP Enabled
***TCPUDPChecksumOffloadIPv4**	TCP/UDP Checksum Offload (IPv4)	0	Disabled
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Tx and Rx Enabled
***TCPUDPChecksumOffloadIPv6**	TCP/UDP Checksum Offload (IPv6)	0	Disabled
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Tx and Rx Enabled

Keywords That Can Be Edited

Article • 12/15/2021

NDIS 6.0 and later versions of NDIS provide standardized keywords that can be edited for miniport drivers of network devices. These standardized keywords are associated with numeric or text values that you can edit in the user interface.

The following example shows an INF file definition for a keyword that can be edited.

INF

```
HKR, Ndi\params\<SubkeyName>,ParamDesc, 0, "<ParamDesc>"
HKR, Ndi\params\<SubkeyName>,Type, 0, "int"
HKR, Ndi\params\<SubkeyName>,Default, 0, "<IHV defined>"
HKR, Ndi\params\<SubkeyName>,Optional, 0, "0"
HKR, Ndi\params\<SubkeyName>,Min, 0, "0"
HKR, Ndi\params\<SubkeyName>,Max, 0, "<IHV defined>"
```

The standard keywords that can be edited are:

__*JumboPacket__ The size, in bytes, of the largest supported Jumbo Packet (an Ethernet frame that is greater than 1514 bytes) that the hardware can support. This is also known as a Jumbo Frame. _*JumboPacket_'s range of values and maximum value are IHV-defined. For more info, check with your IHV.

__*ReceiveBuffers__
The number of receive descriptors used by the miniport adapter. The miniport driver can choose any default value that is appropriate for performance-tuning. Note that if the value is too small, the miniport adapter may run out of receive buffers under heavy load. If the value is too large, system resources are wasted.

__*TransmitBuffers__
The size, in bytes, of the transmit buffers that the hardware can support. This size is hardware-dependent and can include data buffers, buffer descriptors, and so on. Hardware vendors can assign any value that is appropriate for their purposes.

__*NetworkAddress__
The network address of the device. The format for a MAC address is: XX-XX-XX-XX-XX-XX. The hyphens (-) are optional.

The columns in the table at the end of this topic describe the following attributes for keywords that can be edited:

SubkeyName
The name of the keyword that you must specify in the INF file and that appears in the registry.

ParamDesc
The display text that is associated with SubkeyName.

Type
The type of value that can be edited. The value can be either numeric (**Int**) or text that can be edited (**Edit**).

Default value
The default value for the integer or text. <IHV defined> indicates that the value is associated with the particular independent hardware vendor (IHV) requirements.

Min
The minimum value that is allowed for an integer. <IHV defined> indicates that the minimum value is associated with the particular IHV requirements.

Max
The maximum value that is allowed for an integer. <IHV defined> indicates that the minimum value is associated with the particular IHV requirements.

The following table lists all of the keywords and describes the values that a driver must use for the preceding attributes. For more information about a keyword, search for the keyword in the WDK documentation.

SubkeyName	ParamDesc	Type	Default value	Min	Max
***JumboPacket**	Jumbo Packet	Int	1514	1514	
***ReceiveBuffers**	Receive Buffers	Int		1	
***TransmitBuffers**	Transmit Buffers	Int		0	
***NetworkAddress**	Network Address	Edit	N/A	N/A	N/A

Keywords Not Displayed in the User Interface

Article • 12/15/2021

NDIS 6.0 and later versions of NDIS provide some standardized keywords for miniport drivers of network devices. These standardized keywords appear in INF files but not in the user interface.

These general keywords are described in the following list. For more information about a particular keyword, search for the keyword in the WDK documentation.

***IfType**
The NDIS interface type for a device. For more information about the NDIS interface type, see NDIS Interface Types.

***MediaType**
The media type for a device. For more information about the media type of the miniport adapter, see OID_GEN_MEDIA_SUPPORTED.

***PhysicalMediaType**
The physical media type for a device. For more information about the physical media type of the miniport adapter, see OID_GEN_PHYSICAL_MEDIUM.

***NdisDeviceType**
The type of the device. The default value is zero, which indicates a standard networking device that connects to a network. Set ***NdisDeviceType** to NDIS_DEVICE_TYPE_ENDPOINT (1) if this device is an endpoint device and is not a true network interface that connects to a network. For example, you must specify NDIS_DEVICE_TYPE_ENDPOINT for devices such as smart phones that use a networking infrastructure to communicate to the local computer system but do not provide connectivity to an external network. However, you must ***not*** set this keyword to NDIS_DEVICE_TYPE_ENDPOINT for virtual adapters such as VPN interfaces, because they provide connectivity to an external network.

Note Windows Vista automatically identifies and monitors the networks a computer connects to. If the NDIS_DEVICE_TYPE_ENDPOINT flag is set, the device is an endpoint device and is not a connection to a true external network. Consequently, Windows ignores the endpoint device when it identifies networks. The Network Awareness APIs indicate that the device does not connect the computer to a network. For end users in this situation, the Network and Sharing Center and the network icon in the notification area do not show the NDIS endpoint device as connected. However, the connection is shown in the Network Connections Folder.

Roadmap for Developing NDIS Protocol Drivers

Article • 03/14/2023

To create a Network Driver Interface Specification (NDIS) protocol driver package, follow these steps:

- Step 1: Learn about Windows architecture and drivers.

  You must understand the fundamentals of how drivers work in Windows operating systems. Knowing the fundamentals will help you make appropriate design decisions and let you streamline your development process. For more information about driver fundamentals, see Concepts for all driver developers.

- Step 2: Learn about NDIS.

  For general information about NDIS and NDIS drivers, see the following topics:

  Windows Network Architecture and the OSI Model

  Network Driver Programming Considerations

  Driver Stack Management

  NET_BUFFER Architecture

- Step 3: Determine additional Windows driver design decisions.

  For more information about how to make additional Windows design decisions, see Creating Reliable Kernel-Mode Drivers, Programming Issues for 64-Bit Drivers, and Creating International INF Files.

- Step 4: Learn about the Windows driver build, test, and debug processes and tools.

  Building a driver differs from building a user-mode application. For more information about Windows driver build, debug, and test processes, driver signing, and Windows Hardware Lab Kit (HLK) testing, see Building, Debugging, and Testing Drivers. For more information about building, testing, verifying, and debugging tools, see Driver Development Tools.

- Step 5: Read the protocol driver introduction topics. Introduction to NDIS Protocol Drivers Protocol Driver Design Concepts

- Step 6: Read the writing protocol drivers section.

This section provides an overview of the primary protocol driver interfaces. These interfaces included functions that protocol drivers provide (*ProtocolXxx* functions) and NDIS calls to initiate operations. NDIS provides **Ndis*Xxx*** functions that protocol drivers call to perform NDIS operations.

- Step 7: Review the NDIS protocol driver sample in the Windows driver samples repository on GitHub.

- Step 8: Develop (or port), build, test, and debug your NDIS driver.

  See the porting guides if you are porting an existing driver:
  - Porting NDIS 5.x Drivers to NDIS 6.0
  - Porting NDIS 6.x Drivers to NDIS 6.20
  - Porting NDIS 6.x Drivers to NDIS 6.30

  For more information about iterative building, testing, and debugging, see Overview of Build, Debug, and Test Process. This process will help ensure that you build a driver that works.

- Step 9: Create a driver package for your driver.

  For more information about how to install drivers, see Providing a Driver Package. For more information about how to install an NDIS driver, see Components and Files Used for Network Component Installation and Notify Objects for Network Components.

- Step 10: Sign and distribute your driver.

  The final step is to sign (optional) and distribute the driver. If your driver meets the quality standards that are defined for the Windows Hardware Lab Kit (HLK), you can distribute it through the Microsoft Windows Update program. For more information about how to distribute a driver, see Get started with the hardware submission process.

These are the basic steps. Additional steps might be necessary based on the needs of your individual driver.

Introduction to NDIS Protocol Drivers

Article • 03/14/2023

An NDIS protocol driver exports a set of *ProtocolXxx* functions at its lower edge. Such a protocol driver communicates with NDIS to send and receive network data. The protocol driver binds to an underlying miniport driver or intermediate driver that exports a *MiniportXxx* interface at its upper edge.

Note The miniport driver upper edge of an intermediate driver (virtual miniport) does not manage physical devices. Underlying miniport drivers manage physical devices.

Protocol drivers always use NDIS-provided functions to communicate with underlying NDIS drivers to send and receive network data. For example, a protocol driver that has a connectionless lower-edge (which communicates with underlying drivers for connectionless media, such as Ethernet) must call **NdisSendNetBufferLists** to send network data to an underlying NDIS driver. The protocol driver can call **NdisOidRequest** to query or set OIDs that underlying connectionless drivers support. A protocol driver that has a connection-oriented lower edge (which communicates with underlying drivers for connection-oriented media, such as ISDN) must call **NdisCoSendNetBufferLists** to send network data to a lower-level NDIS driver. It can also call **NdisCoOidRequest** to query or set OIDs that are supported by underlying connection-oriented drivers.

NDIS also provides a set of **Ndis*Xxx*** functions that hide the details of the underlying operating system. For example, a protocol driver can call **NdisInitializeEvent** to create an event for synchronization purposes and **NdisInitializeListHead** to create a linked list. Protocol drivers that use the NDIS versions of such functions are more portable across Microsoft operating systems. However, protocol drivers can also call kernel-mode support routines, such as **IoCreateDevice**. For more information, see Summary of Kernel-Mode Support Routines.

Developers of protocol drivers should use the same programming considerations that are applied to other NDIS drivers.

Initializing a Protocol Driver

Article • 12/15/2021

The system calls a protocol driver's DriverEntry routine after it loads the driver. Protocol drivers load as system services. They can load at any time before, during, or after the miniport drivers load.

Protocol drivers allocate driver resources and register *ProtocolXxx* functions in **DriverEntry**. This includes CoNDIS clients and stand-alone call managers. To register its *ProtocolXxx* functions with NDIS, a protocol driver calls the NdisRegisterProtocolDriver function.

DriverEntry returns STATUS_SUCCESS, or its equivalent NDIS_STATUS_SUCCESS, if the driver registered as an NDIS protocol driver successfully. If **DriverEntry** fails initialization by propagating an error status that was returned by an **NdisXxx** function or by a kernel-mode support routine, the driver will not remain loaded. **DriverEntry** must execute synchronously; that is, it cannot return STATUS_PENDING or its equivalent NDIS_STATUS_PENDING.

The DriverEntry function of an NDIS protocol driver must call the NdisRegisterProtocolDriver function. To register the driver's *ProtocolXxx* entry points with the NDIS library, a protocol driver initializes an **NDIS_PROTOCOL_DRIVER_CHARACTERISTICS** structure and passes it to **NdisRegisterProtocolDriver**.

Drivers that call NdisRegisterProtocolDriver must be prepared for an immediate call to any of their ProtocolXxx functions.

NDIS protocol drivers provide the following *ProtocolXxx* functions, which are updated versions of the functions that legacy drivers provide:

ProtocolSetOptions

ProtocolBindAdapterEx

ProtocolUnbindAdapterEx

ProtocolOpenAdapterCompleteEx

ProtocolCloseAdapterCompleteEx

ProtocolNetPnPEvent

ProtocolUninstall

NDIS protocol drivers provide the following *ProtocolXxx* functions for send and receive operations:

ProtocolReceiveNetBufferLists

ProtocolSendNetBufferListsComplete

All types of NDIS protocol drivers should register fully functional *ProtocolBindAdapterEx* and *ProtocolUnbindAdapterEx* functions to support Plug and Play (PnP). In general, a DriverEntry function should call NdisRegisterProtocolDriver immediately before it returns control with a status value of STATUS_SUCCESS or NDIS_STATUS_SUCCESS.

Any protocol driver that exports a set of standard kernel-mode driver routines in addition to its NDIS-defined *ProtocolXxx* functions must set the entry points for those driver routines in the given driver object that is passed in to its DriverEntry function. For more information about the functionality of such a protocol driver's **DriverEntry** function, see Writing a DriverEntry Routine.

If an attempt to allocate resources that the driver needs to carry out network I/O operations fails, DriverEntry should release all resources that it already allocated before it returns control with a status other than STATUS_SUCCESS or NDIS_STATUS_SUCCESS.

If an error occurs after a successful call to NdisRegisterProtocolDriver, the driver must call the NdisDeregisterProtocolDriver function before **DriverEntry** returns.

To allow a protocol driver to configure optional services, NDIS calls the *ProtocolSetOptions* function within the context of the protocol driver's call to **NdisRegisterProtocolDriver**. For more information about optional services, see Configuring Optional Protocol Driver Services.

CoNDIS client drivers must call the NdisSetOptionalHandlers function from the *ProtocolSetOptions* function. The driver initializes an **NDIS_CO_CLIENT_OPTIONAL_HANDLERS** structure and passes it at the *OptionalHandlers* parameter of **NdisSetOptionalHandlers**.

CoNDIS stand-alone call managers must also call the NdisSetOptionalHandlers function from the *ProtocolSetOptions* function. The driver initializes an **NDIS_CO_CALL_MANAGER_OPTIONAL_HANDLERS** structure and passes it at the *OptionalHandlers* parameter of **NdisSetOptionalHandlers**.

MCMs are not protocol drivers. Therefore, they must call the NdisSetOptionalHandlers function from the MiniportSetOptions function. The MCM initializes an **NDIS_CO_CALL_MANAGER_OPTIONAL_HANDLERS** structure and passes it at the *OptionalHandlers* parameter of **NdisSetOptionalHandlers**.

To unregister with NDIS, a protocol driver calls NdisDeregisterProtocolDriver from its Unload routine.

To perform cleanup operations before a protocol driver is uninstalled, a protocol driver can register a *ProtocolUninstall* function. The *ProtocolUninstall* function is optional. For example, the protocol lower edge of an intermediate driver might require a *ProtocolUninstall* function. The intermediate driver can release its protocol edge resources in *ProtocolUninstall* before NDIS calls its *MiniportDriverUnload* function.

Protocol Binding States and Operations

Article • 12/15/2021

An NDIS protocol driver must support the following operational states for each binding that the driver manages:

Unbound
The Unbound state is the initial state of a binding. In this state, the protocol driver waits for NDIS to call the *ProtocolBindAdapterEx* function.

Opening
In the Opening state, a protocol driver allocates resources for the binding and attempts to open the adapter.

Running
In the Running state, a protocol driver performs send and receive processing for a binding.

Closing
In the Closing state, the protocol driver closes the binding to the adapter and then releases the resources for the binding.

Pausing
In the Pausing state, a protocol driver completes any operations that are required to stop send and receive operations for a binding.

Paused
In the Paused state, the protocol driver does not perform send or receive operations for a binding.

Restarting
In the Restarting state, a protocol driver completes any operations that are required to restart send and receive operations for a binding.

In the following table, the headings represent the binding states, and events are listed in the first column. The rest of the entries in the table specify the next state that the binding enters after an event occurs within a state. The blank entries represent invalid event/state combinations.

Event \ State	Unbound	Opening	Closing	Paused	Restarting	Running	Pausing
ProtocolBindAdapterEx	Opening						
Bind failed		Unbound					
Bind is complete		Paused					

Event \ State	Unbound	Opening	Closing	Paused	Restarting	Running	Pausing
ProtocolUnbindAdapterEx				Closing			
Unbind is complete			Unbound				
PnP pause						Pausing	
Pause is complete							Paused
PnP restart				Restarting			
Restart is complete					Running		
Restart failed					Paused		
Send and receive operations						Running	Pausing
OID requests			Closing	Paused	Restarting	Running	Pausing

Note The events listed in the preceding table are the primary events for an NDIS protocol binding. Additional events will be added to this table as the information becomes available.

The primary binding events are defined as follows:

ProtocolBindAdapterEx
After NDIS calls the driver's *ProtocolBindAdapterEx* function, the binding enters the Opening state. For more information, see Binding to an Adapter.

Bind failed
If the protocol driver fails to bind to the adapter, the binding returns to the Unbound state.

Bind is complete
If the driver successfully opens the adapter, the binding enters the Paused state. The driver completes the bind operation.

ProtocolUnbindAdapterEx
After NDIS calls the driver's *ProtocolUnbindAdapterEx* hander, the binding enters the *Closing* state. For more information, see Unbinding from an Adapter.

Unbind is complete
After the driver completes the unbind operation, the binding enters the Unbound state.

PnP Pause
After NDIS sends the protocol driver a network Plug and Play (PnP) pause event notification, the binding enters the Pausing state. For more information see Pausing a Binding.

Pause is complete
After the driver has completed all operations that are required to stop send and receive

operations, the pause operation is complete and the binding is in the Paused state.

Note The driver must wait for all its outstanding send requests to complete before the pause operation is complete.

PnP Restart
After NDIS sends the protocol driver a network PnP restart event notification, the binding enters the Restarting state. For more information, see Restarting a Binding.

Restart is complete
After the driver is ready to handle send and receive operations, the restart operation is complete and the binding is in the Running state.

Restart failed
If NDIS sends the protocol driver a network PnP restart event notification and the restart attempt fails, the binding returns to the Paused state.

Send and Receive Operations
A protocol driver must handle send and receive operations in the Running and Pausing states. For more information about send and receive operations, see Protocol Driver Send and Receive Operations.

OID Requests
A protocol driver can initiate OID requests to set or query information in underlying drivers. A protocol driver can initiate OID requests from all states, except Unbound and Opening.

Related topics

Writing NDIS Protocol Drivers

Binding to an Adapter

Article • 12/15/2021

NDIS calls a protocol driver's *ProtocolBindAdapterEx* function to open a binding whenever an underlying adapter to which the driver can bind becomes available. After NDIS calls *ProtocolBindAdapterEx*, the binding enters the Opening state. In the *Opening* state, the protocol driver allocates resources for the binding and opens the adapter.

NDIS passes to *ProtocolBindAdapterEx* the NDIS context for the binding operation as well as a pointer to an **NDIS_BIND_PARAMETERS** structure. This structure contains information about the adapter such as:

- The name of the adapter.
- The registry location for parameters specific to this binding under protocol service entry in the registry.
- The physical device object for the adapter.

To open an adapter, protocol drivers call the **NdisOpenAdapterEx** function. The protocol driver passes the following to **NdisOpenAdapterEx**:

- The handle that NDIS returned to the driver at the *NdisProtocolHandle* parameter of the **NdisRegisterProtocolDriver** function.
- The protocol driver's context for this binding.
- A pointer to a structure of type **NDIS_OPEN_PARAMETERS**.

NDIS_OPEN_PARAMETERS contains information such as name of the adapter that **NdisOpenAdapterEx** should open, an array of medium types that the protocol driver supports and, optionally, an array of frame types that the driver can receive on this binding.

If a protocol driver returns NDIS_STATUS_PENDING from *ProtocolBindAdapterEx*, it must call **NdisCompleteBindAdapterEx** with the final status to complete the bind request.

If NDIS returns NDIS_STATUS_PENDING from **NdisOpenAdapterEx**, NDIS later calls the protocol driver's *ProtocolOpenAdapterCompleteEx* function with the final status after the open request has been completed.

After the driver successfully opens the binding to the adapter, the binding is in the Paused state.

A protocol driver calls the **NdisCloseAdapterEx** function to close the adapter. The driver can call **NdisCloseAdapterEx** from the *ProtocolBindAdapterEx* function or *ProtocolUnbindAdapterEx* function.

If after opening the adapter and before completing the bind request, *ProtocolBindAdapterEx* encounters a failure and must close the binding to the adapter, it can call **NdisCloseAdapterEx**. For more information about closing an adapter, see Unbinding from an Adapter.

Unbinding from an Adapter

Article • 12/15/2021

NDIS calls a protocol driver's *ProtocolUnbindAdapterEx* function to request that the driver unbind from an underlying adapter. As the reciprocal of *ProtocolBindAdapterEx*, NDIS calls *ProtocolUnbindAdapterEx* to close the binding to the adapter and to release the resources that the driver allocated for the binding.

In *ProtocolUnbindAdapterEx*, a protocol driver calls **NdisCloseAdapterEx** to close the binding to an underlying adapter. The protocol driver passes **NdisCloseAdapterEx** the handle that **NdisOpenAdapterEx** provided at its *NdisBindingHandle* parameter. This handle identifies the binding that NDIS should close.

Protocol drivers must close an adapter from the *ProtocolBindAdapterEx* function or *ProtocolUnbindAdapterEx* function.

If a protocol driver must initiate an operation to close a binding, the driver can call **NdisUnbindAdapter**. **NdisUnbindAdapter** schedules a work item that results in an NDIS call to *ProtocolUnbindAdapterEx*. This work item can run before the call to **NdisUnbindAdapter** returns. Therefore, driver writers must assume that the binding handle is invalid after **NdisUnbindAdapter** returns.

If a protocol driver returns NDIS_STATUS_PENDING from *ProtocolUnbindAdapterEx*, it must call **NdisCompleteUnbindAdapterEx** with the final status to complete the bind request.

If NDIS returns NDIS_STATUS_PENDING from **NdisCloseAdapterEx**, NDIS later calls the protocol driver's *ProtocolCloseAdapterCompleteEx* function.

NDIS can call *ProtocolUnbindAdapterEx* if the binding is in the Paused state.

After all the unbind operations are complete, the binding is in the Unbound state.

Starting and Pausing a Binding

Article • 12/15/2021

NDIS pauses a binding to stop data flow that could interfere with Plug and Play (PnP) operations, for example, adding or removing a filter module in a driver stack, or, to add a new binding. For more information about how to modify a running driver stack, see Modifying a Running Driver Stack.

NDIS starts a binding from the *Paused* state. The binding enters the *Paused* state after the bind operation is complete or after a pause operation is complete.

The following topics provide more information about starting and pausing a binding:

Restarting a Binding

Pausing a Binding

Restarting a Binding

Article • 12/15/2021

To restart a binding that is paused, NDIS sends the protocol driver a network Plug and Play (PnP) restart event notification. After the protocol driver receives the restart notification, the affected binding enters the Restarting state.

To send a restart notification, NDIS calls a protocol driver's *ProtocolNetPnPEvent* function. The **NET_PNP_EVENT_NOTIFICATION** structure that NDIS passes to *ProtocolNetPnPEvent* specifies **NetEventRestart** in the **NetEvent** member and the **Buffer** member contains a pointer to the **NDIS_PROTOCOL_RESTART_PARAMETERS** structure. NDIS provides a pointer to an **NDIS_RESTART_ATTRIBUTES** structure in the **RestartAttributes** member of the NDIS_PROTOCOL_RESTART_PARAMETERS structure.

Note While the binding was paused, NDIS could have reconfigured the driver stack. The new stack configuration can support a different set of capabilities for the underlying adapter. These new capabilities can affect how the protocol driver communicates on a binding.

The protocol driver should use the information in the **NDIS_PROTOCOL_RESTART_PARAMETERS** structure to avoid unnecessary OID requests.

In the Restarting state, the protocol driver can:

- Use OID requests to query the driver stack. For example, the driver can find out about support for receive side scaling by using OID_GEN_RECEIVE_SCALE_CAPABILITIES.

- Reallocate **NET_BUFFER** and **NET_BUFFER_LIST** pools, if necessary.

- Enumerate the list of the underlying filter modules.

- Use OID requests to reveal new adapter capabilities.

After the driver is ready to resume send and receive operations for the binding, the binding enters the Running state.

Pausing a Binding

Article • 12/15/2021

After NDIS sends a protocol driver a network Plug and Play (PnP) pause event notification for a binding, the binding enters the Pausing state.

To notify the protocol driver of the PnP pause event, NDIS calls the *ProtocolNetPnPEvent* function with the **NetEvent** member of the **NET_PNP_EVENT_NOTIFICATION** structure is set to **NetEventPause**. The **Buffer** member contains an **NDIS_PROTOCOL_PAUSE_PARAMETERS** structure.

For a binding in the Pausing state, the protocol driver:

- Should not initiate any new send requests.

- Must wait for outstanding send requests to complete. The pause operation is not complete until NDIS calls the **ProtocolSendNetBufferListsComplete** function for all of the driver's outstanding send requests.

- Should handle receive indications as usual. The underlying miniport driver waits for outstanding receive data to return before completing a pause operation. This ensures that there are no ongoing receive operations in the driver stack after the miniport driver is paused.

- Should return new receive indications to NDIS immediately. If necessary, the driver can copy such receive indications before it returns them.

For more information about protocol driver send and receive operations, see Protocol Driver Send and Receive Operations.

A binding enters the Paused state after the protocol driver is done returning outstanding receive indications for the binding and NDIS has completed all of the outstanding send requests for the binding.

For a binding in the Paused state, the protocol driver:

- Must not make any send requests.

- Should return receive indications immediately. If necessary, the driver can copy such receive indications before it returns them.

Configuring Optional Protocol Driver Services

Article • 12/15/2021

NDIS calls a protocol driver's *ProtocolSetOptions* function to allow a protocol driver to configure optional services. NDIS calls *ProtocolSetOptions* within the context of the protocol driver's call to the **NdisRegisterProtocolDriver** function

ProtocolSetOptions registers default entry points for optional *ProtocolXxx* functions and can allocate other driver resources. To register optional *ProtocolXxx* functions, the protocol driver calls the **NdisSetOptionalHandlers** function and passes a characteristics structure at the *OptionalHandlers* parameter. In this case, the protocol driver passes the handle from the *NdisDriverHandle* parameter of *ProtocolSetOptions* at the *NdisHandle* parameter of **NdisSetOptionalHandlers**.

A protocol driver can also call **NdisSetOptionalHandlers** from the *ProtocolBindAdapterEx* function or the *ProtocolOpenAdapterCompleteEx* function after the protocol driver has a valid handle from the **NdisOpenAdapterEx** function. In this case, the protocol driver passes the handle from the *NdisBindingHandle* parameter of **NdisOpenAdapterEx** at the *NdisHandle* parameter of **NdisSetOptionalHandlers**.

In this case, the valid characteristics structures are:

NDIS_PROTOCOL_CO_CHARACTERISTICS

NDIS_CO_CLIENT_OPTIONAL_HANDLERS

NDIS_CO_CALL_MANAGER_OPTIONAL_HANDLERS

NDIS_CLIENT_CHIMNEY_OFFLOAD_GENERIC_CHARACTERISTICS (see NDIS 6.0 TCP chimney offload documentation)

NDIS_CLIENT_CHIMNEY_OFFLOAD_TCP_CHARACTERISTICS (see NDIS 6.0 TCP chimney offload documentation)

Protocol Driver Send and Receive Operations

Article • 12/15/2021

Protocol drivers originate send requests and handle the receive indications of underlying drivers. In a single function call, NDIS protocol drivers can send multiple **NET_BUFFER_LIST** structures with multiple **NET_BUFFER** structures on each NET_BUFFER_LIST structure. In the receive path, protocol drivers can receive a list of NET_BUFFER_LIST structures.

Protocol drivers must manage send buffer pools. Proper management of such pools requires preallocation of sufficient buffer space to optimize system performance.

The following topics provide more information about protocol driver buffer management, send operations, and receive operations:

Protocol Driver Buffer Management

Sending Data from a Protocol Driver

Receiving Data in Protocol Drivers

Protocol Driver Buffer Management

Article • 12/15/2021

A protocol driver must manage NET_BUFFER_LIST structure pools and NET_BUFFER structure pools for send operations. To create these pools, drivers call the following functions:

NdisAllocateNetBufferListPool

NdisAllocateNetBufferPool

Protocol drivers can use the following functions to allocate structures from the pools:

NdisAllocateNetBufferAndNetBufferList

NdisAllocateNetBufferList

NdisAllocateNetBuffer

Calling **NdisAllocateNetBufferAndNetBufferList** is more efficient than calling **NdisAllocateNetBufferList** followed by **NdisAllocateNetBuffer**. However, **NdisAllocateNetBufferAndNetBufferList** only creates one NET_BUFFER structure on the NET_BUFFER_LIST structure. To use **NdisAllocateNetBufferAndNetBufferList**, the driver must set the *AllocateNetBuffer* parameter to **TRUE** when it calls **NdisAllocateNetBufferListPool**.

Protocol drivers can use OID requests to query the back-fill and context space requirements of the underlying drivers. A protocol driver should determine the back-fill and context requirements for a binding in the *Opening* or *Restarting* states. The driver should allocate sufficient back-fill and context space for the entire stack. If necessary, a protocol driver can free the pools and reallocate them in the *Restarting* state.

Protocol drivers use the following functions to free the pools:

NdisFreeNetBufferListPool

NdisFreeNetBufferPool.

Protocol drivers use the following functions to free the structures allocated from the pools:

NdisFreeNetBufferList

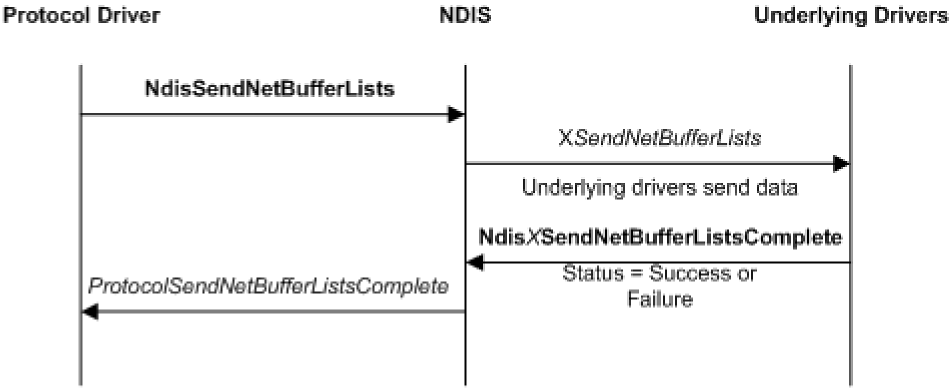
NdisFreeNetBuffer

Drivers should free NET_BUFFER structures allocated with **NdisAllocateNetBuffer** before freeing the associated NET_BUFFER_LIST structure. NET_BUFFER structures allocated with **NdisAllocateNetBufferAndNetBufferList** are freed when the driver calls **NdisFreeNetBufferList** for the associated NET_BUFFER_LIST structure.

Sending Data from a Protocol Driver

Article • 12/15/2021

The following figure illustrates a protocol driver send operation, which involves a protocol driver, NDIS, and underlying drivers in a driver stack.



Protocol Driver
NDIS
Underlying Drivers
NdisSendNetBufferLists
XSendNetBufferLists
Underlying drivers send data
NdisXSendNetBufferListsComplete
Status = Success or Failure
ProtocolSendNetBufferListsComplete

Protocol drivers call the NdisSendNetBufferLists function to send the network data that is defined in a list of NET_BUFFER_LIST structures.

A protocol driver must set the **SourceHandle** member of each NET_BUFFER_LIST structure to the same value that it passes to the *NdisBindingHandle* parameter. The binding handle provides the information that NDIS requires to return the NET_BUFFER_LIST structure to the protocol driver after the underlying miniport driver calls NdisMSendNetBufferListsComplete.

Before calling **NdisSendNetBufferLists**, a protocol driver can set information that accompanies the send request with the NET_BUFFER_LIST_INFO macro. The underlying drivers can retrieve this information with the NET_BUFFER_LIST_INFO macro.

As soon as a protocol driver calls **NdisSendNetBufferLists**, it relinquishes ownership of the NET_BUFFER_LIST structures and all associated resources. NDIS calls the ProtocolSendNetBufferListsComplete function to return the structures and data to the protocol driver. NDIS can collect the structures and data from multiple send requests into a single linked list of NET_BUFFER_LIST structures before it passes the list to *ProtocolSendNetBufferListsComplete*.

Until NDIS calls *ProtocolSendNetBufferListsComplete*, the current status of a protocol-driver-initiated send is unknown. A protocol driver temporarily releases ownership of all resources it allocated for a send request when it calls **NdisSendNetBufferLists**. A protocol driver should never attempt to examine the NET_BUFFER_LIST structures or any associated data before NDIS returns the structures to *ProtocolSendNetBufferListsComplete*.

ProtocolSendNetBufferListsComplete performs whatever postprocessing is necessary to complete a send operation. For example, the protocol driver can notify the clients, that requested the protocol driver to send the network data, that the send operation is complete.

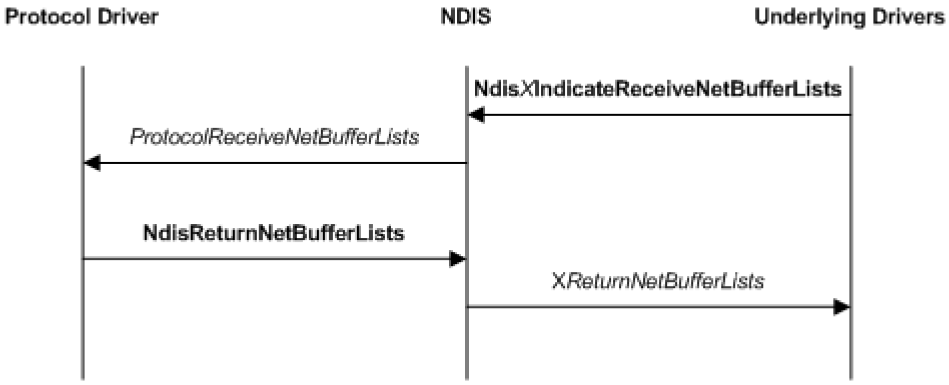
When NDIS calls *ProtocolSendNetBufferListsComplete*, the protocol driver regains ownership of all of the resources associated with the NET_BUFFER_LIST structures that are specified by the *NetBufferLists* parameter. *ProtocolSendNetBufferListsComplete* can either free these resources (for example, by calling **NdisFreeNetBuffer** and **NdisFreeNetBufferList**) or prepare them for reuse in a subsequent call to **NdisSendNetBufferLists**.

Although NDIS always submits protocol-supplied network data to the underlying miniport driver in the protocol-determined order as passed to **NdisSendNetBufferLists**, the underlying driver can complete the send requests in random order. That is, every bound protocol driver can rely on NDIS to submit the network data that the protocol driver passes to **NdisSendNetBufferLists** in FIFO order to the underlying driver. However, no protocol driver can rely on the underlying driver to call **NdisMSendNetBufferListsComplete** in the same order.

Receiving Data in Protocol Drivers

Article • 12/15/2021

The following figure illustrates a basic receive operation, which involves a protocol driver, NDIS, and underlying drivers in a driver stack.



NDIS calls a protocol driver's *ProtocolReceiveNetBufferLists* function to process receive indications that come from underlying drivers. NDIS calls *ProtocolReceiveNetBufferLists* after an underlying driver calls a receive indication function (for example, **NdisMIndicateReceiveNetBufferLists**) to indicate received network data or loop-back data.

If the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of *ProtocolReceiveNetBufferLists* is not set, the protocol driver retains ownership of the **NET_BUFFER_LIST** structures until it calls the **NdisReturnNetBufferLists** function. If NDIS sets the **NDIS_RECEIVE_FLAGS_RESOURCES** flag, the protocol driver cannot retain the **NET_BUFFER_LIST** structure and the associated resources. The set **NDIS_RECEIVE_FLAGS_RESOURCES** flag indicates that an underlying driver is running low on receive resources. In this case, the *ProtocolReceiveNetBufferLists* function should copy the received data into protocol-allocated storage and return as quickly as possible.

Note NDIS can change the flags that an underlying driver indicates. For example, if a miniport driver sets the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of the **NdisMIndicateReceiveNetBufferLists** function, NDIS can copy the indicated data and pass the copy to *ProtocolReceiveNetBufferLists* with the **NDIS_RECEIVE_FLAGS_RESOURCES** flag cleared.

Note If the **NDIS_RECEIVE_FLAGS_RESOURCES** flag is set, the protocol driver must retain the original set of **NET_BUFFER_LIST** structures in the linked list. For example, when this flag is set the driver might process the structures and indicate them up the stack one at a time but before the function returns it must restore the original linked list.

Protocol drivers call the **NdisReturnNetBufferLists** function to release ownership of a list of **NET_BUFFER_LIST** structures, along with the associated **NET_BUFFER** structures, and network data.

Protocol Driver OID Requests

Article • 12/15/2021

NDIS defines object identifier (OID) values to identify adapter parameters which include operating parameters such as device characteristics, configurable settings and statistics. For more information about OIDs, see NDIS OIDs.

Protocol drivers can query or set the operating parameters of underlying drivers.

NDIS also provides a direct OID request interface for NDIS 6.1 and later protocol drivers. The *direct OID request path* supports OID requests that are queried or set frequently. For example, the IPsec offload version 2 (IPsecv2) interface provides the OID_TCP_TASK_IPSEC_OFFLOAD_V2_ADD_SA OID for direct OID requests. The direct OID request interface is optional for NDIS drivers.

The following topics provide more information about protocol driver OID requests:

Generating OID Requests from an NDIS Protocol Driver

Protocol Driver Direct OID Requests

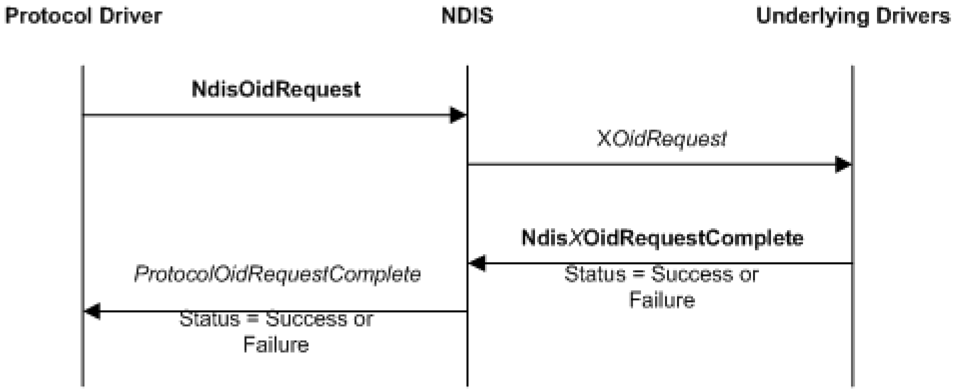
Protocol Driver Synchronous OID Requests

Generating OID Requests from an NDIS Protocol Driver

Article • 03/14/2023

To originate an OID request to underlying drivers, a protocol calls the **NdisOidRequest** function.

The following figure illustrates an OID request that is originated by a protocol driver.



After a protocol driver calls the **NdisOidRequest** function, NDIS calls the request function of the next underlying driver. For more information about how a miniport driver handles OID requests, see OID Requests for an Adapter. For more information about how a filter driver handles OID requests, see Filter Module OID Requests.

To complete synchronously, **NdisOidRequest** returns NDIS_STATUS_SUCCESS or an error status. To complete asynchronously, **NdisOidRequest** returns NDIS_STATUS_PENDING.

If **NdisOidRequest** returns NDIS_STATUS_PENDING, NDIS calls the **ProtocolOidRequestComplete** function after the underlying drivers complete the OID request. In this case, NDIS passes the results of the request at the *OidRequest* parameter of *ProtocolOidRequestComplete*. NDIS passes the final status of the request at the *Status* parameter of *ProtocolOidRequestComplete*.

If **NdisOidRequest** returns NDIS_STATUS_SUCCESS, it returns the results of a query request in the **NDIS_OID_REQUEST** structure at the *OidRequest* parameter. In this case, NDIS does not call the *ProtocolOidRequestComplete* function.

To determine what information was successfully handled by an underlying driver, protocol drivers that issue OID requests must check the value in the **SupportedRevision** member in the NDIS_OID_REQUEST structure after the OID request returns. For more information about NDIS version information, see Specifying NDIS Version Information.

If the underlying driver should associate the OID request with a subsequent status indication, the protocol driver should set the **RequestId** member in the NDIS_OID_REQUEST structure. When the underlying driver makes a status indication, it sets the **RequestId** member in the NDIS_STATUS_INDICATION structure to the value that is provided in the OID request.

A driver can call **NdisOidRequest** when a binding is in the *Restarting*, *Running*, *Pausing*, or *Paused* state.

Protocol Driver Direct OID Requests

Article • 12/15/2021

To support the direct OID request path, protocol drivers provide *ProtocolXxx* function entry points in the NDIS_PROTOCOL_DRIVER_CHARACTERISTICS structure and NDIS provides **Ndis*Xxx*** functions for protocol drivers.

The *direct OID request interface* is similar to the standard OID request interface. For example, the **NdisDirectOidRequest** and **ProtocolDirectOidRequestComplete** functions are similar to the **NdisOidRequest** and **ProtocolOidRequestComplete** functions.

Note NDIS 6.1 and later support specific OIDs for use with the direct OID request interface. OIDs that existed before NDIS 6.1 and some NDIS 6.1 OIDs are not supported. To determine if an OID can be used in the direct OIDs interface, see the OID reference page. For example, see the note in the OID_TCP_TASK_IPSEC_OFFLOAD_V2_ADD_SA OID.

To support the direct OIDs request interface, use the documentation for the standard OID request interface. The following table shows the relationship between the functions in the direct OID request interface and the standard OID request interface.

Direct OID function	Standard OID function
ProtocolDirectOidRequestComplete	ProtocolOidRequestComplete
NdisDirectOidRequest	NdisOidRequest
NdisCancelDirectOidRequest	NdisCancelOidRequest

Protocol Driver Synchronous OID Requests

Article • 12/15/2021

To support the Synchronous OID request path, protocol drivers call the **NdisSynchronousOidRequest** function to issue a Synchronous OID.

For protocol drivers, the *Synchronous OID request interface* differs from the Regular and Direct OID request interfaces in that protocol drivers do not have to implement an asynchronous *complete* callback function. This is because of the synchronous nature of the path. For more info about the differences between Regular, Direct, and Synchronous OIDs in general, see Synchronous OID Request Interface in NDIS 6.80.

> ⓘ Note
>
> NDIS 6.80 supports specific OIDs for use with the Synchronous OID request interface. OIDs that existed before NDIS 6.80 and some NDIS 6.80 OIDs are not supported. To determine if an OID can be used in the Synchronous OID request interface, see the OID reference page.

To support the Synchronous OID request interface, use the documentation for the standard OID request interface. The following table shows the relationship between the functions in the Synchronous OID request interface and the standard OID request interface.

Synchronous OID function	Standard OID function
NdisSynchronousOidRequest	*NdisOidRequest*

Handling Status Indications in a Protocol Driver

Article • 01/18/2023

Protocol drivers must supply a **ProtocolStatusEx** function that NDIS calls when an underlying driver reports status.

NDIS calls a protocol driver's *ProtocolStatusEx* function, after an underlying driver calls a status indication function (**NdisMIndicateStatus** or **NdisFIndicateStatus**). For more information about indicating status from a miniport driver, see Adapter Status Indications.

For more information about indicating status from a filter driver, see Filter Module Status Indications.

If the status indication is associated with an OID request, the underlying driver can set the **DestinationHandle** and **RequestId** members so that NDIS can provide the status indication to a specific protocol binding. For more information about OID requests, see Protocol Driver OID Requests.

Handling PnP Event Notifications in a Protocol Driver

Article • 12/15/2021

NDIS 6.0 and later protocol drivers handle the same Plug and Play (PnP) event notifications as NDIS 5.x drivers in addition to event notifications that are specific to NDIS 6.0 and later. The handling of PnP event notifications is driver specific.

To notify a protocol driver of a network PnP event, NDIS calls the driver's *ProtocolNetPnPEvent* function. To define the type of event and characteristics of the event, NDIS passes a **NET_PNP_EVENT_NOTIFICATION** structure at the *NetPnPEvent* event parameter of *ProtocolNetPnPEvent*.

Protocol drivers should handle driver stack changes. For more information about driver stack changes, see Modifying a Running Driver Stack.

Protocol drivers that do not handle stack change notifications are unbound from the adapter and rebound. Bindings for protocol drivers that handle driver stack notifications successfully are not affected.

Protocol drivers should handle driver stack pause notifications. For more information about these notifications, see Pausing a Driver Stack.

Protocol drivers should handle driver stack restart notifications. For more information about these notifications, see Restarting a Driver Stack.

NDIS protocol driver installation

Article • 05/30/2023

To install a protocol driver, you must first provide a single INF file. The configuration manager reads configuration information about the protocol driver from the INF file and copies it to the registry.

For more information about protocol driver INF files, see Installation Requirements for Network Protocols. For an example protocol driver INF file, see the ndisprot 630 sample driver.

Once you have provided your protocol driver INF file, to install or uninstall your protocol driver you must use the `INetCfg` family of Network Configuration Interfaces. For example, to install or remove network components, call into the INetCfgClassSetup interface. You can either call into these interfaces programmatically or you can indirectly call them with netcfg.exe, which calls `INetCfg` for you. You can't install a driver package through the `INetCfg` and use the Driver Store feature on older Windows versions. To successfully install the driver package in this scenario, you need to have a minimum OS build number of 25319. You can't use SetupAPI to install or uninstall an NDIS protocol driver.

For an example of calling into `INetCfg` through code, see the Bindview Network Configuration Utility sample .

Pageable and Discardable Code in a Protocol Driver

Article • 12/15/2021

Driver developers should designate code as pageable whenever possible, freeing system space for code that must be memory-resident. You can mark functions as pageable with the **NDIS_PAGEABLE_FUNCTION** macro. The IRQL, resource management features, and other characteristics of a function might prohibit the function from being pageable.

Every *ProtocolXxx* function runs at an IRQL in the range from PASSIVE_LEVEL to DISPATCH_LEVEL. Functions that run exclusively at IRQL = PASSIVE_LEVEL should be marked as pageable.

A driver function that runs at IRQL = PASSIVE_LEVEL can be made pageable as long as it neither calls nor is called by any function that runs at IRQL >= DISPATCH_LEVEL--such as a function that acquires a spin lock. Acquiring a spin lock causes the IRQL of the acquiring thread to be raised to DISPATCH_LEVEL. A driver function, such as *ProtocolBindAdapterEx*, that runs at IRQL = PASSIVE_LEVEL must not call any **Ndis*Xxx*** functions that run at IRQL >= DISPATCH_LEVEL if that driver function is marked as pageable code. For more information about the IRQL for each **Ndis*Xxx*** function, see NDIS Library Functions.

The **DriverEntry** function of NDIS protocol drivers, as well as code that is called only from **DriverEntry**, should be specified as initialization-only code, by using the **NDIS_INIT_FUNCTION** macro. Code that is identified with this macro is assumed to run only once at system initialization time, and, as a result, is mapped only during that time. After a function marked as initialization-only returns, it is discarded.

Protocol Driver Reset Operations

Article • 12/15/2021

Protocol drivers cannot initiate a reset operation in NDIS 6.0 and later versions.

Typically, an underlying miniport driver resets a NIC because the NIC is timing out during send or request operations. This condition causes NDIS to call the miniport driver's *MiniportCheckForHangEx* and subsequently *MiniportResetEx* functions. Alternatively, the miniport driver determines a NIC's receive capability is dysfunctional.

If a reset is initiated by NDIS and *MiniportResetEx* returns NDIS_STATUS_PENDING, NDIS calls the **ProtocolStatusEx**(or **ProtocolCoStatusEx**) function of each bound protocol driver with a status of NDIS_STATUS_RESET_START. When the miniport driver calls **NdisMResetComplete**, NDIS again calls *ProtocolStatusEx*(or *ProtocolCoStatusEx*) with a status of NDIS_STATUS_RESET_END.

A protocol driver must handle the possibility that outstanding sends on a binding to an underlying NIC can be canceled because the NIC is reset. If a bound protocol driver has any transmit requests pending, NDIS will indicate a send complete to the protocol driver with an appropriate status. The protocol driver must resubmit the send requests when the reset operation is completed, assuming the NIC becomes operational again.

When a protocol driver receives a status of NDIS_STATUS_RESET_START, it should:

- Hold any network data that is ready to be transmitted until *Protocol(Co)Status* receives an NDIS_STATUS_RESET_END notification.

- Not make any NDIS calls that are directed to the underlying miniport driver, except calls to return resources such as returning network data with **NdisReturnNetBufferLists**.

After *ProtocolStatusEx*(or *ProtocolCoStatusEx*) receives an NDIS_STATUS_RESET_END message, the protocol driver can resume sending network data and OID requests.

Handling PnP Events and Power Management Events in a Protocol Driver

Article • 12/15/2021

When the operating system issues a Plug and Play (PnP) I/O request packet (IRP) or a power management IRP to a target device object that represents a network interface card (NIC), NDIS intercepts the IRP. NDIS indicates the event to each bound protocol driver and each bound intermediate driver by calling the driver's *ProtocolNetPnPEvent* function. In the call to *ProtocolNetPnPEvent*, NDIS passes a pointer to a **NET_PNP_EVENT_NOTIFICATION** that contains a NET_PNP_EVENT structure. The NET_PNP_EVENT structure describes the PnP event or power management event being indicated. For more information about the protocol driver PnP interface, see Handling PnP Event Notifications in a Protocol Driver.

The following list contains PnP and power management events, as indicated by the **NetEvent** code in the NET_PNP_EVENT structure:

- **NetEventSetPower**

  Indicates a Set Power request, which specifies that the miniport adapter should transition to a particular power state. A power management–aware protocol driver should always succeed this event by returning NDIS_STATUS_SUCCESS. An old protocol driver can return NDIS_STATUS_NOT_SUPPORTED to indicate that NDIS should unbind it from the miniport adapter.

  After issuing the set power request, NDIS pauses the driver stack if the miniport adapter is transitioning to a low-power state. NDIS restarts the driver stack before the set-power request if the miniport adapter is transitioning to the working state (D0). For more information about pausing and restarting the driver stack, see Pausing a Driver Stack.

  If the miniport adapter is in a low-power state, the protocol driver cannot issue any OID requests. This requirement is an additional power management restriction that is added to the other restrictions that apply when the driver stack is in the Paused state.

  If the underlying miniport adapter is not power management–aware, the miniport driver sets the **PowerManagementCapabilities** member of **NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES** to **NULL** and NDIS sets the **PowerManagementCapabilities** member of **NDIS_BIND_PARAMETERS** to **NULL**.

Note Starting with NDIS 6.30, after being notified of this event, the protocol driver must stop generating new I/O requests and should not wait for the completion of any pending I/O requests within the context of the call to *ProtocolNetPnPEvent*.

For more information about set-power events, see Handling PnP Events and Power Management Events in an Intermediate Driver.

- **NetEventQueryPower**

  Indicates a Query Power request, which queries whether the underlying miniport adapter can make a transition to a particular power state. A protocol driver should always succeed a **NetEventQueryPower** . After establishing an active connection, a protocol driver can call **PoRegisterSystemState** to register a continuous busy state. As long as the state registration is in effect, the power manager does not attempt to put the system to sleep. After the connection becomes inactive, the protocol driver cancels the state registration by calling **PoUnregisterSystemState**. A protocol driver should never try to prevent the system from transitioning to the sleeping state by failing a **NetEventQueryRemoveDevice**. Note that a **NetEventQueryPower** is always followed by a **NetEventSetPower**. A **NetEventSetPower** that sets the device's current power state in effect cancels the **NetEventQueryPower**.

  Note Starting with NDIS 6.30, after being notified of this event, the protocol driver should not wait for the completion of any pending I/O requests within the context of the call to *ProtocolNetPnPEvent*.

- **NetEventQueryRemoveDevice**

  Indicates a Query Remove Device request, which queries whether the NIC can be removed without disrupting operations. If a protocol driver cannot release a device (for example, because the device is in use), it must fail a **NetEventQueryRemoveDevice** by returning NDIS_STATUS_FAILURE.

- **NetEventCancelRemoveDevice**

  Indicates a Cancel Remove Device request, which cancels the removal of an underlying NIC. The protocol driver should always succeed this event by returning NDIS_STATUS_SUCCESS.

- **NetEventReconfigure**

  Indicates that the configuration has changed for a network component. For example, if a user changes the IP address for TCP/IP, NDIS indicates this event to the TCP/IP protocol with the **NetEventReconfigure** code. The protocol driver can, in rare circumstances, return a failure code if it is not able to apply the indicated configuration changes and there are no available default values. A failed attempt to allocate memory is an example of a case in which the protocol returns a failure code. Returning an error code can result in prompting the user to restart the system.

A protocol should validate **NetEventReconfigure**-related data passed to its *ProtocolNetPnPEvent* function. For more information about such data, see **NET_PNP_EVENT for Protocol Drivers**.

- **NetEventBindList**

  Indicates to a protocol driver that its bind list processing order has been reconfigured. This list indicates a relative order to be applied to the protocol's bindings when processing, for example, a user request that might be routed to one of several bindings. The buffer passed with this event contains a list of device names formatted as NULL-terminated Unicode strings. The format of each device name is identical to the *DeviceName* parameter that is passed to a call to *ProtocolBindAdapterEx*.

  A protocol should validate **NetEventBindList**-related data passed to its *ProtocolNetPnPEvent* function. For more information about such data, see **NET_PNP_EVENT for Protocol Drivers**.

  A protocol should validate **NetEventBindList**-related data passed to its *ProtocolNetPnPEvent* function. For more information about such data, see **NET_PNP_EVENT for Protocol Drivers**.

- **NetEventBindsComplete**

  Indicates that a protocol driver has bound to all the NICs to which it can bind. NDIS will not indicate any more bindings to the protocol driver unless, for example, a PnP NIC is plugged into the system.

- **NetEventPnPCapabilities**

  Indicates that the user enabled or disabled the wake-up capabilities of the underlying adapter. (The *ProtocolBindingContext* parameter that NDIS passes to *ProtocolNetPnPEvent* specifies the binding .)

- **NetEventPause**

  Indicates that the specified protocol binding should enter thePausing state. The binding will enter the Paused state after NDIS has completed all of the outstanding send requests for the binding. For more information about pausing a binding, see Pausing a Binding.

- **NetEventRestart**

  Indicates that the specified protocol binding has entered the Restarting state. After the protocol driver is ready to resume send and receive operations for the binding, the binding enters the Running state. For more information about restarting a binding, see Restarting a Binding.

- **NetEventPortActivation**

  Indicates the activation of a list of ports that are associated with the specified binding. For more information about pausing a binding, see Handling the Port Activation PnP Event.

- **NetEventPortDeactivation**

  Indicates the deactivation of a list of ports that are associated with the specified binding. For more information about pausing a binding, see Handling the Port Deactivation PnP Event.

- **NetEventIMReEnableDevice**

  Indicates that the configuration has changed for a virtual miniport of an NDIS 6.0 or later intermediate driver. **NetEventIMReEnableDevice** is similar to the **NetEventReconfigure** event except that the intermediate driver receives this event for a single virtual miniport and the **NetEventReconfigure** event applies to all of the intermediate driver's virtual miniports. For example, an intermediate driver receives the **NetEventIMReEnableDevice** event when a user disables and then enables a single virtual miniport from the Device Manager or another source. For examples of intermediate driver power management, see the NDIS MUX Intermediate Driver and Notify Object driver sample available in the Windows driver samples repository on GitHub.

The **Buffer** member of the NET_PNP_EVENT structure points to a buffer that contains information specific to the event being indicated.

A protocol driver can complete the call to *ProtocolNetPnPEvent* asynchronously with **NdisCompleteNetPnPEvent**.

Send and Receive Operations in Protocol Drivers

Article • 12/15/2021

There are two different interfaces for send and receive operations in NDIS protocol drivers. Protocol drivers with a connectionless lower edge call the **NdisSendNetBufferLists** function to send network data. A connectionless protocol driver must supply a **ProtocolReceiveNetBufferLists** function. NDIS calls *ProtocolReceiveNetBufferLists* when an underlying connectionless miniport driver calls the **NdisMIndicateReceiveNetBufferLists** function to indicate received network data. For more information about sending and receiving data in connectionless protocol drivers, see Protocol Driver Send and Receive Operations.

Connection-oriented NDIS (CoNDIS) protocol drivers call the **NdisCoSendNetBufferLists** function to send network data. A CoNDIS protocol driver must supply a **ProtocolCoReceiveNetBufferLists** function. NDIS calls *ProtocolCoReceiveNetBufferLists* when an underlying CoNDIS miniport driver calls the **NdisMCoIndicateReceiveNetBufferLists** function to indicate received network data. For more information about send and operations in connection-oriented protocol drivers, see Connection-Oriented Operations.

For an introduction to send and receive operations, see Send and Receive Operations.

OID Request Operations in a Protocol Driver

Article • 12/15/2021

There are two different interfaces for OID request operations in a protocol driver. NDIS protocol drivers with a connectionless lower edge call the **NdisOidRequest** function to initiate an OID request. An NDIS protocol driver with a connectionless lower edge must supply a **ProtocolOidRequestComplete** function. NDIS calls *ProtocolOidRequestComplete* when the underlying drivers complete a pending OID request. For more information about OID requests in connectionless protocol drivers, see Protocol Driver OID Requests.

Connection-oriented NDIS (CoNDIS) protocol drivers call the **NdisCoOidRequest** function to initiate an OID request. A CoNDIS protocol driver must supply a **ProtocolCoOidRequestComplete** function. NDIS calls *ProtocolOidRequestComplete* when the underlying drivers complete a pending OID request. For more information OID requests in connection-oriented protocol drivers, see Connection-Oriented Operations.

For more information about OIDs, see NDIS OIDs.

Status Indications in a Protocol Driver

Article • 12/15/2021

There are two different interfaces for status indications in a protocol driver. An NDIS protocol driver with a connectionless lower edge is required to supply a **ProtocolStatusEx** function. NDIS calls *ProtocolStatusEx* when an underlying connectionless miniport driver calls **NdisMIndicateStatusEx** to report a change in its hardware status. NDIS calls *ProtocolStatusEx* when the status change begins. For more information about status indications in connectionless protocol drivers, see Handling Status Indications in a Protocol Driver.

A connection-oriented protocol driver must supply a **ProtocolCoStatusEx** function. NDIS calls *ProtocolCoStatusEx* when an underlying connection-oriented miniport driver calls **NdisMCoIndicateStatusEx** to report a change in its hardware status. NDIS calls *ProtocolCoStatusEx* when the status change begins. For more information about status indications in connection-oriented protocol drivers, see Connection-Oriented Operations

For a complete list of the possible status indications, see Status Indications.

Roadmap for Developing NDIS Filter Drivers

Article • 03/14/2023

To create a Network Driver Interface Specification (NDIS) filter driver package, follow these steps:

- Step 1: Learn about Windows architecture and drivers.

  You must understand the fundamentals of how drivers work in Windows operating systems. Knowing the fundamentals will help you make appropriate design decisions and let you streamline your development process. For more information about driver fundamentals, see Concepts for all driver developers.

- Step 2: Learn about NDIS.

  For general information about NDIS and NDIS drivers, see the following topics:

  Windows Network Architecture and the OSI Model

  Network Driver Programming Considerations

  Driver Stack Management

  NET_BUFFER Architecture

- Step 3: Determine additional Windows driver design decisions.

  For more information about how to make additional Windows design decisions, see Creating Reliable Kernel-Mode Drivers, Programming Issues for 64-Bit Drivers, and Creating International INF Files.

- Step 4: Learn about the Windows driver build, test, and debug processes and tools.

  Building a driver differs from building a user-mode application. For more information about Windows driver build, debug, and test processes, driver signing, and Windows Hardware Compatibilty testing, see Building, Debugging, and Testing Drivers. For more information about building, testing, verifying, and debugging tools, see Driver Development Tools.

- Step 5: Read the filter driver introduction topics.

- Step 6: Read the writing protocol drivers section.

This section provides an overview of the primary protocol driver interfaces. These interfaces included functions that protocol drivers provide (*ProtocolXxx* functions) and NDIS calls to initiate operations. NDIS provides **Ndis*Xxx*** functions that protocol drivers call to perform NDIS operations.

- Step 7: Review the NDIS filter driver sample in the Windows driver samples repository on GitHub.

- Step 8: Develop (or port), build, test, and debug your NDIS driver.

  See the porting guides if you are porting an existing driver:
  - Porting NDIS 5.x Drivers to NDIS 6.0
  - Porting NDIS 6.x Drivers to NDIS 6.20
  - Porting NDIS 6.x Drivers to NDIS 6.30

  For more information about iterative building, testing, and debugging, see Overview of Build, Debug, and Test Process. This process will help ensure that you build a driver that works.

- Step 9: Create a driver package for your driver.

  For more information about how to install drivers, see Providing a Driver Package. For more information about how to install an NDIS driver, see Components and Files Used for Network Component Installation and Notify Objects for Network Components.

- Step 10: Sign and distribute your driver.

  The final step is to sign (optional) and distribute the driver. If your driver meets the quality standards that are defined for the Windows Hardware Compatibilty Program, you can distribute it through the Microsoft Windows Update program. For more information about how to distribute a driver, see Get started with the hardware submission process.

These are the basic steps. Additional steps might be necessary based on the needs of your individual driver.

Getting started with NDIS Filter Drivers

Article • 03/14/2023

Filter drivers provide filtering services for miniport drivers. NDIS driver stacks must include miniport drivers and protocol drivers and optionally include filter drivers. For more information about NDIS drivers and the driver stack, see Driver Stack Management.

The following applications might require a filter driver:

- Data filtering applications for security or other purposes.
- Applications that monitor and collect network data statistics.

The following topics provide an introduction to filter driver characteristics and services:

Filter Driver Characteristics

Filter Driver Services

Types of Filter Drivers

Mandatory Filter Drivers

Filter Driver Characteristics

Article • 12/15/2021

Filter drivers have the following characteristics:

- An instance of a filter driver is called a *filter module*. Filter modules are attached to an underlying miniport adapter. Multiple filter modules from the same filter driver or different filter drivers can be stacked over an adapter.

- Overlying protocol drivers are not required to provide alternate functionality when filter modules are installed between such drivers and the underlying miniport drivers (otherwise stated, filter modules are transparent to overlying protocol drivers).

- Because filter drivers do not implement virtual miniports like an intermediate driver, filter drivers are not associated with a device object. A miniport adapter with overlying filter modules functions as a modified version of the miniport adapter. For more information about the driver stack, see NDIS 6.0 Driver Stack.

- NDIS uses configuration information to attach the filter modules to the adapter in the correct driver stack order. For more information about the driver stack order of filter modules, see INF File Settings for Filter Drivers.

- NDIS can dynamically insert or delete filter modules in the driver stack, or reconfigure the filter modules, without tearing down the entire stack. For more information, see Modifying a Running Driver Stack.

- Protocol drivers can obtain the list of filter modules in a driver stack when NDIS restarts the driver stack.

  For more information about the list of filter modules, see **NDIS_PROTOCOL_RESTART_PARAMETERS**.

- Filter drivers can filter most communication to and from the underlying miniport adapter. Filter modules are not associated with any particular binding between overlying protocol drivers and the miniport adapter. For more information about the types of filtering services that a filter driver can provide, see Filter Driver Services.

- Filter drivers can select the services that are filtered and can be bypassed for the services that are not filtered. The selection of the services that are bypassed and the services that are filtered can be reconfigured dynamically. For more information, see Data Bypass Mode.

- NDIS guarantees the availability of context space (see NET_BUFFER_LIST_CONTEXT structure) for filter drivers. Therefore, filter drivers are not required to include the code to copy buffers to obtain context space. For more information about how to manage buffers, see Filter Driver Buffer Management.

Filter Driver Services

Article • 12/15/2021

Filter drivers can provide the following services:

- Originate send requests and receive indications.
- Modify data buffer ordering or timing in the send and receive data paths.
- Add, modify, delete network data buffers in both the send and receive data paths of a driver stack. For more information about filtering send and receive data, see Filter Module Send and Receive Operations.
- Originate query and set OID requests to the underlying drivers.
- Filter query and set OID requests to the underlying drivers.
- Filter responses of OID requests from the underlying drivers. For more information about OID requests, see Filter Module OID Requests.
- Originate status indications to the overlying drivers.
- Filter status indications from the underlying drivers. For more information, see Filter Module Status Indications.
- Manage configuration parameters in the registry for each miniport adapter with which it interfaces. For more information, see Accessing Configuration Information for a Filter Driver.

Types of Filter Drivers

Article • 12/15/2021

There are two primary types of filter drivers:

Monitoring
These filter drivers monitor the behavior in a driver stack. However, they only pass on information and do not modify the behavior of the driver stack. Monitoring filter drivers cannot modify or originate data.

Modifying
These filter drivers modify the behavior of the driver stack. The type of modification is driver-specific.

The **FilterType** entry in the INF file is 0x00000001 for monitoring filter drivers and 0x00000002 for modifying filter drivers.

You can specify that a filter driver is mandatory. This feature is generally used with modifying filter drivers. If a mandatory filter driver does not load, the associated driver stack will be torn down. For more information about mandatory filter drivers, see Mandatory Filter Drivers.

Mandatory Filter Drivers

Article • 12/15/2021

Mandatory filter drivers are filter drivers that must be present for a driver stack to function properly. If the mandatory filter module does not attach, the rest of the driver stack will be torn down. Modifying or monitoring filter drivers can be mandatory. All filter intermediate drivers are optional.

To attach a mandatory filter module to a driver stack, NDIS unbinds all the protocol bindings, attaches the filter module, and then reestablishes all the protocol bindings. If the driver does not attach, NDIS tears down the underlying driver stack.

To detach a mandatory filter module from a driver stack, NDIS unbinds all the protocol bindings detaches the filter module, and then reestablishes the protocol bindings. To detach an optional filter module, NDIS pauses the stack and restarts it without unbinding the protocol drivers.

When a computer restarts, NDIS will not bind any protocol drivers to a miniport adapter if any mandatory filter module that is associated with the adapter does not attach to the miniport adapter.

To install a mandatory filter driver, you must specify a value of 0x00000001 for **FilterRunType** in the INF file. To install an optional filter driver, you must specify a value of 0x00000002 for **FilterRunType** in the INF file.

Initializing a Filter Driver

Article • 12/15/2021

Filter driver initialization occurs immediately after the system loads the driver. Filter drivers load as system services. The system can load the filter drivers at any time before, during, or after the miniport drivers load. NDIS can attach a filter module to a miniport adapter after a miniport adapter of the type supported by the filter driver becomes available and the filter driver initialization is complete.

While a driver stack is starting, the system loads the filter drivers if they are not already loaded. For more information about starting a driver stack that includes filter modules, see Starting a Driver Stack.

After a filter driver loads, the system calls the driver's DriverEntry routine.

The system passes two arguments to DriverEntry:

- A pointer to the driver object, which was created by the I/O system.
- A pointer to the registry path, which specifies where driver-specific parameters are stored.

DriverEntry returns STATUS_SUCCESS, or its equivalent NDIS_STATUS_SUCCESS, if the driver successfully registered as an NDIS filter driver. If **DriverEntry** fails initialization by propagating an error status returned by an **NdisXxx** function or by a kernel-mode support routine, the driver will not remain loaded. **DriverEntry** must execute synchronously; that is, it cannot return STATUS_PENDING or its equivalent NDIS_STATUS_PENDING.

The filter driver passes the driver object to the NdisFRegisterFilterDriver function when it registers with NDIS as a filter driver. The driver can use the registry path to obtain configuration information. For more information about how to access filter driver configuration information, see Accessing Configuration Information for a Filter Driver.

A filter driver calls **NdisFRegisterFilterDriver** from its **DriverEntry** routine. Filter drivers export a set of *FilterXxx* functions by passing an **NDIS_FILTER_DRIVER_CHARACTERISTICS** structure to **NdisFRegisterFilterDriver** at the *FilterCharacteristics* parameter.

The NDIS_FILTER_DRIVER_CHARACTERISTICS structure specifies entry points for mandatory and optional *FilterXxx* functions. Some optional functions can be bypassed. For more information about bypassing functions, see Data Bypass Mode.

Drivers that call NdisFRegisterFilterDriver must be prepared for an immediate call to any of their *FilterXxx* functions.

The NDIS_FILTER_DRIVER_CHARACTERISTICS structure specifies the entry points for these mandatory *FilterXxx* functions:

FilterAttach

FilterDetach

FilterRestart

FilterPause

The NDIS_FILTER_DRIVER_CHARACTERISTICS structure specifies the entry points for these optional, and not changeable at run-time, *FilterXxx* functions:

FilterSetOptions

FilterSetModuleOptions

FilterOidRequest

FilterOidRequestComplete

FilterStatus

FilterNetPnPEvent

FilterDevicePnPEventNotify

FilterCancelSendNetBufferLists

The NDIS_FILTER_DRIVER_CHARACTERISTICS structure specifies the default entry points for these optional, and changeable at run-time, *FilterXxx* functions:

FilterSendNetBufferLists

FilterSendNetBufferListsComplete

FilterReturnNetBufferLists

FilterReceiveNetBufferLists

The preceding four functions are also defined in the **NDIS_FILTER_PARTIAL_CHARACTERISTICS** structure. This structure specifies the functions that can be changed at a run time by calling the **NdisSetOptionalHandlers** function from the *FilterSetModuleOptions* function. If a filter driver will change these partial characteristics at runtime, it must provide the entry point for *FilterSetModuleOptions*. The partial characteristics can be different for each filter module. For more information, see Starting a Filter Module.

NDIS calls the *FilterSetOptions* function within the context of the call to **NdisFRegisterFilterDriver**. *FilterSetOptions* registers optional services with NDIS. For more information, see Configuring Optional Filter Driver Services.

If the call to **NdisFRegisterFilterDriver** succeeds, NDIS fills the variable at *NdisFilterDriverHandle* with a filter driver handle. The filter driver saves this handle and later passes this handle to NDIS functions, such as **NdisFDeregisterFilterDriver**, that require a filter driver handle as an input parameter. When the driver unloads, it must call the **NdisFDeregisterFilterDriver** function to release the driver resources allocated by **NdisFRegisterFilterDriver**.

After *FilterSetOptions* returns, the filter modules are in the *Detached* state. NDIS can call the filter driver's *FilterAttach* function at any time after the call to *FilterSetOptions* returns. The driver performs filter module-specific initialization in the *FilterAttach* function. For more information about attaching a filter module to a driver stack, see Attaching a Filter Module.

A filter driver also performs any other driver-specific initialization that it requires in **DriverEntry**. The filter driver must release the driver-specific resources that it allocates in its *FilterDriverUnload* routine. For more information, see Unloading a Filter Driver.

Unloading a Filter Driver

Article • 12/15/2021

The driver object that is associated with an NDIS filter driver specifies an *Unload* routine called *FilterDriverUnload*. The system can call the *FilterDriverUnload* routine when all the miniport adapters that the filter driver services have been removed.

Unload should release any driver-specific resources. Any device objects that the filter driver created must be destroyed. The system can complete a driver unload operation after *FilterDriverUnload* returns.

The functionality of the unload function is driver-specific. As a general rule, *Unload* should undo the operations that were performed during driver initialization. For more information about driver initialization, see Initializing a Filter Driver.

A filter driver must call the **NdisFDeregisterFilterDriver** function from *Unload*. **NdisFDeregisterFilterDriver** calls *FilterDetach* to detach all currently attached filter modules that are associated with this filter driver.

For more information about unloading filter drivers, see Stopping a Driver Stack.

Filter Module States and Operations

Article • 12/15/2021

A filter driver must support the following operational states for each filter module (instance of a filter driver) that the driver manages:

Detached
The *Detached* state is the initial state of a filter module. When a filter module is in this state, NDIS can call the filter driver's *FilterAttach* function to attach the filter module to the driver stack.

Attaching
In the *Attaching* state, a filter driver prepares to attach the filter module to the driver stack.

Paused
In the *Paused* state, the filter driver does not perform send or receive operations.

Restarting
In the *Restarting* state, a filter driver completes any operations that are required to restart send and receive operations for a filter module.

Running
In the *Running* state, a filter driver performs normal send and receive processing for a filter module.

Pausing
In the *Pausing* state, a filter driver completes any operations that are required to stop send and receive operations for a filter module.

In the following table, the headings are the filter module states. Major events are listed in the first column. The rest of the entries in the table specify the next state that the filter module enters after an event occurs within a state. The blank entries represent invalid event/state combinations.

Event/State	Detached	Attaching	Paused	Restarting	Running	Pausing
Filter attach	Attaching					
Attach is complete		Paused				
Filter detach			Detached			

Event/State	Detached	Attaching	Paused	Restarting	Running	Pausing
Filter restart			Restarting			
Restart is complete				Running		
Filter pause					Pausing	
Pause is complete						Paused
Attach failed		Detached				
Restart failed				Paused		
Send and Receive					Running	Pausing
OID Requests			Paused	Restarting	Running	Pausing

The primary filter driver events are defined as follows:

Filter attach
NDIS called the driver's *FilterAttach* function to attach a filter module to a driver stack. For more information about attaching a filter module, see Attaching a Filter Module.

Attach is complete
When a filter module is in the *Attaching* state and the filter driver completes initialization of all the resources that the filter module requires, the filter module enters the *Paused* state.

Filter detach
NDIS called the driver's *FilterDetach* function to detach a filter module from a driver stack. For more information, see Detaching a Filter Module.

Filter restart
NDIS called the driver's *FilterRestart* function to restart a paused filter module. For more information, see Starting a Filter Module.

Restart is complete
When the filter module is in the *Restarting* state and the driver is ready to perform send and receive operations, the filter module enters the *Running* state.

Filter pause
NDIS called the driver's *FilterPause* function to pause a filter module. For more

information, see Pausing a Filter Module.

Pause is complete
After the driver has completed all operations that are required to stop send and receive operations, the pause operation is complete and the filter module is in the *Paused* state.

Attach failed
If NDIS calls a driver's *FilterAttach* function and the attach operation fails (for example, because the required resources are not available), the filter module returns to the *Detached* state.

Restart failed
If NDIS calls a driver's *FilterRestart* function and the restart attempt fails, the filter module returns to the *Paused* state.

Send and Receive Operations
A driver can handle send and receive operations in the *Running* and *Pausing* states. For more information about send and receive operations, see Filter Module Send and Receive Operations.

OID Requests
A driver can handle OID requests in the *Running*, *Restarting*, *Paused*, and *Pausing* states. For more information about OID requests, see Filter Module OID Requests.

Attaching a Filter Module

Article • 12/15/2021

To initiate the process of inserting a filter module into a driver stack, NDIS calls a filter driver's *FilterAttach* function. At the start of execution in the *FilterAttach* function, the filter module enters the *Attaching* state. For more information about attaching a filter module to a driver stack, see Starting a Driver Stack.

A filter driver uses the handle, that NDIS passes at the *NdisFilterHandle* parameter of *FilterAttach* in all future **NdisXxx** function calls that refer to this filter module. Such functions include status indications, send requests, receive indications, and OID requests.

While a filter module is in the *Attaching* state, the driver:

- Creates a context area for the filter module and allocates buffer pools and other filter module-specific resources. For more information about buffer pools, see Filter Driver Buffer Management.
- Calls the **NdisFSetAttributes** function by using the *NdisFilterHandle* value that NDIS passed to *FilterAttach*. The *FilterModuleContext* parameter of **NdisFSetAttributes** specifies the filter driver's context area for this filter module. NDIS passes this context area to the filter driver's *FilterXxx* functions.
- Optionally, reads configuration parameters for this filter module from the registry. For more information, see Accessing Configuration Information for a Filter Driver.
- If the preceding operations completed successfully, the filter module is in the *Paused* state.
- If the preceding operations failed, the filter driver must release any resources that it allocated in the *FilterAttach* function and return the filter module to the *Detached* state.
- Returns NDIS_STATUS_SUCCESS or an appropriate failure code. If the driver returns a failure code, NDIS terminates the driver stack.

Note The registry can contain a flag, which specifies that a filter module is optional. If an optional filter module does not attach, NDIS does not terminate the rest of the driver stack.

A filter driver cannot make send requests, indicate received data, make OID requests, or make status indications from the *Attaching* state. Send and receive operations are supported in the *Running* and *Pausing* states. OID requests and status indications are supported in the *Paused*, *Restarting*, *Running*, and *Pausing* states.

NDIS calls the *FilterDetach* function to detach a filter module that NDIS attached with *FilterAttach*. For more information, see Detaching a Filter Module.

Detaching a Filter Module

Article • 12/15/2021

To initiate the process of detaching a filter module from a driver stack, NDIS calls a filter driver's *FilterDetach* function. At the start of execution in the *FilterDetach* function, the filter module enters the *Detached* state. Before detaching a filter module, NDIS must pause the driver stack. For more information about pausing the driver stack, see Pausing a Driver Stack.

In its *FilterDetach* function, the driver frees its context areas and other resources (such as buffer pools) for the affected filter module. A filter driver cannot fail the call to *FilterDetach*. Therefore, filter drivers should preallocate, during the attach operation, all the resources required to perform the detach operation successfully. For more information about attaching a filter module, see Attaching a Filter Module.

After the filter module returns from *FilterDetach*, NDIS can start the paused driver stack. For more information about starting a driver stack, see Starting a Driver Stack.

Starting and Pausing a Filter Module

Article • 12/15/2021

NDIS pauses a filter module to stop data flow that could interfere with Plug and Play operations, for example, adding or removing a filter module in a driver stack, or to add a new binding. For more information about how to modify a running driver stack, see Modifying a Running Driver Stack.

NDIS starts a filter module from the *Paused* state. The filter module enters the *Paused* state after the attach operation is complete or after a pause operation is complete.

The following topics provide more information about starting and pausing a filter module:

Starting a Filter Module

Pausing a Filter Module

Starting a Filter Module

Article • 12/15/2021

To start a paused filter module, NDIS calls the filter driver's *FilterSetModuleOptions* function, if any, followed by a call to the *FilterRestart* function. The filter module enters the *Restarting* state at the start of execution in the *FilterRestart* function.

If the driver provided an entry point for *FilterSetModuleOptions*, the driver can change the partial characteristic for a filter module. For more information, see Data Bypass Mode.

When it calls a filter driver's *FilterRestart* function, NDIS passes a pointer to an **NDIS_RESTART_ATTRIBUTES** structure to filter driver in the **RestartAttributes** member of the **NDIS_FILTER_RESTART_PARAMETERS** structure. Filter drivers can modify the restart attributes that are specified by underlying drivers. For more information about how to modify restart attributes, see *FilterRestart*.

Note NDIS calls *FilterSetModuleOptions* for all filter modules in a stack before NDIS calls the *FilterRestart* function for any filter module in the stack.

NDIS starts a filter module as part of a Plug and Play operation to restart a driver stack. For an overview of restarting the driver stack, see Restarting a Driver Stack.

On behalf of a filter module that is in the *Restarting* state, the filter driver:

- Completes any operations that are required to restart normal send and receive operations.

  For more information about send and receive operations, see Filter Module Send and Receive Operations.

- Can read or write configurable parameters for the filter module.

- Can receive network data indications. The driver can copy and queue such data and indicate it to overlying drivers later, or it can discard the data.

- Should not initiate any new receive indications.

- Should reject all new send requests made to its *FilterSendNetBufferLists* function immediately by calling the **NdisFSendNetBufferListsComplete** function. It should set the complete status in each NET_BUFFER_LIST to NDIS_STATUS_PAUSED.

- Can provide status indications with the **NdisFIndicateStatus** function.

For more information about status indications, see Filter Module Status Indications.

- Should handle OID requests in the *FilterOidRequest* function.

  For more information about OID requests, see Filter Module OID Requests.

- Should not initiate any new send requests.

- Should return new receive indications to NDIS immediately by calling the **NdisFReturnNetBufferLists** function. If necessary, the driver can copy such receive indications before it returns them.

- Can make OID requests to the underlying drivers to set or query updated configuration information.

- Should handle status indications in its *FilterStatus* function.

- Should Indicate NDIS_STATUS_SUCCESS or a failure status. If a filter module does not restart, NDIS will detach it and if it is a mandatory filter, NDIS terminates the entire driver stack.

After the filter driver successfully restarts the send and receive operations, it must complete the restart operation. The filter driver can complete the restart operation synchronously or asynchronously by returning NDIS_STATUS_SUCCESS or NDIS_STATUS_PENDING respectively from *FilterRestart*.

If the driver returns NDIS_STATUS_PENDING, it must call the **NdisFRestartComplete** function after it completes the restart operation. In this case, the driver passes the final status of the restart operation to **NdisFRestartComplete**.

After the restart operation is complete, the filter module is in the *Running* state. The driver resumes normal send and receive processing.

NDIS does not initiate other Plug and Play operations, such as, attach, detach, or pause requests, while the filter driver is in the *Restarting* state. NDIS can initiate pause requests after a filter driver is in the *Running* state. For more information about pausing a filter module, see Pausing a Filter Module.

Pausing a Filter Module

Article • 12/15/2021

To pause a running filter module, NDIS calls the filter driver's *FilterPause* function. The filter module enters the *Pausing* state at the start of execution in the *FilterPause* function.

NDIS pauses a filter module as part of a Plug and Play operation to pause a driver stack. For an overview of pausing the driver stack, see Pausing a Driver Stack.

On behalf of a filter module that is in the *Pausing* state, the filter driver:

- Should not originate any new receive indications.

  For more information about send and receive operations, see Filter Module Send and Receive Operations.

- If there are receive operations that the filter driver originated and that NDIS has not completed, the filter driver must wait for NDIS to complete such operations. The pause operation is not complete until NDIS calls the *FilterReturnNetBufferLists* function for all such outstanding receive indications.

- Should return any outstanding receive indications that underlying drivers originated to NDIS immediately. The pause operation is not complete until the driver calls the **NdisFReturnNetBufferLists** function for such outstanding receive indications. These outstanding receive indications can exist if the driver queues the buffers that it receives from underlying drivers.

- Should return new receive indications that underlying drivers originate to NDIS immediately by calling the **NdisFReturnNetBufferLists** function. If necessary, the driver can copy receive indications and queue them before it returns them.

  Note **NdisFReturnNetBufferLists** should not be called for NBLs indicated with NDIS_RECEIVE_FLAGS_RESOURCES flag set in a corresponding *FilterReceiveNetBufferLists* call. Such NBLs are returned to NDIS synchronously by returning from the *FilterReceiveNetBufferLists* routine.

- Should not originate any new send requests.

- If there are send operations that the filter driver originated and that NDIS has not completed, the filter driver must wait for NDIS to complete such operations. The pause operation is not complete until NDIS calls the *FilterSendNetBufferListsComplete* function for all such outstanding send requests.

- Should return all new send requests made to its *FilterSendNetBufferLists* function immediately by calling the **NdisFSendNetBufferListsComplete** function. The filter driver should set the **Status** member in each NET_BUFFER_LIST structure to NDIS_STATUS_PAUSED.

- Can provide status indications with the **NdisFIndicateStatus** function.

  For more information about status indications, see Filter Module Status Indications.

- Should handle status indications in its *FilterStatus* function.

- Should handle OID requests in the *FilterOidRequest* function.

  For more information about OID requests, see Filter Module OID Requests.

- Can initiate OID requests.

- Should not free the resources the driver allocated during the attach operation.

- Should cancel timers, if required to stop send and receive operations.

  For more information about timers, see NDIS 6.0 Timer Services.

After the filter driver successfully pauses the send and receive operations, it must complete the pause operation. The filter driver can complete the pause operation synchronously or asynchronously by returning NDIS_STATUS_SUCCESS or NDIS_STATUS_PENDING respectively from *FilterPause*.

If the driver returns NDIS_STATUS_PENDING, it must call the **NdisFPauseComplete** function after it completes the pause operation.

On behalf of a filter module that is in the *Paused* state, the filter driver:

- Should not originate new receive indications.

- Should return new receive indications that underlying drivers originate to NDIS immediately by calling the **NdisFReturnNetBufferLists** function. If necessary, the driver can copy receive indications and queue them before it returns them.

- Should not originate new send requests.

- Should return all new send requests made to its *FilterSendNetBufferLists* function immediately by calling the **NdisFSendNetBufferListsComplete** function. The filter driver should set the **Status** member in each NET_BUFFER_LIST structure to NDIS_STATUS_PAUSED.

- Can provide status indications with the **NdisFIndicateStatus** function.

- Should handle status indications in its *FilterStatus* function.

- Should handle OID requests in the *FilterOidRequest* function.

- Can initiate OID requests.

NDIS does not initiate other Plug and Play operations, such as, attach, detach, or a restart requests, while the filter driver is in the *Pausing* state. NDIS can initiate detach or restart requests after a filter driver is in the *Paused* state. For more information about how to detach a filter module, see Detaching a Filter Module. For more information about how to restart a filter module, see Starting a Filter Module.

Data Bypass Mode

Article • 12/15/2021

The filter driver *data bypass mode* can provide improved system performance. NDIS does not call *FilterXxx* functions that are bypassed. For example, if the send and receive services are not required for a given filter application, the filter driver can bypass the send and receive functions.

A filter driver specifies the default entry points, for functions that can be bypassed, during driver initialization when it calls the **NdisFRegisterFilterDriver** function. The entry points are **NULL** for functions that are bypassed by default. For more information about initialization, see Initializing a Filter Driver.

To change the bypass state at runtime, the driver must specify an entry point for the *FilterSetModuleOptions* function during driver initialization. The driver can initialize an **NDIS_FILTER_PARTIAL_CHARACTERISTICS** structure and pass the new characteristics to the **NdisSetOptionalHandlers** function from within the context of *FilterSetModuleOptions*.

NDIS calls the *FilterSetModuleOptions* function, if any, at the start of a restart operation. A filter driver can set bypass mode independently for each filter module. For more information, see Starting a Filter Module.

Filter drivers can bypass the following optional *FilterXxx* functions that are specified in the **NDIS_FILTER_DRIVER_CHARACTERISTICS** structure:

FilterSendNetBufferLists

FilterSendNetBufferListsComplete

FilterCancelSendNetBufferLists

FilterReturnNetBufferLists

FilterReceiveNetBufferLists

To set a *FilterXxx* function to bypass mode, a filter driver specifies **NULL** for that function's entry point. However, if a driver calls any NDIS function that has an associated *FilterXxx* function, it must provide an entry point for that *FilterXxx* function. For example, if a driver calls the **NdisFIndicateReceiveNetBufferLists** function, it must provide a *FilterReturnNetBufferLists* function.

If a filter driver specifies a *FilterSendNetBufferLists* function and it queues send requests, it must also specify a *FilterCancelSendNetBufferLists* function.

If a filter driver specifies a *FilterReceiveNetBufferLists* or **FilterReturnNetBufferLists** function, the driver must also specify a *FilterStatus* function.

To change its bypass mode settings at run time, a filter driver can call the **NdisFRestartFilter** function. **NdisFRestartFilter** schedules a pause operation that is followed by a restart operation for the specified filter module. When NDIS calls *FilterSetModuleOptions*, the filter driver can change the functions for that filter module by calling **NdisSetOptionalHandlers** and specifying a new set of entry points.

Note Pause and restart could cause some network packets to be dropped on the transmit path, or receive path, or both. Network protocols that provide a reliable transport mechanism might retry the network I/O operation in the case of a lost packet, but other protocols that do not guarantee reliability do not retry the operation.

A filter driver can register additional optional functions that support optional driver services. The driver registers these optional services in the *FilterSetOptions* function. For more information about these optional services, see Configuring Optional Filter Driver Services.

Configuring Optional Filter Driver Services

Article • 12/15/2021

NDIS calls a filter driver's *FilterSetOptions* function to configure optional filter driver services. NDIS calls *FilterSetOptions* within the context of the filter driver's call to the **NdisFRegisterFilterDriver** function

FilterSetOptions registers the default entry points for optional *FilterXxx* functions that are required for optional services, and can allocate other driver resources. To register optional services, the filter driver calls the **NdisSetOptionalHandlers** function and passes a characteristics structure at the *OptionalHandlers* parameter.

There are no optional filter driver services in the current Windows version.

Filter drivers can also call **NdisSetOptionalHandlers** to set the some *FilterXxx* function entry points for a given filter module. For more information, see Data Bypass Mode.

If the filter driver calls **NdisSetOptionalHandlers** from *FilterRestart*, the configuration changes only affect the filter module that NDIS is restarting. The configuration of other filter modules is not affected.

Filter Module Send and Receive Operations

Article • 12/15/2021

This section documents send and receive operations for NDIS 6.0 filter drivers. Filter drivers can initiate send requests and receive indications or filter the requests and indications of other drivers.

Filter modules are stacked over a miniport adapter. For more information about the driver stack, see NDIS 6.0 Driver Stack.

The filter modules in the driver stack can filter all send requests and receive indications that are associated with the underlying adapter. This is true for all protocol bindings to an adapter. For more information about NDIS 6.0 send and receive operations, see Send and Receive Operations.

Filter drivers do not provide direct support for legacy send and receive operations that are based on the **NDIS_PACKET** structure. Instead, NDIS converts receive indications from legacy miniport drivers to **NET_BUFFER** structures. Also, NDIS handles the required conversions from send requests that are based on NET_BUFFER structures to legacy send requests that are based on NDIS_PACKET structures.

Note A filter driver can change the send and receive *FilterXxx* functions for a filter module dynamically. For more information, see Data Bypass Mode.

The following topics provide additional information about filter driver send and receive operations:

Filter Driver Buffer Management

Sending Data from a Filter Driver

Canceling a Send Request in a Filter Driver

Receiving Data in a Filter Driver

Filter Driver Buffer Management

Article • 12/15/2021

Filter drivers create buffers to copy network data obtained from other drivers, or to initiate send or receive operations.

If a filter driver does not create buffers, the driver does not manage buffer pools. Such a driver simply passes on the buffers that it receives from other drivers.

A filter driver that creates buffers to support send or receive operations must manage NET_BUFFER_LIST structure pools and NET_BUFFER structure pools.

To create these pools, drivers call the following functions:

NdisAllocateNetBufferListPool

NdisAllocateNetBufferPool

Filter drivers can use the following functions to allocate structures from the pools:

NdisAllocateNetBufferAndNetBufferList

NdisAllocateNetBufferList

NdisAllocateNetBuffer

Calling **NdisAllocateNetBufferAndNetBufferList** is more efficient than calling **NdisAllocateNetBufferList** followed by **NdisAllocateNetBuffer**. However, **NdisAllocateNetBufferAndNetBufferList** only creates one NET_BUFFER structure on the NET_BUFFER_LIST structure. To use **NdisAllocateNetBufferAndNetBufferList**, the driver must set the *AllocateNetBuffer* parameter to **TRUE** when it calls **NdisAllocateNetBufferListPool**.

Filter drivers that originate send requests should determine the context and backfill space requirements of the underlying drivers. Filter drivers use restart attributes to determine the backfill requirements of underlying drivers. A filter driver should determine the backfill and context requirements in the *Restarting* state. The driver should allocate sufficient backfill and context space for the entire stack. If necessary, a filter driver can free the pools and reallocate them in the *Restarting* state.

Filter drivers use the following functions to free the pools:

NdisFreeNetBufferListPool

NdisFreeNetBufferPool

Filter drivers use the following functions to free the structures allocated from the pools:

NdisFreeNetBufferList

NdisFreeNetBuffer

Drivers should free NET_BUFFER structures allocated with **NdisAllocateNetBuffer** before freeing the associated NET_BUFFER_LIST structure. NET_BUFFER structures allocated with **NdisAllocateNetBufferAndNetBufferList** are freed when the driver calls **NdisFreeNetBufferList** for the associated NET_BUFFER_LIST structure.

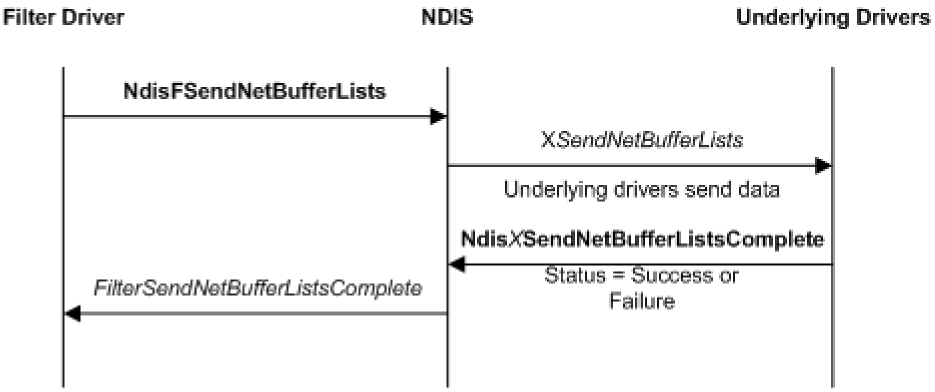
Sending Data from a Filter Driver

Article • 12/15/2021

Filter drivers can initiate send requests or filter send requests that overlying drivers initiate. When a protocol driver calls the NdisSendNetBufferLists function, NDIS submits the specified NET_BUFFER_LIST structure to the topmost filter module in the driver stack.

Send Requests Initiated by a Filter Driver

The following figure illustrates a send operation that is initiated by a filter driver.



Filter Driver
NDIS
Underlying Drivers
NdisFSendNetBufferLists
XSendNetBufferLists
Underlying drivers send data
NdisXSendNetBufferListsComplete
Status = Success or Failure
FilterSendNetBufferListsComplete

Filter drivers call the NdisFSendNetBufferLists function to send the network data that is defined in a list of NET_BUFFER_LIST structures.

A filter driver must set the **SourceHandle** member of each NET_BUFFER_LIST structure that it creates to the same value that it passes to the *NdisFilterHandle* parameter of **NdisFSendNetBufferLists**. NDIS drivers should not modify the **SourceHandle** member for NET_BUFFER_LIST structures that the driver did not originate.

Before calling **NdisFSendNetBufferLists**, a filter driver can set information that accompanies the send request with the NET_BUFFER_LIST_INFO macro. The underlying drivers can retrieve this information with the NET_BUFFER_LIST_INFO macro.

As soon as a filter driver calls **NdisFSendNetBufferLists**, it relinquishes ownership of the NET_BUFFER_LIST structures and all associated resources. NDIS can handle the send request or pass the request to underlying drivers.

NDIS calls the *FilterSendNetBufferListsComplete* function to return the structures and data to the filter driver. NDIS can collect the structures and data from multiple send requests into a single linked list of NET_BUFFER_LIST structures before it passes the list to *FilterSendNetBufferListsComplete*

Until NDIS calls *FilterSendNetBufferListsComplete*, the current status of a send request is unknown. A filter driver should *never* try to examine the NET_BUFFER_LIST structures or any associated data before NDIS returns the structures to *FilterSendNetBufferListsComplete*.

FilterSendNetBufferListsComplete performs whatever postprocessing is necessary to complete a send operation.

When NDIS calls *FilterSendNetBufferListsComplete*, the filter driver regains ownership of all the resources associated with the NET_BUFFER_LIST structures that are specified by the *NetBufferLists* parameter. *FilterSendNetBufferListsComplete* can either free these resources (for example, by calling the NdisFreeNetBuffer and NdisFreeNetBufferList functions) or prepare them for reuse in a subsequent call to **NdisFSendNetBufferLists**.

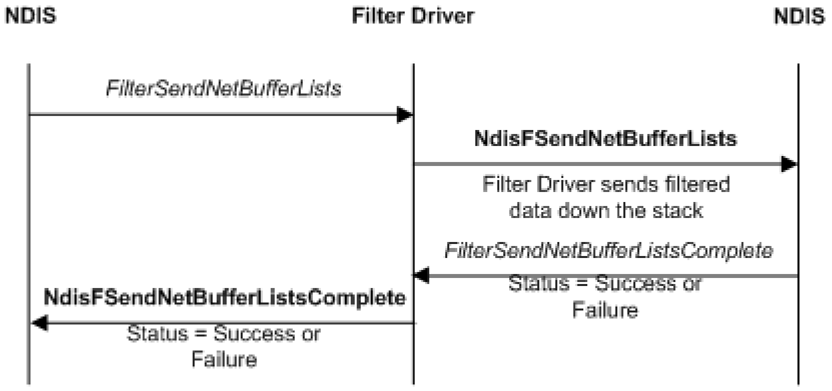
NDIS always submits filter-supplied network data to the underlying drivers in the filter-driver-determined order as passed to **NdisFSendNetBufferLists**. However, after sending the data in the specified order, the underlying drivers can return the buffers in any order.

A filter driver can request loopback for send requests that it originates. To request loopback, the driver sets the NDIS_SEND_FLAGS_CHECK_FOR_LOOPBACK flag in the *SendFlags* parameter of NdisFSendNetBufferLists. NDIS indicates a received packet that contains the send data.

Note A filter driver should keep track of send requests that it originates and make sure that it does not call the NdisFSendNetBufferListsComplete function when such requests are complete.

Filtering Send Requests

The following figure illustrates filtering a send request that is initiated by an overlying driver.



NDIS
Filter Driver
NDIS
FilterSendNetBufferLists
NdisFSendNetBufferLists
Filter Driver sends filtered data down the stack
FilterSendNetBufferListsComplete
Status = Success or Failure
NdisFSendNetBufferListsComplete
Status = Success or Failure

NDIS calls a filter driver's *FilterSendNetBufferLists* function to filter the send request of an overlying driver.

The filter driver must not modify the **SourceHandle** member in the NET_BUFFER_LIST structures that it receives from other drivers.

The filter driver can filter the data and send the filtered data to underlying drivers. For each NET_BUFFER structure submitted to *FilterSendNetBufferLists*, a filter driver can do the following:

- Pass the buffer on to the next underlying driver by calling the **NdisFSendNetBufferLists** function. NDIS guarantees the availability of context space (see NET_BUFFER_LIST_CONTEXT structure) for filter drivers. The filter driver can modify the buffer contents before calling **NdisFSendNetBufferLists**. The processing of the filtered data proceeds as with a send operation initiated by a filter driver.

- Drop the buffer by calling the **NdisFSendNetBufferListsComplete** function.

- Queue the buffer in a local data structure for later processing. The design of the filter driver dictates what causes the driver to process a queued buffer. Some examples include processing after a time-out or processing after a specific buffer is received.

  Note If the driver queues send requests for later processing, it must support send cancellation requests. For more information about send cancellation requests, see Canceling Send Requests in a Filter Driver.

- Copy the buffer and originate a send request with the copy. The send operation is similar to a filter driver initiated send request. In this case, the driver must return the original buffer to the overlying driver by calling the **NdisFSendNetBufferListsComplete** function.

Completion of send requests proceeds up the driver stack. When the miniport driver calls the **NdisMSendNetBufferListsComplete** function, NDIS calls the *FilterSendNetBufferListsComplete* function for the lowest overlying filter module.

After the send operation is complete, the filter driver reverses the modifications to the overlying driver's buffer descriptors that the filter driver made in *FilterSendNetBufferLists*. The driver calls the **NdisFSendNetBufferListsComplete** function to return the linked list of NET_BUFFER_LIST structures to the overlying drivers and to return the final status of the send request.

When the topmost filter module calls **NdisFSendNetBufferListsComplete**, NDIS calls the originating protocol driver's **ProtocolSendNetBufferListsComplete** function.

A filter driver that does not provide a *FilterSendNetBufferLists* function can still initiate a send request. If such a driver does initiate a send request, it must provide a *FilterSendNetBufferListsComplete* function and it must not pass the complete event up the driver stack.

A filter driver can pass on or filter the loopback request of an overlying driver. To pass on a loopback request, if NDIS set NDIS_SEND_FLAGS_CHECK_FOR_LOOPBACK in the *SendFlags* parameter of *FilterSendNetBufferLists*, the filter driver sets NDIS_SEND_FLAGS_CHECK_FOR_LOOPBACK in the *SendFlags* parameter when it calls **NdisFSendNetBufferLists**. NDIS indicates a received packet that contains the send data.

In general, if a filter driver modifies any behavior in such a way that NDIS cannot provide a standard service (such as loopback), the filter driver must provide that service for NDIS. For example, a filter driver that modifies a request for the hardware address (see OID_802_3_CURRENT_ADDRESS), should handle loopback of buffers directed to the new hardware address. In this case, NDIS cannot provide the loopback service it typically provides because the filter altered the address. Also, if the filter driver sets promiscuous mode (see OID_GEN_CURRENT_PACKET_FILTER), it should not pass on the extra data that it receives to overlying drivers.

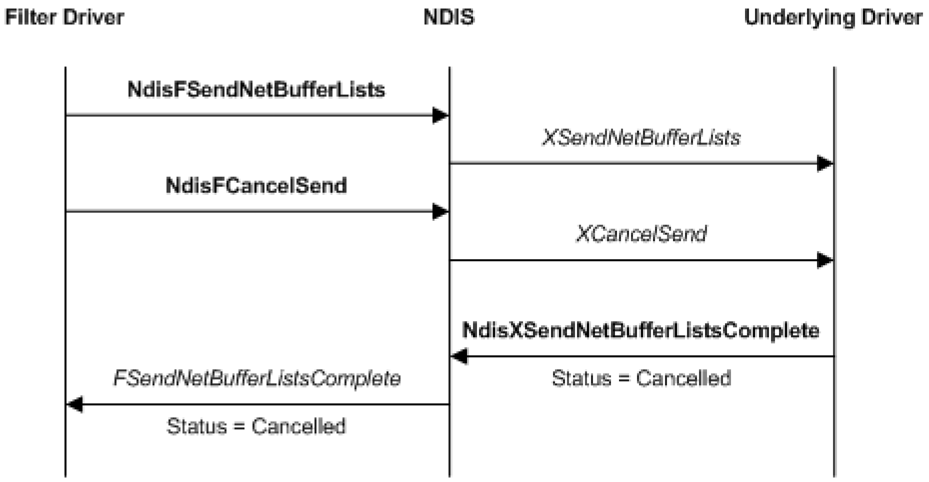
Canceling a Send Request in a Filter Driver

Article • 12/15/2021

Filter drivers can cancel send requests that were originated by the filter driver or that were originated by overlying drivers.

Canceling Filter Driver Send Requests

The following figure illustrates canceling a send request that was originated by a filter driver.



A filter driver calls the NDIS_SET_NET_BUFFER_LIST_CANCEL_ID macro for each NET_BUFFER_LIST structure that it creates for send operations. The NDIS_SET_NET_BUFFER_LIST_CANCEL_ID function marks the specified data with a cancellation identifier.

Before assigning cancellation IDs to network data, a filter driver must call NdisGeneratePartialCancelId to obtain the high-order byte of each cancellation ID that it assigns. This ensures that the driver does not duplicate cancellation IDs assigned by other drivers in the system. Drivers typically call **NdisGeneratePartialCancelId** one time from the DriverEntry routine. However, drivers can obtain more than one partial cancellation identifier by calling **NdisGeneratePartialCancelId** multiple times.

To cancel the pending transmission of data in a marked NET_BUFFER_LIST structure, a filter driver passes the cancellation ID to the NdisFCancelSendNetBufferLists function. Drivers can obtain a NET_BUFFER_LIST structure's cancellation ID by calling the NDIS_GET_NET_BUFFER_LIST_CANCEL_ID macro.

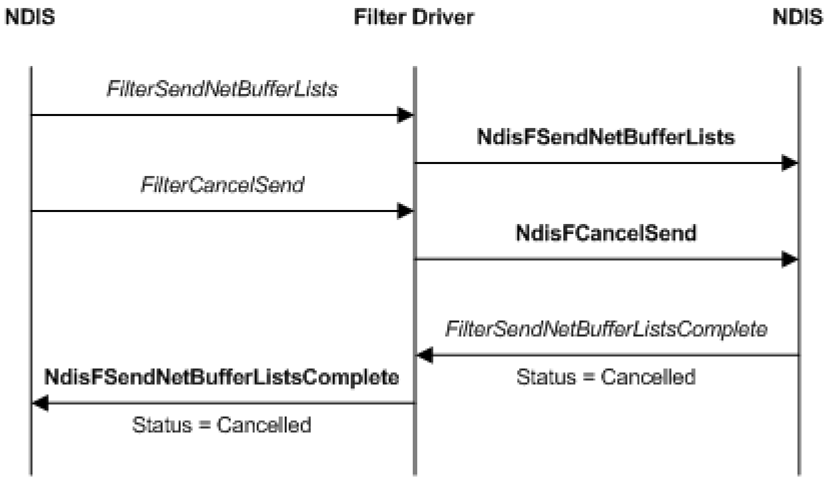
If a filter driver marks all NET_BUFFER_LIST structures with the same cancellation identifier, it can cancel all pending transmissions with a single call to **NdisFCancelSendNetBufferLists**. If a filter driver marks all NET_BUFFER_LIST structures within a subgroup of NET_BUFFER_LIST structures with a unique identifier, it can cancel all pending transmissions within that subgroup with a single call to **NdisFCancelSendNetBufferLists**.

NDIS calls the cancel send function of the underlying drivers. After aborting the pending transmission, the underlying drivers call a send complete function (for example **NdisMSendNetBufferListsComplete**) to return the NET_BUFFER_LIST structures with a completion status of NDIS_STATUS_SEND_ABORTED. NDIS, in turn, calls the filter driver's *FilterSendNetBufferListsComplete* function.

In *FilterSendNetBufferListsComplete*, a filter driver can call NDIS_SET_NET_BUFFER_LIST_CANCEL_ID with *CancelId* set to **NULL**. This prevents the NET_BUFFER_LIST from accidentally being used again with a stale cancellation ID.

Canceling Send Requests Originated by Overlying Drivers

The following figure illustrates canceling a send request that was originated by an overlying driver.



Overlying drivers call a cancel send function (**NdisFCancelSendNetBufferLists** or **NdisCancelSendNetBufferLists**) to cancel outstanding send requests. These overlying drivers must mark the send data with a cancellation ID before making a send request.

NDIS calls a filter driver's *FilterCancelSendNetBufferLists* function to cancel the transmission of all **NET_BUFFER_LIST** structures that are marked with a specified cancellation identifier.

FilterCancelSendNetBufferLists performs the following operations:

1. Traverses the filter driver's list of queued NET_BUFFER_LIST structures for the specified filter module and calls the **NDIS_GET_NET_BUFFER_LIST_CANCEL_ID** macro to obtain the cancellation identifier for each structure. The filter driver compares the cancellation ID that NDIS_GET_NET_BUFFER_LIST_CANCEL_ID returns with the cancellation ID that NDIS passed to *FilterCancelSendNetBufferLists*.

2. Removes from the send queue (unlinks) all NET_BUFFER_LIST structures whose cancellation identifiers match the specified cancellation identifier.

3. Calls the **NdisFSendNetBufferListsComplete** function for all unlinked NET_BUFFER_LIST structures to return the structures. The filter driver sets the status field of the NET_BUFFER_LIST structures to NDIS_STATUS_SEND_ABORTED.

4. Calls the **NdisFCancelSendNetBufferLists** function to pass the cancel send request to underlying drivers. The filter driver passes on the cancellation identifier that it received from the overlying driver. The cancel operation proceeds as with a filter-driver-originated cancel send operation.

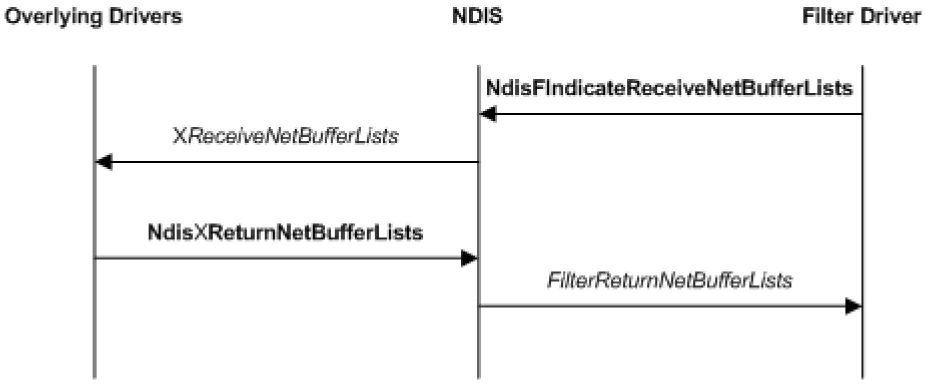
Receiving Data in a Filter Driver

Article • 12/15/2021

Filter drivers can initiate receive indications or filter receive indications from underlying drivers. When a miniport driver calls the NdisMIndicateReceiveNetBufferLists function, NDIS submits the specified NET_BUFFER_LIST structure to the lowest overlying filter module in the driver stack.

Receive Indications Initiated by a Filter Driver

The following figure illustrates a receive indication that is initiated by a filter driver.



Overlying Drivers
NDIS
Filter Driver
NdisFIndicateReceiveNetBufferLists
XReceiveNetBufferLists
NdisXReturnNetBufferLists
FilterReturnNetBufferLists

Filter drivers call the NdisFIndicateReceiveNetBufferLists function to indicate received data. The **NdisFIndicateReceiveNetBufferLists** function passes the indicated list of NET_BUFFER_LIST structures up the stack to overlying drivers. The filter driver allocates the structures from pools that it created during initialization.

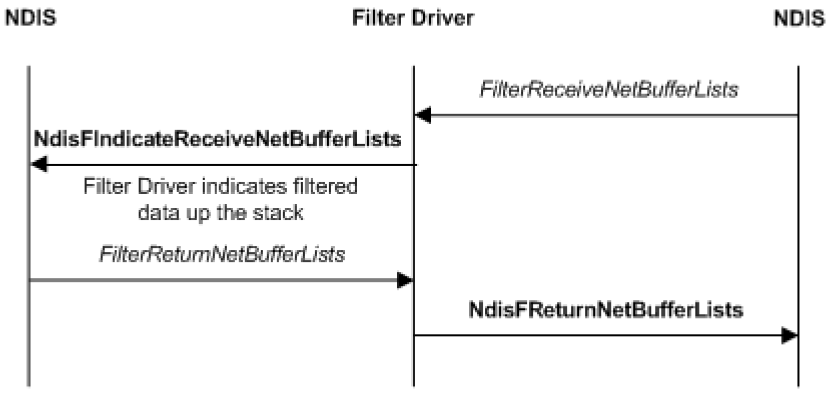
If a filter driver sets the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of NdisFIndicateReceiveNetBufferLists, this indicates that the filter driver must regain ownership of the NET_BUFFER_LIST structures immediately. In this case, NDIS does not call the filter driver's *FilterReturnNetBufferLists* function to return the **NET_BUFFER_LIST** structures. The filter driver regains ownership immediately after **NdisFIndicateReceiveNetBufferLists** returns.

If a filter driver does not set the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of NdisFIndicateReceiveNetBufferLists, NDIS returns the indicated NET_BUFFER_LIST structures to the filter driver's *FilterReturnNetBufferLists* function. In this case, the filter driver relinquishes ownership of the indicated structures until NDIS returns them to *FilterReturnNetBufferLists*.

Note A filter driver should keep track of receive indications that it initiates and make sure that it does not call the NdisFReturnNetBufferLists function when the receive operation is complete.

Filtering Receive Indications

The following figure illustrates a filtered receive indication that is initiated by an underlying driver.



NDIS
Filter Driver
NDIS
FilterReceiveNetBufferLists
NdisFIndicateReceiveNetBufferLists
Filter Driver indicates filtered data up the stack
FilterReturnNetBufferLists
NdisFReturnNetBufferLists

NDIS calls a filter driver's *FilterReceiveNetBufferLists* function to process receive indications that come from underlying drivers. NDIS calls *FilterReceiveNetBufferLists* after an underlying driver calls a receive indication function (for example, **NdisMIndicateReceiveNetBufferLists**) to indicate received network data or loopback data.

If the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of *FilterReceiveNetBufferLists* is not set, the filter driver keeps ownership of the **NET_BUFFER_LIST** structures until it calls the **NdisFReturnNetBufferLists** function.

If the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter is set, the filter driver cannot keep the **NET_BUFFER_LIST** structure and the associated underlying driver-allocated resources. This flag can indicate that the underlying driver is running low on receive resources. The *FilterReceiveNetBufferLists* function should return as quickly as possible.

Note If the **NDIS_RECEIVE_FLAGS_RESOURCES** flag is set, the filter driver must retain the original set of **NET_BUFFER_LIST** structures in the linked list. For example, when this flag is set, the driver might process the structures and indicate them up the stack one at a time but before the function returns, it must restore the original linked list.

Filter drivers can perform filter operations on received data before indicating the data to overlying drivers. For each buffer submitted to its *FilterReceiveNetBufferLists* function a filter driver can do the following:

- Pass it on to the next overlying driver by calling **NdisFIndicateReceiveNetBufferLists**. The driver can modify the contents of the buffer. NDIS guarantees the availability of context space (see NET_BUFFER_LIST_CONTEXT structure).

  A filter driver can change the status that NDIS passed to *FilterReceiveNetBufferLists* or simply pass it on to **NdisFIndicateReceiveNetBufferLists**.

  Note A filter driver can pass on a buffer with **NdisFIndicateReceiveNetBufferLists** even if NDIS sets the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of *FilterReceiveNetBufferLists*. In this case, the filter driver must not return from *FilterReceiveNetBufferLists* until it regains ownership of the buffer.

- Discard the buffer. If NDIS cleared the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of *FilterReceiveNetBufferLists*, call the **NdisFReturnNetBufferLists** function to discard the buffer. If NDIS set the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of *FilterReceiveNetBufferLists*, take no action and return from *FilterReceiveNetBufferLists* to discard the buffer.

- Queue the buffer in a local data structure for later processing. If NDIS set the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of *FilterReceiveNetBufferLists*, the filter driver must create a copy before returning from *FilterReceiveNetBufferLists*.

- Copy the buffer and originate a receive indication with the copy. The receive indication is similar to a filter-driver-initiated receive indication. In this case, the driver must return the original buffer to the underlying driver.

The **NdisFIndicateReceiveNetBufferLists** function passes the indicated list of **NET_BUFFER_LIST** structures up the driver stack to overlying drivers. The receive operation proceeds similarly to a filter-driver-initiated receive operation.

If an overlying driver retained ownership of the buffer, NDIS calls the *FilterReturnNetBufferLists* function for the filter module. In its *FilterReturnNetBufferLists* function, the filter driver will undo the operations that it performed on the buffer on the receive indication path.

When the lowest layer filter module indicates that it is done with a buffer, NDIS returns the buffer to the miniport driver. If NDIS cleared the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of *FilterReceiveNetBufferLists*, the filter driver calls **NdisFReturnNetBufferLists** to return the buffer. If NDIS set the **NDIS_RECEIVE_FLAGS_RESOURCES** flag in the *ReceiveFlags* parameter of *FilterReceiveNetBufferLists*, returning from *FilterReceiveNetBufferLists* returns the buffer.

Filter Module OID Requests

Article • 12/15/2021

NDIS defines object identifier (OID) values to identify adapter parameters, which include operating parameters such as device characteristics, configurable settings and statistics. For more information about OIDs, see NDIS OIDs.

Filter drivers can query or set the operating parameters of underlying drivers or filter the OID requests of overlying drivers.

NDIS also provides a direct OID request interface for NDIS 6.1 and later filter drivers. The *direct OID request path* supports OID requests that are queried or set frequently. For example, the IPsec offload version 2 (IPsecv2) interface provides the OID_TCP_TASK_IPSEC_OFFLOAD_V2_ADD_SA OID for direct OID requests. The direct OID request interface is optional for NDIS drivers.

For NDIS 6.81 and later filter drivers, NDIS provides a Synchronous OID Request Interface. The *Synchronous OID request path* supports OIDs that require synchronization or OIDs that should not be queued by filter drivers, such as RSSv2 OIDs. The Synchronous OID Request Interface is optional for NDIS drivers but is required if the filter driver advertises support for RSSv2.

The following topics provide more information about filter driver OID requests:

Filtering OID Requests in an NDIS Filter Driver

Generating OID Requests from an NDIS Filter Driver

Filter Module Direct OID Requests

Filter Module Synchronous OID Requests

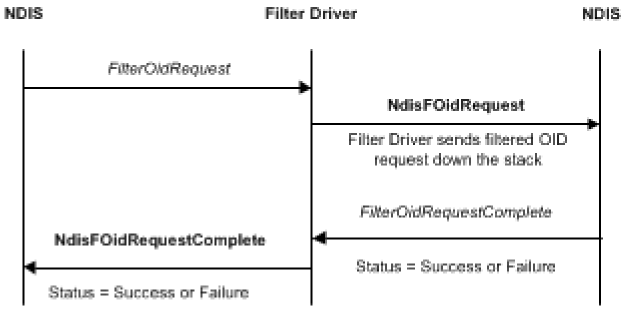
Filtering OID Requests in an NDIS Filter Driver

Article • 03/14/2023

Filter drivers can process OID requests that are originated by overlying drivers. NDIS calls the *FilterOidRequest* function to process each OID request. Filter drivers can forward OID requests to underlying drivers by calling the **NdisFOidRequest** function.

NDIS can call a filter driver's *FilterCancelOidRequest* function to cancel an OID request. When NDIS calls *FilterCancelOidRequest*, the filter driver should try to call the **NdisFOidRequest** function as soon as possible.

The following figure illustrates a filtered OID request.



NDIS
Filter Driver
NDIS
FilterOidRequest
NdisFOidRequest
Filter Driver sends filtered OID request down the stack
FilterOidRequestComplete
NdisFOidRequestComplete
Status = Success or Failure
Status = Success or Failure

The filter driver can complete the OID request synchronously or asynchronously by returning NDIS_STATUS_SUCCESS or NDIS_STATUS_PENDING, respectively, from *FilterOidRequest*. *FilterOidRequest* can also complete synchronously with an error status.

A filter driver that successfully handles an OID set request must set the **SupportedRevision** member in the **NDIS_OID_REQUEST** structure upon return from the OID set request. The **SupportedRevision** member notifies the initiator of the OID request about which revision the driver supported. For more information about version information in NDIS structures, see Specifying NDIS Version Information.

If *FilterOidRequest* returns NDIS_STATUS_PENDING, it must call the **NdisFOidRequestComplete** function after it completes the OID request. In this case, the driver passes the results of the request at the *OidRequest* parameter of **NdisFOidRequestComplete**. The driver passes the final status of the request at the *Status* parameter of **NdisFOidRequestComplete**.

If *FilterOidRequest* returns NDIS_STATUS_SUCCESS, it returns the results of a query request in the **NDIS_OID_REQUEST** structure at the *OidRequest* parameter. In this case, the driver does not call the **NdisFOidRequestComplete** function.

To forward an OID request to underlying drivers, a filter driver calls the **NdisFOidRequest** function. If a request should not be forwarded to the underlying drivers, a filter driver can complete the request immediately. To complete the request without forwarding, the driver can return NDIS_STATUS_SUCCESS (or an error status) from *FilterOidRequest*, or it can call **NdisFOidRequestComplete** after returning NDIS_STATUS_PENDING.

Note Before the driver calls **NdisFOidRequest**, the driver must allocate an **NDIS_OID_REQUEST** structure and transfer the request information to the new structure by calling **NdisAllocateCloneOidRequest**.

The forwarded request proceeds the same as a request initiated by a filter driver. For more information, see Generating OID Requests from an NDIS Filter Driver.

After the underlying drivers complete a forwarded request, the filter driver can modify the response, if necessary, and pass it to overlying drivers.

A filter driver can receive OID requests from overlying drivers when it is in the *Restarting*, *Running*, *Pausing*, or *Paused* state.

Note Like miniport drivers, filter drivers can receive only one OID request at a time. Because NDIS serializes requests that are sent to a filter module, a filter driver cannot be called at *FilterOidRequest* before it completes the previous request.

The following is an example of a filter driver modifying an OID request:

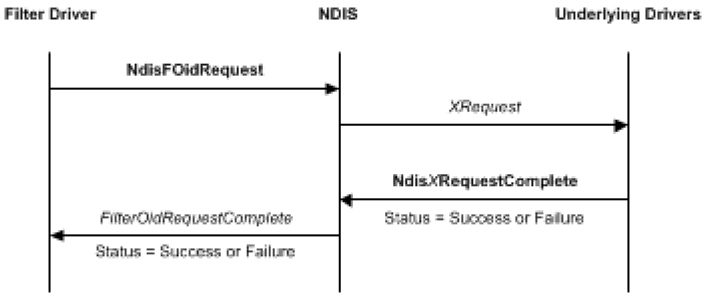
- A filter driver adds a header. In this case, after the driver receives a response to a query for OID_GEN_MAXIMUM_FRAME_SIZE from the underlying drivers, the filter subtracts the size of its header from the response. The driver subtracts its header size because the driver inserts a header in front of each sent packet and removes the header in each received packet.

Generating OID Requests from an NDIS Filter Driver

Article • 03/14/2023

A filter driver can originate OID query or set requests to underlying drivers by calling the **NdisFOidRequest** function.

The following figure illustrates an OID request that is originated by a filter driver.



After a filter driver calls the **NdisFOidRequest** function, NDIS calls the request function of the next underlying driver. For more information about how a miniport driver handles OID requests, see OID Requests for an Adapter.

To complete synchronously, **NdisFOidRequest** returns NDIS_STATUS_SUCCESS or an error status. To complete asynchronously, **NdisFOidRequest** returns NDIS_STATUS_PENDING.

To determine what information was successfully handled by an underlying driver, filter drivers that issue OID requests must check the value in the **SupportedRevision** member in the NDIS_OID_REQUEST structure after the OID request returns. For more information about NDIS version information, see Specifying NDIS Version Information.

If **NdisFOidRequest** returns NDIS_STATUS_PENDING, NDIS calls the *FilterOidRequestComplete* function after the underlying drivers complete the OID request. In this case, NDIS passes the results of the request at the *OidRequest* parameter of *FilterOidRequestComplete*. NDIS passes the final status of the request at the *Status* parameter of *FilterOidRequestComplete*.

If **NdisFOidRequest** returns NDIS_STATUS_SUCCESS, it returns the results of a query request in the **NDIS_OID_REQUEST** structure at the *OidRequest* parameter. In this case, NDIS does not call the *FilterOidRequestComplete* function.

A driver can call **NdisFOidRequest** when it is in the *Restarting*, *Running*, *Pausing*, or *Paused* state.

Note A filter driver should keep track of OID requests that it originates and make sure that it does not call the **NdisFOidRequestComplete** function when such requests are complete.

Filter Module Direct OID Requests

Article • 12/15/2021

To support the direct OID request path, filter drivers provide *FilterXxx* function entry points in the **NDIS_FILTER_DRIVER_CHARACTERISTICS** structure and NDIS provides **NdisF*Xxx*** functions for filter drivers.

The *direct OID request interface* is similar to the standard OID request interface. For example, the **NdisFDirectOidRequest** and *FilterDirectOidRequest* functions are similar to the **NdisFOidRequest** and *FilterOidRequest* functions.

Note NDIS 6.1 and later support specific OIDs for use with the direct OID request interface. OIDs that existed before NDIS 6.1 and some NDIS 6.1 OIDs are not supported. To determine if an OID can be used in the direct OIDs interface, see the OID reference page. For example, see the note in the OID_TCP_TASK_IPSEC_OFFLOAD_V2_ADD_SA OID.

Filter drivers must be able to handle direct OID requests that are not serialized. Unlike the standard OID request interface, NDIS does not serialize direct OID requests with other requests that are sent with the direct OID interface or with the standard OID request interface. Also, filter drivers must be able to handle direct OID requests at IRQL <= DISPATCH_LEVEL.

To support the direct OIDs request interface, use the documentation for the standard OID request interface. The following table shows the relationship between the functions in the direct OID request interface and the standard OID request interface.

Direct OID function	Standard OID function
FilterDirectOidRequest	*FilterOidRequest*
FilterCancelDirectOidRequest	*FilterCancelOidRequest*
FilterDirectOidRequestComplete	*FilterOidRequestComplete*
NdisFDirectOidRequest	**NdisFOidRequest**
NdisFDirectOidRequestComplete	**NdisFDirectOidRequestComplete**
NdisFCancelDirectOidRequest	**NdisFCancelOidRequest**

Filter Module Synchronous OID Requests

Article • 12/15/2021

To support the Synchronous OID request path, filter drivers provide a *FilterSynchronousOidRequest* function entry point in the **NDIS_FILTER_DRIVER_CHARACTERISTICS** structure when they call the **NdisFRegisterFilterDriver** function.

ⓘ Note

NDIS 6.81 supports specific OIDs for use with the Synchronous OID request interface. OIDs that existed before NDIS 6.80 and some NDIS 6.80 OIDs are not supported. To determine if an OID can be used in the Synchronous OID request interface, see the OID reference page.

To support the Synchronous OID request interface, use the documentation for the standard OID request interface. The following table shows the relationship between the functions in the Synchronous OID request interface and the standard OID request interface.

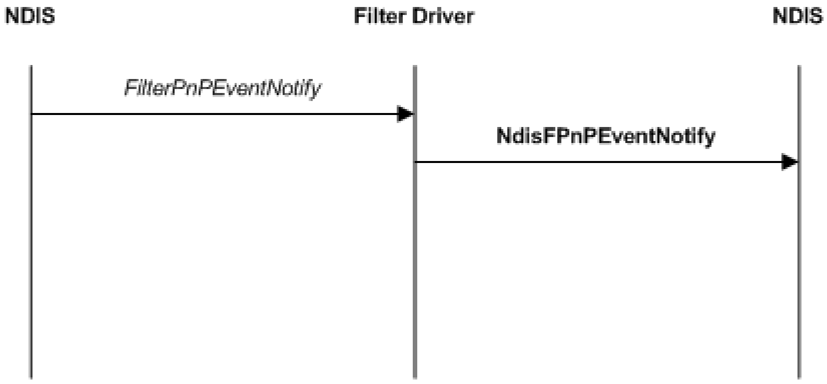
Synchronous OID function	Standard OID function
FilterSynchronousOidRequest	*FilterOidRequest*
FilterSynchronousOidRequestComplete	*FilterOidRequestComplete*

Filter Module PnP Event Notifications

Article • 12/15/2021

Filter drivers can receive all the device Plug and Play (PnP) notifications that underlying miniport drivers receive. Also, filter drivers can receive all the network PnP notifications that overlying protocol drivers receive.The handling of PnP notifications is driver specific.

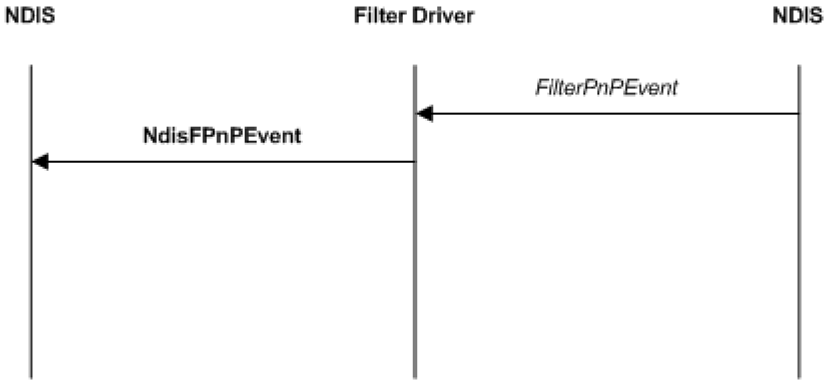
The following figure illustrates a filtered device PnP event notification.



Filter drivers provide a *FilterDevicePnPEventNotify* function that NDIS calls to pass in device PnP and Power Management event notifications. This is similar to the *MiniportDevicePnPEventNotify* function.

Filter drivers can forward device PnP and Power Management events to underlying drivers. To forward a device PnP or Power Management event, call the **NdisFDevicePnPEventNotify** function.

The following figure illustrates a filtered network PnP event notification.



Filter drivers provide a *FilterNetPnPEvent* function that NDIS calls to pass in network PnP and Power Management event notifications. This is similar to the *ProtocolNetPnPEvent* function.

Filter drivers can forward network PnP and Power Management events to overlying drivers. To forward a network PnP or Power Management event, call the

NdisFNetPnPEvent function.

Filter drivers should handle driver stack changes. For more information about driver stack changes, see Modifying a Running Driver Stack.

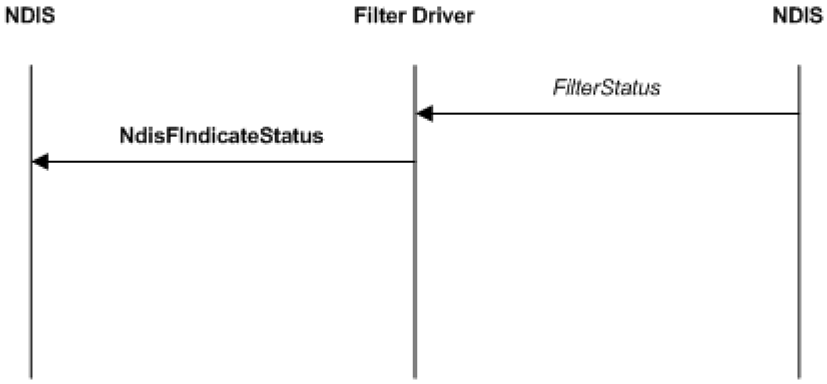
If necessary to allow handling of these events, NDIS can initiate a pause operation after the PnP or Power Management notification. For more information, see Pausing a Driver Stack.

Filter Module Status Indications

Article • 12/15/2021

Filter drivers can supply a *FilterStatus* function that NDIS calls when an underlying driver reports status. Filter drivers can also initiate status indications.

The following figure illustrates a filtered status indication.



NDIS calls a filter driver's *FilterStatus* function, after an underlying driver calls a status indication function (**NdisMIndicateStatusEx** or **NdisFIndicateStatus**). For more information about how to indicate status from a miniport driver, see Adapter Status Indications.

A filter driver calls **NdisFIndicateStatus** in its *FilterStatus* function, to pass on a filtered status indication to overlying drivers. A filter driver can filter out status indications (by not calling **NdisFIndicateStatus**) or modify the indicated status before it calls **NdisFIndicateStatus**.

To originate status indications, filter drivers call **NdisFIndicateStatus** without a prior call to *FilterStatus*.

In this case, the filter driver should set the **SourceHandle** member to the handle that NDIS passed to the *NdisFilterHandle* parameter of the *FilterAttach* function. If the status indication is associated with an OID request, the filter driver can set the **DestinationHandle** and **RequestId** members so that NDIS can provide the status indication to a specific protocol binding.

After a filter driver calls **NdisFIndicateStatus**, NDIS calls the status function (**ProtocolStatusEx** or *FilterStatus*) of the next overlying driver.

NDIS Filter Driver Installation

Article • 05/30/2023

This section provides information about installing NDIS filter drivers. Lightweight Filter drivers are different from filter intermediate drivers. The configuration manager supplies NDIS with a list of filter modules for each miniport adapter. There's no virtual device (or virtual miniport) that is associated with a filter driver as there is with an NDIS filter intermediate driver.

To install a filter driver, you must provide a single INF file. The configuration manager reads configuration information about the filter driver from the INF file and copies it to the registry.

The filter driver INF file defines a network service. Filter drivers don't have a miniport INF file. For an example filter driver INF file, see the ndislwf sample driver.

Once you have provided your filter driver INF file, to install or uninstall your filter driver you must use the `INetCfg` family of Network Configuration Interfaces. For example, to install or remove network components, call into the INetCfgClassSetup interface. You can either call into these interfaces programmatically or you can indirectly call them with netcfg.exe, which calls `INetCfg` for you. You can't install a driver package through the `INetCfg` and use the Driver Store feature on older Windows versions. To successfully install the driver package in this scenario, you need to have a minimum OS build number of 25319. You can't use SetupAPI to install or uninstall an NDIS filter driver.

For an example of calling into `INetCfg` through code, see the Bindview Network Configuration Utility sample .

Specifying Filter Driver Binding Relationships

INF File Settings for Filter Drivers

Accessing Configuration Information for a Filter Driver

Specifying Filter Driver Binding Relationships

Article • 12/15/2021

In a network driver INF file, the **UpperRange** entry lists the possible upper bindings and the **LowerRange** entry lists the possible lower bindings. These entries can contain various system-defined values.

For filter drivers, you must set the value of the **UpperRange** and **LowerRange** entries to **noupper** and **nolower**, respectively. The following example illustrates these INF file entries for a filter driver.

```INF
HKR, Ndi\Interfaces,UpperRange,,"noupper"
HKR, Ndi\Interfaces,LowerRange,,"nolower"
```

In a filter driver, the **FilterMediaTypes** entry in the filter INF file defines the driver's bindings to other drivers. **FilterMediaTypes** specifies the media types that the filter driver services. For a list of possible media types, see the list of Microsoft-supplied **LowerRange** values in Specifying Binding Interfaces. The following example illustrates a **FilterMediaTypes** entry for a filter driver.

```INF
HKR, Ndi\Interfaces, FilterMediaTypes,,"ethernet"
```

When the computer loads a filter driver, the driver is inserted into all of the existing protocol-to-adapter bindings, depending on the media types that **FilterMediaTypes** lists.

INF File Settings for Filter Drivers

Article • 12/15/2021

The filter driver INF file settings specify the characteristics of the filter driver. For example, filter drivers can be modifying or monitoring and can be mandatory or optional. The INF file also specifies general configuration parameters and other information to associate the filter driver with particular miniport adapters. Filter drivers are identified by a unique filter identification GUID (FID GUID).

This section includes:

Configuring an INF File for a Monitoring Filter Driver

Configuring an INF File for a Modifying Filter Driver

Configuring an INF File for a Monitoring Filter Driver

Article • 05/30/2023

The following NDIS filter driver installation issues are associated with monitoring filter drivers:

- Set the **Class** INF file entry to **NetService** in the INF file. The following example shows a sample **Class** entry for the INF file.

  INF

  ```
  Class = NetService
  ```

- The *DDInstall* section in a filter driver INF file must have a **Characteristics** entry. The following example shows how you should define the **Characteristics** entry in your filter INF file.

  INF

  ```
  Characteristics=0x40000
  ```

  The 0x40000 value indicates that NCF_LW_FILTER (0x40000) is set. Filter drivers must not set the NCF_FILTER (0x400) flag. The values of the NCF_ *Xxx* flags are defined in *Netcfgx.h*. For more information about NCF_ *Xxx* flags, see DDInstall Section in a Network INF File.

- Set the **NetCfgInstanceId** INF file entry in the INF file, as the following example shows.

  INF

  ```
  NetCfgInstanceId="{5cbf81bf-5055-47cd-9055-a76b2b4e3697}"
  ```

  You can use the *Uuidgen.exe* tool to create the GUID for the **NetCfgInstanceId** entry.

- The *DDInstall* section of the INF file for a filter driver must include an **Addreg** directive for an **Ndi** key. The INF file must specify the **Service** entry under the **Ndi** key. The **ServiceBinary** entry in the *service-install* section of the INF file specifies the path to the binary for the filter driver. For more information, see Adding

Service-Related Values to the Ndi Key and DDInstall.Services Section in a Network INF File.

- The *DDInstall* section in a filter driver INF file must have **FilterType** and **FilterRunType** entries. To specify a monitoring filter, define the **FilterType** entry in your INF file, as the following example shows.

  INF

  ```
  HKR, Ndi,FilterType,0x00010001 ,0x00000001
  ```

  The **FilterType** value 0x00000001 indicates that the filter is a monitoring filter.

- Define the **FilterRunType** entry in your INF file, as the following example shows.

  INF

  ```
  HKR, Ndi,FilterRunType,0x00010001 ,0x00000002
  ```

  The 0x00000002 value in the preceding example indicates that the filter module is optional. To install a mandatory filter module, set the **FilterRunType** entry to 0x00000001. For more information, see Mandatory Filter Drivers.

  Note We highly recommend that a monitoring lightweight filter (LWF) driver should not be mandatory, unless it is to be used in a controlled environment where there will be no optional modifying LWF drivers. This is because a mandatory monitoring LWF driver can cause optional modifying LWF drivers to fail *FilterAttach*. A monitoring LWF driver is bound over every modifying filter and binding by design to facilitate monitoring of networking traffic at all levels. Consider the following scenario:

  - An instance of a mandatory monitoring LWF driver is installed over an optional modifying LWF driver.
  - The lower modifying optional LWF driver fails to attach to a lower component. This will cause the mandatory monitoring LWF driver's *FilterAttach* handler not to be called.
  - Because now an instance of a mandatory LWF driver is not loaded, NDIS will not bind any protocols (such as TCP/IP) to the interface or NIC, thus rendering the interface to be unusable.

- The following example shows how a filter driver INF file specifies the name of the service.

  INF

```
HKR, Ndi,Service,,"NdisMon"
```

In this example, "NdisMon" is the name of the driver's service as it is reported to NDIS. Note that the name of a filter driver's service can be different from the name of the binary for the driver, but typically they are the same.

- The following example shows how the filter INF file references the name of the filter driver's service when it adds that service.

  INF

  ```
  [Install.Services]
  AddService=NdisMon,,NdisMon_Service_Inst

  [NdisMon_Service_Inst]
  DisplayName     = %NdisMon_Desc%
  ServiceType     = 1 ;SERVICE_KERNEL_DRIVER
  StartType       = 1 ;SERVICE_SYSTEM_START
  ErrorControl    = 1 ;SERVICE_ERROR_NORMAL
  ServiceBinary   = %13%\ndisMon.sys
  LoadOrderGroup  = NDIS
  Description     = %NdisMon_Desc%
  AddReg          = Common.Params.Reg
  ```

- A filter INF file must specify at least the primary service name of the filter for the **CoServices** attribute, as the following example shows.

  INF

  ```
  HKR, Ndi,CoServices,0x00010000,"NdisMon"
  ```

  For more information about the **CoServices** attribute, see Adding Service-Related Values to the Ndi Key.

- The **FilterClass** value in the INF file for a filter driver determines its order in a stack of modifying filters. However, monitoring filter drivers do not define the **FilterClass** key. Instead the monitoring filter module that is installed first is closest to the miniport adapter.

- You must define the following entries in the monitoring filter driver INF file to control the driver bindings:

  INF

  ```
  HKR, Ndi\Interfaces,UpperRange,,"noupper"
  HKR, Ndi\Interfaces,LowerRange,,"nolower"
  ```

```
HKR, Ndi\Interfaces, FilterMediaTypes,,"ethernet"
```

For more information about controlling the driver bindings, see Specifying Filter Driver Binding Relationships.

- A monitoring filter INF file can specify common parameter definitions for the filter driver, parameters that are associated with a specific adapter, and parameters that are associated with a particular instance (filter module). The following example shows some common parameter definitions.

> ⊗ **Caution**
>
> Using **HKR AddReg** to put keys directly under the service state is a compliance violation. These keys need to be added under the Parameters key of the service to be compliant.

INF

```
[Common.Params.reg]

HKR, FilterDriverParams\DriverParam, ParamDesc, ,"Driverparam for
filter"
HKR, FilterDriverParams\DriverParam, default, ,"5"
HKR, FilterDriverParams\DriverParam, type,   ,"int"

HKR, FilterAdapterParams\AdapterParam, ParamDesc, ,"Adapterparam for
filter"
HKR, FilterAdapterParams\AdapterParam, default, ,"10"
HKR, FilterAdapterParams\AdapterParam, type,   ,"int"

HKR, FilterInstanceParams\InstanceParam, ParamDesc, ,"Instance param
for filter"
HKR, FilterInstanceParams\InstanceParam, default, ,"15"
HKR, FilterInstanceParams\InstanceParam, type,   ,"int"
```

Configuring an INF File for a Modifying Filter Driver

Article • 11/30/2022

The following NDIS filter driver installation issues are associated with modifying filter drivers. To create your own modifying filter driver INF file, you can also adapt the sample NDIS 6.0 filter driver.

- Set the **Class** INF file entry to **NetService** in the INF file. The following example shows a sample **Class** entry for the INF file.

  INF

  ```
  Class = NetService
  ```

- The *DDInstall* section in a filter driver INF file must have a **Characteristics** entry. The following example shows how you should define the **Characteristics** entry in your filter INF file.

  INF

  ```
  Characteristics=0x40000
  ```

  The 0x40000 value indicates that NCF_LW_FILTER (0x40000) is set. Filter drivers must not set the NCF_FILTER (0x400) flag. The values of the NCF_ *Xxx* flags are defined in *Netcfgx.h*. For more information about NCF_ *Xxx* flags, see DDInstall Section in a Network INF File.

- Set the **NetCfgInstanceId** INF file entry in the INF file, as the following example shows.

  INF

  ```
  NetCfgInstanceId="{5cbf81bd-5055-47cd-9055-a76b2b4e3697}"
  ```

  You can use the *Uuidgen.exe* tool to create the GUID for the **NetCfgInstanceId** entry.

- The *DDInstall* section of the INF file for a filter driver must include an **Addreg** directive for an **Ndi** key. The INF file must specify the **Service** entry under the **Ndi** key. The **ServiceBinary** entry in the *service-install* section of the INF file specifies the path to the binary for the filter driver. For more information, see Adding Service Related Values to the Ndi Key and DDInstall.Services Section in a Network INF File.

- The *DDInstall* section in a filter driver INF file must have **FilterType** and **FilterRunType** entries. To specify a modifying filter, define the **FilterType** entry in your INF file, as the following example shows.

  INF

  ```
  HKR, Ndi,FilterType,0x00010001 ,0x00000002
  ```

  The **FilterType** value 0x00000002 indicates that the filter is a modifying filter.

- Define the **FilterRunType** entry in your INF file, as the following example shows.

  INF

  ```
  HKR, Ndi,FilterRunType,0x00010001 ,0x00000001
  ```

  The 0x00000001 value in the preceding example indicates that the filter module is mandatory. To install an optional filter module, set the **FilterRunType** entry to 0x00000002. For more information, see Mandatory Filter Drivers.

- The following example shows how a modifying filter driver INF file specifies the name of the service.

  INF

  ```
  HKR, Ndi,Service,,"NdisLwf"
  ```

  In this example, NdisLwf is the name of the driver's service as it is reported to NDIS. Note that the name of a filter driver's service can be different from the name of the binary for the driver—but typically they are the same.

- The following example shows how the filter INF file references the name of the filter driver's service when it adds that service.

  INF

  ```
  [Install.Services]
  AddService=NdisLwf,,NdisLwf_Service_Inst;, common.EventLog

  [NdisLwf_Service_Inst]
  DisplayName     = %NdisLwf_Desc%
  ```

```
ServiceType      = 1 ;SERVICE_KERNEL_DRIVER
StartType        = 1 ;SERVICE_SYSTEM_START
ErrorControl     = 1 ;SERVICE_ERROR_NORMAL
ServiceBinary    = %13%\ndislwf.sys
LoadOrderGroup   = NDIS
Description      = %NdisLwf_Desc%
AddReg           = Common.Params.reg
```

- A filter INF file must specify at least the primary service name of the filter for the **CoServices** attribute, as the following example shows.

  INF

  ```
  HKR, Ndi,CoServices,0x00010000,"NdisLwf"
  ```

  For more information about the **CoServices** attribute, see Adding Service Related Values to the Ndi Key.

- The **FilterClass** value in the INF file for a filter driver determines its order in a stack of filters. Filter drivers must define the **FilterClass** key. The class of the driver can be one of the values in the following table.

Value	Description
scheduler	Packet scheduling filter service. This class of filter driver is the highest-level driver that can exist above encryption class filters in a driver stack. A packet scheduler detects the 802.1p priority classification that is given to packets by quality of service (QoS) signaling components and the scheduler sends those packets levels to underlying drivers according to their priority.
encryption	Encryption class filter drivers exist between scheduler and compression class filters.
compression	Compression class filter drivers exist between encryption and vpn class filters.
vpn	VPN class filter drivers exist between compression and load balance filter drivers.

Value	Description
loadbalance	Load balancing filter service. This class of filter driver exists between packet scheduling and failover drivers. A load balancing filter service balances its workload of packet transfers by distributing the workload over its set of underlying miniport adapters.
failover	Failover filter service. This class of filter driver exists between load balance and diagnostics drivers.
diagnostic	Diagnostic filter drivers exist below failover drivers in the stack.
custom	Filter drivers in custom class exist below diagnostic drivers.
provider_address	Provider address filter drivers exist below the in-box Hyper-V Network Virtualization ms_wnv filter and operate on provider address (PA) packets.

Note If multiple filter drivers have the same FilterClass, they will all be added to the layered stack of filter drivers. The system assigns a layering order to each modifying filter driver with the same FilterClass. In some cases, the system administrator can rearrange the relative order of filter drivers that have the same FilterClass.

The following example shows a sample **FilterClass** .

```INF
HKR, Ndi,FilterClass,, compression
```

- Only Hyper-V switch extension filter drivers are valid in the Hyper-V Extensible Switch. Hyper-V extensible switch filter drivers must define the FilterClass key with one of the values in the following table.

Value	Description

Value	Description
ms_switch_capture	Starting with NDIS 6.30, capture drivers monitor packet traffic in the Hyper-V extensible switch driver stack. This class of filter driver exists below custom drivers in the stack. For more information about this class of driver, see Capturing Extensions.
ms_switch_filter	Starting with NDIS 6.30, filtering drivers filter packet traffic and enforce port or switch policy for packet delivery through the extensible switch driver stack. This class of filter driver exists below **ms_switch_capture** drivers in the stack. For more information about this class of driver, see Filtering Extensions.
ms_switch_forward	Starting with NDIS 6.30, forwarding drivers filter perform the same functions as a filtering driver. Forwarding drivers also forward packets to and from extensible switch ports. This class of filter driver exists below **ms_switch_filter** drivers in the stack. For more information about this class of driver, see Forwarding Extensions.

- You must define the following entries in the modifying filter driver INF file to control the driver bindings.

  INF

  ```
  HKR, Ndi\Interfaces,UpperRange,,"noupper"
  HKR, Ndi\Interfaces,LowerRange,,"nolower"
  HKR, Ndi\Interfaces, FilterMediaTypes,,"ethernet"
  ```

  For more information about controlling the driver bindings, see Specifying Filter Driver Binding Relationships.

- A modifying filter INF file can specify common parameter definitions for the driver and parameters that are associated with a specific adapter. The following example shows some common parameter definitions.

⊗ Caution

Using **HKR AddReg** to put keys directly under the service state is a compliance violation. These keys need to be added under the Parameters key of the service to be compliant.

INF

```
[Common.Params.reg]

HKR, FilterDriverParams\DriverParam,  ParamDesc, , "Driverparam for lwf"
HKR, FilterDriverParams\DriverParam,  default, , "5"
HKR, FilterDriverParams\DriverParam,  type,  , "int"

HKR, FilterAdapterParams\AdapterParam,  ParamDesc, , "Adapterparam for lwf"
HKR, FilterAdapterParams\AdapterParam,  default, , "10"
HKR, FilterAdapterParams\AdapterParam,  type,  , "int"
```

Accessing Configuration Information for a Filter Driver

Article • 12/15/2021

NDIS supports a set of functions that provide access to filter driver registry parameters. Filter drivers can access these parameters during the attach or restart operations or when they are processing a Plug and Play (PnP) notification. For more information about PnP notifications, see Filter Module PnP Event Notifications. For more information about attaching a filter module, see Attaching a Filter Module. For more information about restart operations, see Starting a Filter Module.

Filter drivers call the **NdisOpenConfigurationEx** function to access the registry settings. If a filter driver obtained the handle in the **NdisHandle** member of the **NDIS_CONFIGURATION_OBJECT** structure by calling the **NdisFRegisterFilterDriver** function, the **NdisOpenConfigurationEx** function provides a handle to the registry location where the filter driver's configuration parameters are stored. Filter drivers can use the configuration handle until they call the **NdisFDeregisterFilterDriver** function.

If a filter driver obtained the handle in **NdisHandle** from the *NdisFilterHandle* parameter of the *FilterAttach* function, **NdisOpenConfigurationEx** provides a handle to the registry location where a filter module's configuration parameters are stored. The filter driver can use the configuration handle until NDIS detaches the filter module and the *FilterDetach* function returns. If a monitoring filter driver specifies the NDIS_CONFIG_FLAG_FILTER_INSTANCE_CONFIGURATION flag in the **Flags** member of the **NDIS_CONFIGURATION_OBJECT** structure, the driver can access the filter module configuration for a specific filter module when there are multiple filter modules that are configured over the same miniport adapter. Modifying filter drivers must not use this flag.

After a driver is done accessing the configuration information, the driver must call the **NdisCloseConfiguration** function to release the configuration handle and related resources.

NDIS Intermediate Drivers Guide

Article • 03/14/2023

NDIS intermediate drivers interface between upper-level protocol drivers and miniport drivers. Some applications that might require an intermediate driver include:

- Media translation between an old transport driver and a miniport driver that manages a media type unknown to the transport driver.
- Data filtering for security or other purposes.
- Load Balancing Failover (LBFO) solutions.
- Monitoring and collecting of network data statistics.

Before attempting to write an intermediate driver, you should read about NDIS miniport and protocol drivers. For more information about NDIS miniport drivers, see NDIS Miniport Drivers. For more information about NDIS protocol drivers, see NDIS Protocol Drivers.

The following sections introduce intermediate drivers and describe how to create and install such drivers:

Roadmap for Developing NDIS Intermediate Drivers

Article • 03/14/2023

To create a Network Driver Interface Specification (NDIS) intermediate driver package, follow these steps:

- Step 1: Learn about Windows architecture and drivers.

  You must understand the fundamentals of how drivers work in Windows operating systems. Knowing the fundamentals will help you make appropriate design decisions and let you streamline your development process. For more information about driver fundamentals, see Concepts for all driver developers.

- Step 2: Learn about NDIS.

  For general information about NDIS and NDIS drivers, see the following topics:

  Windows Network Architecture and the OSI Model

  Network Driver Programming Considerations

  Driver Stack Management

  NET_BUFFER Architecture

- Step 3: Determine additional Windows driver design decisions.

  For more information about how to make additional Windows design decisions, see Creating Reliable Kernel-Mode Drivers, Programming Issues for 64-Bit Drivers, and Creating International INF Files.

- Step 4: Learn about the Windows driver build, test, and debug processes and tools.

  Building a driver differs from building a user-mode application. For more information about Windows driver build, debug, and test processes, driver signing, and Windows Hardware Lab Kit (HLK) testing, see Building, Debugging, and Testing Drivers. For more information about building, testing, verifying, and debugging tools, see Driver Development Tools.

- Step 5: Read the intermediate driver, miniport driver, and protocol driver introduction topics. Introduction to NDIS Intermediate Drivers Introduction to NDIS Miniport Drivers NDIS Protocol Drivers

- Step 6: Read the writing intermediate drivers section.

  Intermediate drivers use a combination of protocol driver and miniport driver interfaces in addition to some intermediate driver specific interfaces. As an option, you can also read the miniport driver and protocol driver design guides.

- Step 7: Review the NDIS intermediate driver sample in the Windows driver samples repository on GitHub.

- Step 8: Develop (or port), build, test, and debug your NDIS driver.

  See the porting guides if you are porting an existing driver:

  - Porting NDIS 5.x Drivers to NDIS 6.0
  - Porting NDIS 6.x Drivers to NDIS 6.20
  - Porting NDIS 6.x Drivers to NDIS 6.30

    For more information about iterative building, testing, and debugging, see Overview of Build, Debug, and Test Process. This process will help ensure that you build a driver that works.

- Step 9: Create a driver package for your driver.

  For more information about how to install drivers, see Providing a Driver Package. For more information about how to install an NDIS driver, see Components and Files Used for Network Component Installation and Notify Objects for Network Components.

- Step 10: Sign and distribute your driver.

  The final step is to sign (optional) and distribute the driver. If your driver meets the quality standards that are defined for the Windows Hardware Lab Kit (HLK), you can distribute it through the Microsoft Windows Update program. For more information about how to distribute a driver, see Get started with the hardware submission process.

These are the basic steps. Additional steps might be necessary based on the needs of your individual driver.

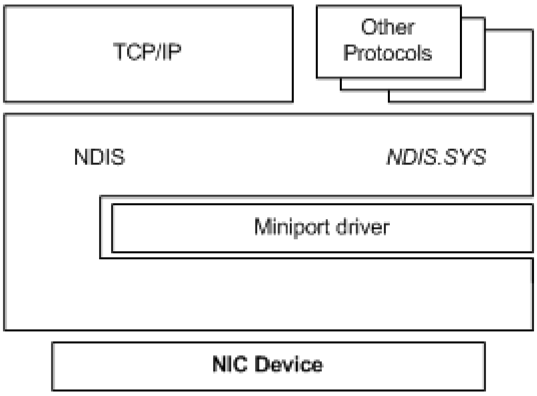
NDIS Intermediate Drivers Overview

Article • 03/14/2023

NDIS driver stacks must include miniport drivers and protocol drivers and can also include intermediate drivers. Because intermediate drivers are optional, you must understand the relationships between miniport drivers, protocol drivers, and NDIS before addressing intermediate drivers.

Miniport drivers control NIC devices and communicate with the lower edge of protocol drivers. Protocol drivers implement protocols, such as TCP/IP, and are above the miniport drivers in the driver stack. NDIS provides services to simplify development and maintenance of miniport drivers and protocol drivers.

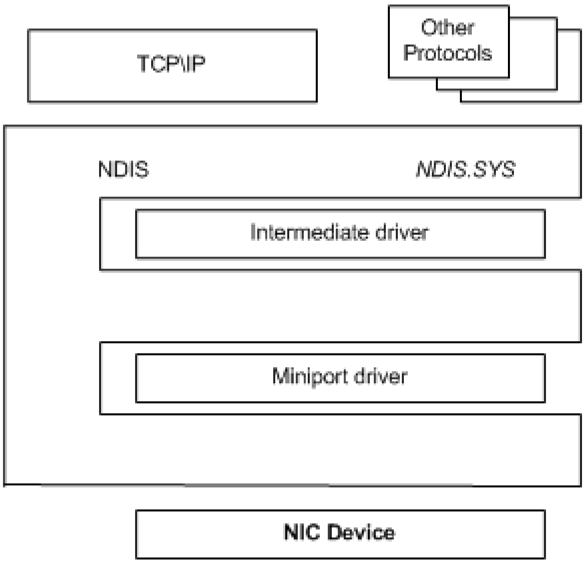
The relationships between miniport drivers, protocol drivers, and NDIS are illustrated in the following figure.



NDIS miniport drivers and protocol drivers are bound together through standard NDIS interfaces.

NDIS intermediate drivers include a protocol driver interface at their upper edge and a miniport driver interface at their lower edge. The intermediate driver's protocol interface allows it to load above a driver with a miniport driver interface. Therefore, intermediate drivers can load above miniport drivers or other intermediate drivers. The intermediate driver's miniport interface allows it to load below a driver with a protocol lower edge interface. Therefore, intermediate drivers can load below protocol drivers or below other intermediate drivers.

The relationships between miniport drivers, protocol drivers, intermediate drivers, and NDIS are illustrated in the following figure.

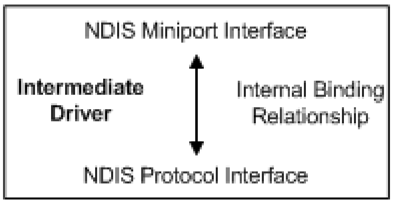


The intermediate driver miniport interface is called a virtual miniport. It is virtual in that it does not control a physical device directly. Instead, it relies on an underlying miniport driver to communicate with the physical device.

Bindings between the intermediate driver and other drivers are called external bindings. NDIS controls external bindings. The upper edge of the virtual miniport binds with the next-higher driver, which can be a protocol driver or another intermediate driver. The lower edge of the intermediate driver protocol binds to the next lower driver, which can be another intermediate driver or an underlying miniport driver.

The lower edge of the virtual miniport and the upper edge of the intermediate driver protocol do not require external bindings. Instead, the intermediate driver binds its virtual miniport and its protocol internally. These internal bindings, which are implementation specific, are not controlled by NDIS.

The following figure illustrates the internal bindings between the virtual miniport and the intermediate driver protocol.



There are two types of NDIS intermediate drivers: filter intermediate drivers and MUX intermediate drivers. The following topics describe these driver types:

NDIS Filter Intermediate Drivers

NDIS MUX Intermediate Drivers

NDIS Filter Intermediate Drivers

Article • 03/14/2023

Note Filter intermediate drivers are not supported in NDIS 6.0 and later. You should use the NDIS filter driver interface instead. For more information about NDIS filter drivers, see NDIS Filter Drivers.

In NDIS 5.*x*, an *NDIS filter intermediate driver* exposes one virtual miniport for each underlying miniport driver that is bound to the intermediate driver's lower (protocol) edge.

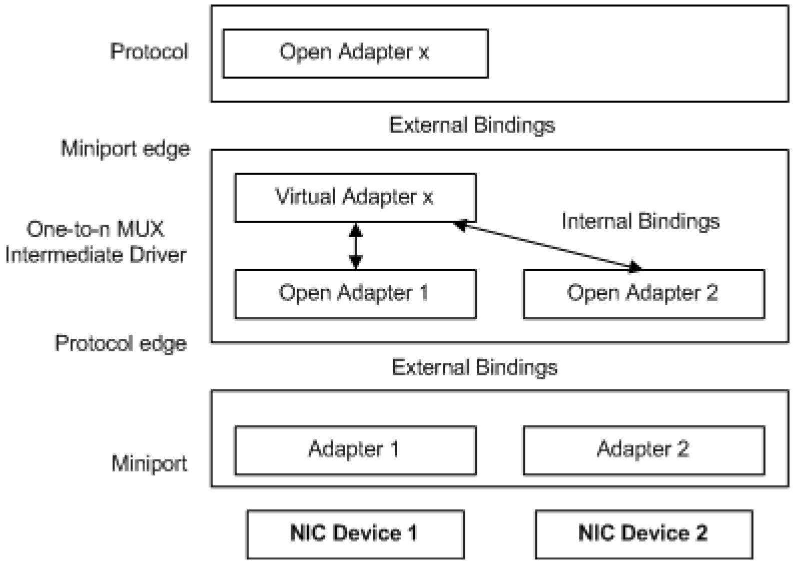
NDIS MUX Intermediate Drivers

Article • 03/14/2023

The number of virtual miniports that are exposed by a MUX intermediate driver can be different than the number of lower physical adapters that are bound to the driver. A MUX intermediate driver exposes virtual miniports in a one-to-*n*, *n*-to-one, or even an *m*-to-*n* relationship with underlying adapters. This variety results in complicated internal bindings and data paths.

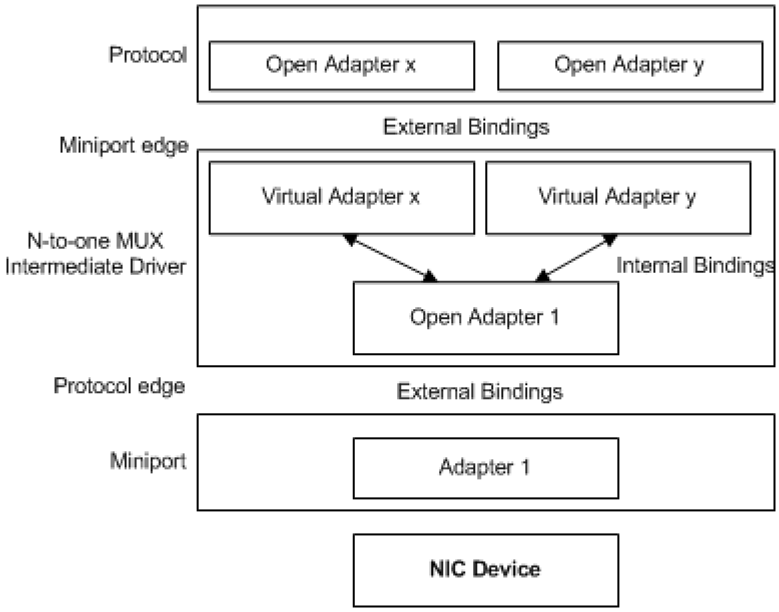
In a one-to-*n* configuration, a single MUX intermediate driver can bind to many physical adapters below. Transport drivers bind to the virtual miniport of the MUX intermediate driver in the same way that they bind to nonvirtual miniports. The MUX intermediate driver repackages and passes down all requests and send packets that are submitted to the intermediate driver for a specific connection. A Load Balancing Failover (LBFO) driver is an example of this type of MUX intermediate driver.

The following figure illustrates a one-to-*n* MUX intermediate driver configuration.



In an *n*-to-one configuration, a MUX intermediate driver can expose many virtual miniports for a single physical adapter below. Overlying protocol drivers bind to these virtual miniports of the MUX intermediate driver in the same way that they bind to nonvirtual miniports. The MUX intermediate driver handles requests and sends that are submitted to the driver for specific connections at each virtual miniport. The driver repackages and transfers these requests and sends down to the NDIS miniport driver for the bound physical adapter.

The following figure illustrates an *n*-to-one MUX intermediate driver configuration.



MUX intermediate drivers require a notify object DLL. When a MUX intermediate driver is initialized, its bindings are determined by the configuration established by its notify object DLL. For more information about installing MUX intermediate drivers, see MUX Intermediate Driver Installation.

The following list describes examples of *n*-to-one MUX intermediate drivers:

- 802 and proprietary virtual LANs are technologies that could be implemented as intermediate drivers similar to the MUX sample.
- The MUX Intermediate Driver Sample is an n-to-one MUX intermediate driver. MUX creates multiple virtual miniports layered above a single underlying miniport adapter.

Getting started writing NDIS Intermediate Drivers

Article • 03/14/2023

Unless noted otherwise, NDIS intermediate drivers provide the same services as miniport drivers and protocol drivers. The intermediate driver's miniport edge provides miniport driver services and the protocol edge provides protocol driver services. (For more information, see Writing NDIS Miniport Drivers and Writing NDIS Protocol Drivers.)The initialization for NDIS 6.0 and later intermediate drivers is different from the initialization for legacy intermediate drivers. Also, NDIS 6.0 and later drivers can register as a combined miniport-intermediate driver.

The following topics provide more information about intermediate driver initialization:

- Initializing an Intermediate Driver
- Initializing a Miniport-Intermediate Driver
- Unloading an Intermediate Driver
- Initializing a Virtual Miniport
- Halting a Virtual Miniport

Initializing an Intermediate Driver

Article • 12/15/2021

An NDIS intermediate driver registers its *MiniportXxx* functions and its *ProtocolXxx* functions in the context of its DriverEntry routine. To register its *MiniportXxx* functions, an intermediate driver must call the NdisMRegisterMiniportDriver function with the NDIS_INTERMEDIATE_DRIVER flag set. This flag is in the **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** structure that the driver passes at *MiniportDriverCharacteristics*. To register its *ProtocolXxx* functions, an intermediate driver must call the NdisRegisterProtocolDriver function.

DriverEntry returns STATUS_SUCCESS, or its equivalent NDIS_STATUS_SUCCESS, if the driver registered as an NDIS intermediate driver successfully. If DriverEntry fails initialization by propagating an error status that was returned by an **NdisXxx** function or by a kernel-mode support routine, the driver will not remain loaded. **DriverEntry** must execute synchronously; that is, it cannot return STATUS_PENDING or its equivalent NDIS_STATUS_PENDING.

To register the intermediate driver with NDIS, the DriverEntry routine must, at a minimum:

- Call the NdisMRegisterMiniportDriver function with the NDIS_INTERMEDIATE_DRIVER flag set to register the driver's *MiniportXxx* functions.
- Call the NdisRegisterProtocolDriver function to register the driver's *ProtocolXxx* functions if the driver subsequently binds itself to an underlying NDIS driver.
- Call the NdisIMAssociateMiniport function to inform NDIS about the association between the driver's miniport upper edge and protocol lower edge.

If an error occurs in **DriverEntry** after **NdisMRegisterMiniportDriver** returns successfully, the driver must call the NdisMDeregisterMiniportDriver function before **DriverEntry** returns. If **DriverEntry** succeeds, the driver must call **NdisMDeregisterMiniportDriver** from its MiniportDriverUnload function.

Intermediate drivers share most of the **DriverEntry** requirements of protocol drivers and miniport drivers.

The initialization of an intermediate driver's virtual miniport occurs when the driver calls the NdisIMInitializeDeviceInstanceEx function from its ProtocolBindAdapterEx function.

NDIS calls the *ProtocolBindAdapterEx* function after all underlying miniport drivers have initialized.

In effect, the **DriverEntry** function of an NDIS intermediate driver can ignore the *RegistryPath* pointer after passing it to **NdisMRegisterMiniportDriver**. Such a driver can also ignore the *DriverObject* pointer after passing it to **NdisMRegisterMiniportDriver**. However, the driver should save the miniport driver handle value that is returned by **NdisMRegisterMiniportDriver** at *NdisMiniportDriverHandle* and the protocol handle value that is returned by **NdisRegisterProtocolDriver** at *NdisProtocolHandle* for subsequent calls to **NdisXxx** functions. The intermediate driver's *ProtocolBindAdapterEx* function binds the driver to each underlying miniport driver before its *MiniportInitializeEx* function is called to initialize the intermediate driver's virtual miniport. Still higher level protocol drivers subsequently bind themselves to the virtual miniport that it creates. This strategy enables an NDIS intermediate driver to allocate resources at the creation of the virtual miniport according to the features of the underlying miniport driver to which it is bound.

Initializing a Miniport-Intermediate Driver

Article • 12/15/2021

A miniport-intermediate driver combines a miniport driver for a virtual device, a protocol driver, and a miniport driver for a physical device. A miniport-intermediate driver functions similarly to an intermediate driver layered over a miniport driver. Such a driver allows an intermediate driver to communicate directly with an underlying miniport driver without incurring the performance penalties that might result with two separate drivers.

To register its physical miniport driver, a miniport-intermediate driver calls the NdisMRegisterMiniportDriver function with appropriate parameters just as for any miniport driver. To register its virtual miniport, the driver calls **NdisMRegisterMiniportDriver** again, but with the NDIS_INTERMEDIATE_DRIVER flag set in the structure at *MiniportDriverCharacteristics* .

For each virtual or physical device instance of a miniport-intermediate driver, if the **IMMiniport** registry key is set to **DWORD:0x0000001**, NDIS calls the *MiniportInitializeEx* function that the driver registered for the virtual device. Otherwise, NDIS calls the driver's *MiniportInitializeEx* function that the driver registered for the physical device.

Unloading an Intermediate Driver

Article • 12/15/2021

NDIS calls the *MiniportDriverUnload* function to unload an intermediate driver. Intermediate drivers must perform the same operations in *MiniportDriverUnload* as other miniport drivers. In addition to calling the **NdisMDeregisterMiniportDriver** function, an intermediate driver also calls **NdisDeregisterProtocolDriver**. *MiniportDriverUnload* should also perform any necessary cleanup operations, such as deallocating any protocol driver resources.

To perform cleanup operations before a intermediate driver is uninstalled, an intermediate driver can register a *ProtocolUninstall* function. For example, the protocol lower edge of an intermediate driver might require a *ProtocolUninstall* function. The intermediate driver can release its protocol edge resources in *ProtocolUninstall* before NDIS calls its *MiniportDriverUnload* function.

A miniport-intermediate driver calls **NdisMDeregisterMiniportDriver** twice, once for its physical device interface, and again for its virtual device interface.

Initializing a Virtual Miniport

Article • 04/29/2024

To initiate the initialization of a virtual miniport, an intermediate driver calls the **NdisIMInitializeDeviceInstanceEx** function. The intermediate driver usually makes this call from its *ProtocolBindAdapterEx* function. After the intermediate driver calls **NdisIMInitializeDeviceInstanceEx** and the Plug and Play manager requests NDIS to start the virtual device, NDIS calls the driver's *MiniportInitializeEx* function.

The call to *MiniportInitializeEx* can be in the context of **NdisIMInitializeDeviceInstanceEx** if the Plug and Play manager starts the virtual device before **NdisIMInitializeDeviceInstanceEx** returns. If the intermediate driver provides more than one virtual miniport, the driver must call **NdisIMInitializeDeviceInstanceEx** for each virtual miniport that it makes available.

NDIS passes initialization parameters to *MiniportInitializeEx* in an **NDIS_MINIPORT_INIT_PARAMETERS** structure at *MiniportInitParameters* . The **IMDeviceInstanceContext** member of the structure specifies a pointer to the context area for a virtual device. The driver passed this pointer to the **NdisIMInitializeDeviceInstanceEx** function at the *DeviceContext* parameter.

In *MiniportInitializeEx*, the intermediate driver performs the operations required to initialize a virtual miniport. This initialization is similar to the initialization of any other miniport adapter.

Halting a Virtual Miniport

Article • 12/15/2021

If an NDIS intermediate driver calls the **NdisIMDeinitializeDeviceInstance** function, NDIS calls the *MiniportHaltEx* function for the affected virtual miniport. An intermediate driver usually calls **NdisIMDeInitializeDeviceInstance** from its *ProtocolUnbindAdapterEx* function.

NDIS sets the *HaltAction* parameter to **NdisHaltDeviceInstanceDeInitialized** to indicate that NDIS is halting the adapter in response to an intermediate driver's call to the **NdisIMDeInitializeDeviceInstance** function.

The intermediate driver's *MiniportHaltEx* function must release all driver-allocated resources that are associated with a virtual miniport.

Intermediate Driver Design Concepts

Article • 12/15/2021

This section provides some basic information to help you start writing an NDIS intermediate driver. To write an NDIS intermediate driver, you must understand the NDIS miniport driver and protocol driver operations and functions.

The MUX intermediate driver sample in the Microsoft Windows Driver Kit (WDK) provides a basic example of an *n*-to-one MUX intermediate driver that you can adapt to your specific needs.

The virtual miniport of an NDIS intermediate driver must be deserialized. *Deserialized drivers* serialize the operation of their own *MiniportXxx* functions and queue internally all incoming send network data instead of relying on NDIS to perform these operations. This action results in significantly better full-duplex performance, if the driver's critical sections (code that can be executed by only one thread at a time) are kept small. For more information about deserialized drivers, see Deserialized NDIS Miniport Drivers.

An NDIS intermediate driver can support only connectionless communication at its virtual miniport. At its protocol interface, however, an NDIS intermediate driver can support either connectionless communication or connection-oriented communication. For more information about connection-oriented communication, see Connection-Oriented NDIS.

An intermediate driver is typically layered above one or more NDIS miniport drivers and below a transport driver. Intermediate drivers can also be layered with other intermediate drivers.

The following topics provide additional information about writing NDIS intermediate drivers:

Intermediate Driver DriverEntry Function

Dynamic Binding in an Intermediate Driver

Intermediate Driver Query and Set Operations

Intermediate Driver Network Data Management

Receiving Data in an Intermediate Driver

Transmitting Network Data Through an Intermediate Driver

Handling PnP Events and Power Management Events in an Intermediate Driver

Intermediate Driver Reset Operations

Status Indications in an Intermediate Driver

Intermediate Driver DriverEntry Function

Article • 12/15/2021

An intermediate driver's initial required entry point must be explicitly named **DriverEntry** so that the loader can properly identify it. All other exported driver functions, which are described in this section as *MiniportXxx* and *ProtocolXxx*, can have any vendor-specified name because they are passed as addresses to NDIS.

In an intermediate driver, **DriverEntry** must at a minimum:

1. Call **NdisMRegisterMiniportDriver** and save the handle that is returned in the *NdisMiniportDriverHandle* parameter.

2. Call **NdisRegisterProtocolDriver** to register the driver's *ProtocolXxx* functions if the driver subsequently binds itself to an underlying NDIS driver.

3. Call **NdisIMAssociateMiniport** to inform NDIS about the association between the driver's miniport upper edge and protocol lower edge.

An intermediate driver must register a *MiniportDriverUnload* unload handler. This unload handler is called when the system unloads the intermediate driver. If **DriverEntry** fails, this unload handler is not called; instead, the driver is simply unloaded. For more information about the unload handler, see Unloading an Intermediate Driver.

The unload handler should call **NdisDeregisterProtocolDriver** to deregister the protocol portion of the intermediate driver. The unload handler should also perform any necessary cleanup operations, such as reallocating resources used by the protocol portion of the driver.

Note that an unload handler differs from a *MiniportHaltEx* function: the unload handler has a more global scope, and the scope of the *MiniportHaltEx* function is restricted to a particular miniport adapter. The intermediate driver should clean up state information and reallocate resources when each underlying miniport driver that is bound to it is halted. For information about handling the halt operation for virtual miniports, see Halting a Virtual Miniport.

ProtocolUninstall is an optional unload handler. Register an entry point for this function in the *ProtocolCharacteristics* structure that you pass to **NdisRegisterProtocolDriver**. NDIS calls *ProtocolUninstall* in response to a user request to uninstall an intermediate driver. NDIS calls *ProtocolUnbindAdapterEx* once for each bound adapter, and then NDIS calls *ProtocolUninstall*. This handler is called before the system actually unloads the driver. This timing provides a chance to release any device objects or other resources that might otherwise prevent the system from calling the unload handler that is registered with **NdisMRegisterMiniportDriver** and unloading the driver.

DriverEntry can initialize spin locks to protect any globally-shared resources that the intermediate driver allocates, such as state variables, structures, and memory areas. The driver uses these resources to track connections and to track sends in progress or driver-allocated queues.

If **DriverEntry** fails to allocate any resources that the driver needs to carry out network I/O operations, it should release any previously allocated resources and return an appropriate error status.

The following topics further describe how to register intermediate drivers:

Registering as an NDIS Intermediate Driver

Registering an Intermediate Driver as a Miniport Driver

Registering an Intermediate Driver as a Protocol Driver

Registering as an NDIS Intermediate Driver

Article • 03/14/2023

An NDIS intermediate driver must register its *MiniportXxx* functions and its *ProtocolXxx* functions with NDIS in the context of its **DriverEntry** function. To register its *MiniportXxx* functions, an intermediate driver must call **NdisMRegisterMiniportDriver** with the NDIS_INTERMEDIATE_DRIVER flag set. This flag is in the **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** structure that the driver passes at *MiniportDriverCharacteristics* . This call exports the intermediate driver's *MiniportXxx* functions. For more information about registering *MiniportXxx* functions, see Registering an Intermediate Driver as a Miniport Driver.

Note that the intermediate driver controls when its virtual miniports are initialized, and thus, when the driver is ready to accept sends and requests on an adapter. NDIS calls the intermediate driver's *MiniportInitializeEx* function after the Plug and Play (PnP) manager has started the virtual miniport device and after the intermediate driver has called **NdisIMInitializeDeviceInstanceEx** for that device. The call to *MiniportInitializeEx* can happen at a later time and therefore is not necessarily within the context of the call to **NdisIMInitializeDeviceInstanceEx**. If the intermediate driver exports more than one virtual miniport, the driver must call **NdisIMInitializeDeviceInstanceEx** for each virtual miniport that it makes available for network requests.

To register its *ProtocolXxx* functions, an intermediate driver must call the **NdisRegisterProtocolDriver** function. For more information about registering *ProtocolXxx* functions, see Registering an Intermediate Driver as a Protocol Driver.

Registering an Intermediate Driver as a Miniport Driver

Article • 12/15/2021

An intermediate driver calls NdisMRegisterMiniportDriver to export its *MiniportXxx* functions. The *NdisMiniportDriverHandle* that is returned by **NdisMRegisterMiniportDriver** must be retained by the intermediate driver and input to NDIS when the driver calls NdisIMInitializeDeviceInstanceEx.

The intermediate driver must:

1. Zero-initialize an NDIS_MINIPORT_DRIVER_CHARACTERISTICS structure with NdisZeroMemory.

2. Store the addresses of the mandatory *MiniportXxx* functions, as well as any optional *MiniportXxx* functions that the driver exports.

An intermediate driver that supports NDIS 6.0 features must register as a version 6.0 miniport driver. For more information about specifying miniport driver version numbers, see NDIS_MINIPORT_DRIVER_CHARACTERISTICS.

You must set the following entries in *MiniportCharacteristics* to a valid *MiniportXxx* function address unless the function is optional and is not exported. If the driver does not export the function, set the address to **NULL**.

SetOptionsHandler
MiniportSetOptions is an optional function. NDIS calls *MiniportSetOptions* so the intermediate driver can specify optional handlers.

InitializeHandlerEx
NDIS calls *MiniportInitializeEx* as a result of the intermediate driver calling **NdisIMInitializeDeviceInstanceEx** to initialize its miniport adapter operations for the virtual miniport being initialized.

HaltHandlerEx
MiniportHaltEx is a required function. NDIS calls *MiniportHaltEx* if the virtual miniport device that the intermediate driver exposed is disabled or stopped, or if the intermediate driver called NdisIMDeInitializeDeviceInstance to initiate its removal.

UnloadHandler
MiniportDriverUnload is a required function. NDIS calls *MiniportDriverUnload* to unload the intermediate driver.

PauseHandler
MiniportPause is a required function. NDIS calls *MiniportPause* to stop the flow of network data through a specified virtual miniport of the intermediate driver.

RestartHandler
MiniportRestart is a required function. NDIS calls *MiniportRestart* to restart the flow of network data through a specified virtual miniport of the intermediate driver.

OidRequestHandler
MiniportOidRequest receives OID_*XXX* requests originating from an overlying driver that has called **NdisOidRequest** or from NDIS. The intermediate driver might handle a request or pass it on to the underlying miniport driver.

SendNetBufferListsHandler
MiniportSendNetBufferLists receives an array of one or more pointers to **NET_BUFFER_LIST** structures that specify network data for transmission over the network. Every intermediate driver should supply a *MiniportSendNetBufferLists* function. For more information, see Transmitting Network Data Through an Intermediate Driver.

ReturnNetBufferListsHandler
MiniportReturnNetBufferLists receives a returned **NET_BUFFER_LIST** structure that it previously indicated to a higher-level driver by calling **NdisMIndicateReceiveNetBufferLists**. The call to **NdisMIndicateReceiveNetBufferLists** relinquishes control of the resources indicated to the higher-level driver. After the higher-level driver consumes each indication, the intermediate driver allocated NET_BUFFER_LIST structure and the resources it describes are returned to the *MiniportReturnNetBufferLists* function.

CancelSendHandler
MiniportCancelSend is a required function. NDIS calls *MiniportCancelSend* to cancel a send request.

CheckForHangHandler
MiniportCheckForHangEx is not required for intermediate drivers, so they should set this entry point to **NULL**.

ResetHandlerEx
MiniportResetEx is not required for intermediate drivers, so they should set this entry point to **NULL**.

DevicePnPEventNotifyHandler
The entry point for the *MiniportDevicePnPEventNotify* function.

ShutdownHandlerEx
MiniportShutdownEx is a required function. *MiniportShutdownEx* restores the virtual miniport to its initial state (before the intermediate driver's **DriverEntry** routine runs).

CancelOidRequestHandler
MiniportCancelOidRequest is a required function. NDIS calls *MiniportCancelOidRequest* to cancel an OID request.

An intermediate driver might require other *MiniportXxx* functions that are implementation specific. For information about registering optional, see Configuring Optional Miniport Driver Services.

Certain miniport driver handler functions are never supplied by an intermediate driver. Reasons for this include: such drivers do not manage interrupting devices, or such drivers do not allocate buffers at raised IRQL.

Note Intermediate drivers must include pause and restart functionality. Include support for pause and restart of virtual miniports, if needed, when NDIS pauses an underlying driver stack. For more information about pause and restart, see Driver Stack Management.

Registering an Intermediate Driver as a Protocol

Article • 12/15/2021

An intermediate driver registers its *ProtocolXxx* functions with NDIS in the context of its **DriverEntry** function by calling **NdisRegisterProtocolDriver**.

Registering an intermediate driver as a protocol is nearly identical to registering as a protocol driver. For more information, see Initializing a Protocol Driver.

An intermediate driver with a connection-oriented lower edge must register as a connection-oriented client. A connection-oriented client uses the call-set-up and tear-down services of a call manager or integrated miniport call manager (MCM). A connection-oriented client also uses the send and receive capabilities of a connection-oriented miniport driver or an MCM to send and receive data. For more information, see Connection-Oriented Operations Performed by Clients.

An intermediate driver might require other *ProtocolXxx* functions that are implementation specific. For information about registering optional *ProtocolXxx* functions, see Configuring Optional Protocol Driver Services.

Dynamic Binding in an Intermediate Driver

Article • 12/15/2021

An intermediate driver must support dynamic binding to underlying miniport adapters by providing both a *ProtocolBindAdapterEx* and a *ProtocolUnbindAdapterEx* function.

When a miniport adapter becomes available, NDIS calls the *ProtocolBindAdapterEx* function of any intermediate driver that can bind to that miniport adapter. As part of the binding operation, the intermediate driver should initialize a virtual miniport that is associated with that miniport adapter. When a miniport adapter is removed, NDIS calls the *ProtocolUnbindAdapterEx* function of any intermediate driver that is bound to that miniport adapter.

The following topics contain additional information about dynamic binding operations in intermediate drivers:

Intermediate Driver Binding Operations

Opening an Adapter Underlying an Intermediate Driver

Initializing Virtual Miniports

Intermediate Driver Unbinding Operations

Intermediate Driver Binding Operations

Article • 12/15/2021

When a miniport adapter becomes available, NDIS calls the *ProtocolBindAdapterEx* function of any intermediate driver that can bind to that miniport adapter.

An intermediate driver must provide the protocol binding operations documented in Binding to an Adapter.

Binding-time actions include allocating and initializing an adapter-specific context area for the binding, initializing any virtual miniports, and calling **NdisOpenAdapterEx** to bind to the adapter.

Intermediate drivers are not required to allocate separate **NET_BUFFER_LIST** structure pools for each binding. Intermediate drivers are required to allocate NET_BUFFER_LIST structure pools only if the drivers design requires it to allocate its own structures. Otherwise, the driver can just pass on the structures that it receives from other drivers. Such drivers should allocate different pools for send and receive.

For information about the requirements to allocate and manage network data, see Intermediate Driver Network Data Management.

Opening an Adapter Underlying an Intermediate Driver

Article • 12/15/2021

Opening an adapter underlying an intermediate driver is the same as opening an underlying adapter in a protocol driver. For more information about opening an underlying adapter in an intermediate driver, see Binding to an Adapter.

Initializing Virtual Miniports

Article • 12/15/2021

An intermediate driver initializes its virtual miniports after it has successfully opened an underlying miniport adapter and is ready to accept requests and sends on its virtual miniports. An intermediate driver calls **NdisIMInitializeDeviceInstanceEx** from its *ProtocolBindAdapterEx* function one or more times to request initialization of one or more virtual miniports.

Note An intermediate driver is not required to call **NdisIMInitializeDeviceInstanceEx** when it opens an underlying miniport adapter. There does not have to be a one-to-one relationship between virtual miniports and open adapters.

Set the *DriverInstance* parameter of **NdisIMInitializeDeviceInstanceEx** to the device name for the virtual miniport being initialized. The intermediate driver obtains the device name from the **UpperBindings** registry key.

For an *n*-to-one MUX intermediate driver that layers multiple virtual miniports over a single physical NIC, there must be a device name for every virtual miniport. The MUX intermediate driver requires a notify object that maintains the list of virtual miniport device names. The recommended location for the list is the **UpperBindings** registry key. In this case, the **UpperBindings** registry key is a MULTI_SZ entry that contains the list of device names. The MUX intermediate driver calls **NdisIMInitializeDeviceInstanceEx** once for each device name that is specified in the device name list.

Calling **NdisIMInitializeDeviceInstanceEx** results in a call to the intermediate driver's *MiniportInitializeEx* function to perform the initialization of the specified virtual miniport, provided that NDIS receives an IRP_MN_START_DEVICE to start the device. If NDIS does not receive such an IRP, NDIS will not call the intermediate driver's *MiniportInitializeEx* function. The call to *MiniportInitializeEx* can happen at a later time and therefore is not necessarily within the context of the call to **NdisIMInitializeDeviceInstanceEx**. If NDIS never calls *MiniportInitializeEx* for the virtual miniport referenced in a call to **NdisIMInitializeDeviceInstanceEx**, and the intermediate driver no longer requires the virtual miniport, the intermediate driver should call **NdisIMCancelInitializeDeviceInstance** to cancel the initialization of the virtual miniport. For example, suppose that an intermediate driver creates a virtual miniport in response to a successful binding to an underlying miniport. If that binding is removed before NDIS calls *MiniportInitializeEx*, the intermediate driver should call **NdisIMCancelInitializeDeviceInstance** to cancel the initialization of the miniport.

MiniportInitializeEx must allocate and initialize a virtual-miniport-specific context area. For more information about specifying the context area, see Initializing a Virtual Miniport.

An intermediate driver must operate as a deserialized driver. For more information about deserialized drivers, see Deserialized NDIS Miniport Drivers.

An intermediate driver should verify that the state information it maintains is properly initialized. If the driver requires send-related resources--for example, new **NET_BUFFER_LIST** structures for network data that *MiniportSendNetBufferLists* will transmit to the next lower layer--the NET_BUFFER_LIST structure pool can be allocated at this time.

Intermediate Driver Unbinding Operations

Article • 12/15/2021

An intermediate driver unbinds from an underlying miniport driver by calling **NdisCloseAdapterEx** from its *ProtocolUnbindAdapterEx* function. NDIS calls *ProtocolUnbindAdapterEx* if the underlying miniport adapter is no longer available.

An intermediate driver's *ProtocolUnbindAdapterEx* function might be called when the driver has an outstanding call to **NdisIMInitializeDeviceInstanceEx**. This situation occurs when NDIS has not yet called *MiniportInitializeEx* to initialize the corresponding virtual miniports. In this case, the intermediate driver must call **NdisIMCancelInitializeDeviceInstance** to attempt to cancel the initialization of these virtual miniports.

If the binding that is being closed is mapped to a device exported by the intermediate driver, and if that device was initialized by calling **NdisIMInitializeDeviceInstanceEx**, the intermediate driver can call **NdisIMDeInitializeDeviceInstance** to close the device. The result is that the intermediate driver's virtual miniport becomes no longer available for sends or requests made by higher-level drivers.

If an NDIS intermediate driver calls the **NdisIMDeInitializeDeviceInstance** function, NDIS calls the *MiniportHaltEx* function for the affected virtual miniport. For information about handling the halt operation for virtual miniports, see Halting a Virtual Miniport.

After an intermediate driver calls **NdisCloseAdapterEx**, it should fail any send requests for that binding with an appropriate error status.

For additional information about intermediate driver unbinding operations, see Unbinding from an Adapter.

Intermediate Driver Query and Set Operations

Article • 12/15/2021

After it has successfully bound to an underlying miniport adapter and initialized its virtual miniports, an intermediate driver queries the operating characteristics of the underlying miniport adapter and sets its own internal state. If appropriate, the intermediate driver also negotiates such parameters as lookahead buffer size for the binding with the underlying miniport adapter. Most of the attributes that are associated with an underlying miniport adapter are passed to the intermediate driver at the *BindParameters* parameter of the *ProtocolBindAdapterEx* function. Intermediate drivers should use the values that are passed to *ProtocolBindAdapterEx*, if possible, instead of issuing OID queries. However, an intermediate driver with a connectionless lower edge can issue OID queries by calling **NdisOidRequest**. An intermediate driver with a connection-oriented lower edge can issue OID queries by calling **NdisCoOidRequest**.

An intermediate driver can also receive query and set requests from higher level drivers through its *MiniportOidRequest* function. The driver can either respond to those requests or pass them down to the underlying driver. How an intermediate driver responds to queries and sets depends on the implementation.

Note The behavior of intermediate drivers can also be affected by the power state of the virtual miniport and the underlying miniport driver. To learn more about the effects of the power state on query and set operations, see Handling a Set Power Request.

The Network Reference section contains information about all of the general, connection-oriented, nonmedia-specific OIDs and about required media-specific OIDs of interest to intermediate driver developers.

The following topics provide additional information about issuing and responding to queries and sets in an intermediate driver:

Issuing Set and Query Requests from an Intermediate Driver

Responding to Sets and Queries in an Intermediate Driver

Issuing Set and Query Requests from an Intermediate Driver

Article • 12/15/2021

The protocol edge of an intermediate driver can issue set and query information requests to the underlying miniport driver. The virtual miniport edge of an intermediate driver can use the information obtained from the underlying driver to determine how to respond to set and query requests.

To cancel an OID request, call the **NdisCancelOidRequest** function.

For more information about responding to set and query requests, see Responding to Sets and Queries in an Intermediate Driver. For more information about issuing OID requests, see OID Request Operations in a Protocol Driver.

Responding to Sets and Queries in an Intermediate Driver

Article • 12/15/2021

Because an NDIS intermediate driver is bound to an overlying NDIS driver, it can also receive queries and sets from its *MiniportOidRequest* function. In some cases, the intermediate driver just passes such requests through to the underlying miniport driver. Otherwise, it can respond to these queries and sets as appropriate to the medium that it exports at its upper edge. Note that an intermediate driver must always pass through any OID_PNP_*Xxx* requests that it receives from an overlying NDIS driver to the underlying miniport driver. NDIS 6.0 intermediate drivers can also cancel OID requests.

To forward a request down to the underlying drivers, an NDIS intermediate driver calls **NdisAllocateCloneOidRequest** to allocate a cloned **NDIS_OID_REQUEST** structure. The driver calls the **NdisOidRequest** function to send the request. When the request is complete, the driver must call the **NdisFreeCloneOidRequest** function to free the NDIS_OID_REQUEST structure.

To cancel an OID request, call the **NdisCancelOidRequest** function.

Typically, the general OIDs that an intermediate driver receives are the same or similar to those that the intermediate driver sends to the underlying miniport driver. The medium-specific OIDs that an intermediate driver receives are the type of the medium that the overlying driver requires.

If an intermediate driver itself processes the setting of an OID rather than passing the set request to an underlying miniport, it should validate the value to be set. If the intermediate driver determines that the value to be set is out of bounds, it should fail the set request.

Note If an intermediate driver modifies the contents of TCP network data that it forwards down to an underlying miniport driver such that TCP offload functions cannot be performed on the network data, the intermediate driver should respond to OID_TCP_OFFLOAD_CURRENT_CONFIG queries with a status of NDIS_STATUS_NOT_SUPPORTED instead of passing the request down to the underlying miniport.

For additional information about responding to sets and queries in an intermediate driver, see Obtaining and Setting Miniport Driver Information and NDIS Support for WMI.

Intermediate Driver Network Data Management

Article • 12/15/2021

An intermediate driver receives **NET_BUFFER_LIST** structures with one or more associated MDLs from a higher-level driver to send over the network. The intermediate driver can pass the data through to the underlying driver by calling **NdisSendNetBufferLists** if the driver has a connectionless lower edge, or by calling **NdisCoSendNetBufferLists** if the driver has a connection-oriented lower edge. Alternatively, the intermediate driver can take some actions to modify either the contents of the chained buffers or the ordering or timing of the incoming data relative to other transmissions.

Depending on the purpose of the intermediate driver, such a driver can repackage buffers that are chained to incoming NET_BUFFER_LIST structures. For example, an intermediate driver repackages network data in the following circumstances:

- The intermediate driver receives a larger data buffer from an overlying protocol driver than can be sent in a single buffer over the underlying medium. Consequently, the intermediate driver must divide the incoming data into smaller buffers.

- The intermediate driver changes the length or content of the network data by compressing or encrypting the data before forwarding each send to the underlying driver.

For information about creating network data management, see Protocol Driver Buffer Management.

NDIS provides interfaces to clone and fragment **NET_BUFFER_LIST** structures. For more information about cloning and fragmenting structures, see Derived NET_BUFFER_LIST Structures.

NET_BUFFER_LIST structures can be allocated as needed, at driver initialization time, or in the *ProtocolBindAdapterEx* function. An intermediate driver developer can, if necessary and for performance reasons, allocate a number of structures at initialization time so that **ProtocolReceiveNetBufferLists** has preallocated resources into which to copy incoming data for indicating to a higher-level driver, and so that *MiniportSendNetBufferLists* has available **NET_BUFFER_LIST** structures (and possibly buffers) to pass incoming send network data on to the next lower driver.

If an intermediate driver copies send data or received data to a new buffer or buffers, and the length of actual data in the last buffer is less than the allocated length of the buffer, the intermediate driver can call **NdisAdjustMdlLength** to adjust the buffer to the actual length of the data.

An intermediate driver with a connectionless lower edge always receives incoming data from an underlying miniport adapter from its ProtocolReceiveNetBufferLists function.

An intermediate driver with a connection-oriented lower edge always receives incoming data from an underlying miniport adapter from its ProtocolCoReceiveNetBufferLists function.

Receiving Data in an Intermediate Driver with a Connectionless Lower Edge

Article • 12/15/2021

An intermediate driver with a connectionless lower edge must have a ProtocolReceiveNetBufferLists function to receive network data.

Underlying connectionless miniport drivers call the **NdisMIndicateReceiveNetBufferLists**, passing a linked list of one or more NET_BUFFER_LIST structures, relinquishing ownership of the indicated structures to higher level drivers. When the higher level drivers have consumed the data, they return the NET_BUFFER_LIST structures (and the resources they specify) to the miniport driver.

For more information about receiving data in an intermediate driver with a connectionless lower edge, see Protocol Driver Send and Receive Operations.

Receiving Data in an Intermediate Driver with a Connection-Oriented Lower Edge

Article • 12/15/2021

If an intermediate driver is layered above a connection-oriented miniport driver, NDIS then calls the intermediate driver's **ProtocolCoReceiveNetBufferLists** function to indicate received data.

An underlying connection-oriented miniport driver indicates network data by calling **NdisMCoIndicateReceiveNetBufferLists**, passing a linked list of one or more **NET_BUFFER_LIST** structures.

For more information about receiving data in an intermediate driver with a connection-oriented lower edge, see Connection-Oriented Operations.

Indicating Receive Network Data to Higher Level Drivers

Article • 12/15/2021

A connectionless intermediate driver indicates receive network data to the next higher driver by calling the NdisMIndicateReceiveNetBufferLists function. A connection-oriented intermediate driver indicates receive network data to the next higher driver by calling the NdisMCoIndicateReceiveNetBufferLists function.

Before indicating the receive network data, the driver processes the data, perhaps converting it to the format expected by a higher-level driver, and if required, copying relevant data into MDLs that are associated with an intermediate-driver-allocated NET_BUFFER structure.

Transmitting Network Data Through an Intermediate Driver

Article • 12/15/2021

As discussed in Registering an Intermediate Driver as a Miniport Driver, an intermediate driver must provide a *MiniportSendNetBufferLists* function when it registers with **NdisMRegisterMiniportDriver**. The *MiniportSendNetBufferLists* function can forward incoming **NET_BUFFER_LIST** structures by calling **NdisSendNetBufferLists** if the driver has a connectionless lower edge . *MiniportSendNetBufferLists* can send the list of NET_BUFFER_LIST structures it receives with **NdisSendNetBufferLists** without regard to the capabilities of the underlying miniport driver.

MiniportSendNetBufferLists receives a list of NET_BUFFER_LIST structures arranged in an order determined by an overlying caller of **NdisSendNetBufferLists**. In most cases, the intermediate driver should maintain this ordering as it passes an incoming array of NET_BUFFER_LIST structures on to the underlying miniport driver. An intermediate driver that modifies data in network data before passing them on to the underlying driver can reorder a list.

NDIS always preserves the ordering of **NET_BUFFER_LIST** structure pointers as passed as a linked list to **NdisSendNetBufferLists**. The underlying miniport driver also assumes that list that is passed in to its *MiniportSendNetBufferLists* function implies the network data should be transmitted in the same order.

Handling PnP Events and Power Management Events in an Intermediate Driver

Article • 12/15/2021

An intermediate driver must be able to handle Plug and Play (PnP) events and power management events. Specifically:

- An intermediate driver must set the NDIS_MINIPORT_ATTRIBUTES_NO_HALT_ON_SUSPEND flag in the **AttributeFlags** member of the **NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES** structure that is passed to **NdisMSetMiniportAttributes**. For more information, see Initializing as a Miniport.

- The virtual miniport of an intermediate driver must handle OID_PNP_*Xxx* requests.

- The protocol section of an intermediate driver should propagate appropriate OID_PNP_*Xxx* requests to the underlying miniport drivers. The virtual miniport of the intermediate driver should pass the underlying miniport driver's responses to these requests back to the protocol driver that originated the requests. The intermediate driver does not have to pass requests that are not required by design. For example, when there is not a one-to-one relationship between virtual miniports and underlying miniport adapters as in Load Balancing Failover (LBFO) applications.

- The protocol portion of an intermediate driver must supply a *ProtocolNetPnPEvent* function.

Intermediate driver protocol and miniport event handlers are not called in any particular order. Event handlers for intermediate drivers should be implemented accordingly.

This section includes the following topics:

Initializing Intermediate Drivers to Handle PnP and Power Management Events

Handling OID_PNP_Xxx Queries and Sets

Implementing a ProtocolNetPnPEvent Handler in an Intermediate Driver

Handling a Set Power Request

Initializing Intermediate Drivers to Handle PnP and Power Management Events

Article • 12/15/2021

To handle Plug and Play (PnP) and power management events, NDIS intermediate drivers must do the following:

- When NDIS calls the intermediate driver's *ProtocolBindAdapterEx* function, the *BindParameters* parameter points to an **NDIS_PM_CAPABILITIES** structure that contains the capabilities of the underlying miniport adapter. The power management capabilities are reported in one of the following members:

  - **PowerManagementCapabilities**

    For NDIS 6.0 and NDIS 6.1 intermediate drivers, this member contains the power management capabilities within an NDIS_PNP_CAPABILITIES structure. For more information about this structure, see OID_PNP_CAPABILITIES.

    Note For NDIS 6.20 and later intermediate drivers, the **PowerManagementCapabilities** member is set to **NULL** and the power management capabilities are reported in the **PowerManagementCapabilitiesEx** member.

  - **PowerManagementCapabilitiesEx**

    For NDIS 6.20 and later intermediate drivers, this member contains the power management capabilities within an **NDIS_PM_CAPABILITIES** structure.

    Note For NDIS 6.0 and NDIS 6.1 intermediate drivers, the **PowerManagementCapabilitiesEx** member is set to **NULL** and the power management capabilities are reported in the **PowerManagementCapabilities** member.

Note If the underlying miniport adapter does not support power management events, the **PowerManagementCapabilities** and **PowerManagementCapabilitiesEx** members are set to **NULL**.

- When NDIS calls MiniportInitializeEx for each virtual miniport supported by the NDIS intermediate driver, the driver reports its power management capabilities by calling **NdisMSetMiniportAttributes** in the following ways:

1. Depending on the version of the NDIS intermediate driver, the power management capabilities are reported in either the **PowerManagementCapabilities** member (for NDIS 6.0 and NDIS 6.1 intermediate drivers) or **PowerManagementCapabilitiesEx** member (for NDIS 6.20 and later intermediate drivers) of NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES. If either the **PowerManagementCapabilities** or **PowerManagementCapabilitiesEx** member of the NDIS_BIND_PARAMETERS structure is not **NULL**, the intermediate driver must do the following:

    - Save the original values of the **MinMagicPacketWakeUp**, **MinPatternWakeUp**, and **MinLinkChangeWakeUp** members of the **PowerManagementCapabilities**(NDIS 6.0 and NDIS 6.1) or **PowerManagementCapabilitiesEx**(NDIS 6.20 and later) members.

    - Disable the power management functionality by setting the **MinMagicPacketWakeUp**, **MinPatternWakeUp**, and **MinLinkChangeWakeUp** members to **NdisDeviceStateUnspecified**.

    - Pass the address of the modified NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES structure as the *MiniportAttributes* parameter in the call to NdisMSetMiniportAttributes.

2. An intermediate driver must set the NDIS_MINIPORT_ATTRIBUTES_NO_HALT_ON_SUSPEND flag in the **AttributeFlags** member of the NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES structure. The driver must pass the address of this structure as the *MiniportAttributes* parameter in the call to NdisMSetMiniportAttributes.

For more information about the initialization requirements of NDIS intermediate drivers, see Initializing Virtual Miniports.

Handling OID_PNP_Xxx Queries and Sets

Article • 12/15/2021

The virtual miniport of an intermediate driver must export the *MiniportOidRequest* function. NDIS calls the intermediate driver's *MiniportOidRequest* function when an overlying driver that is bound to the intermediate driver's virtual miniport calls **NdisOidRequest** to query or set information objects (OID_*Xxx*). NDIS can also call *MiniportOidRequest* on its own behalf. For more information about miniport driver handling of sets and queries to information objects, see Obtaining and Setting Miniport Driver Information and NDIS Support for WMI.

The intermediate driver should retain information about the capabilities of the underlying miniport adapters that it receives in the *ProtocolBindAdapterEx* function. If the miniport adapter is not power management-aware, NDIS sets the **PowerManagementCapabilities** member of **NDIS_BIND_PARAMETERS** to **NULL**.

The intermediate driver can query or set an OID_*Xxx* that is maintained by the underlying miniport driver. It does this with **NdisOidRequest**(if the intermediate driver has a connectionless lower edge), or with **NdisCoOidRequest**(if the intermediate driver has a connection-oriented lower edge).

An intermediate driver should handle queries and sets as follows:

- OID_PNP_CAPABILITIES

  In response to this OID query, intermediate drivers must report the PnP capabilites of the underlying physical miniport adapters. Note that miniport adapters for physical devices do not receive this OID query.

  The intermediate driver receives the PnP capabilities of the underlying miniport adapters in the bind parameters. It should pass them to overlying drivers as appropriate for the intermediate driver's intended use. Intermediate drivers and miniport drivers report PnP capabilities in miniport adapter attributes. The intermediate driver does not issue OID_PNP_CAPABILITIES requests to the underlying miniport driver. If the underlying miniport adapter is power management-aware, in the NDIS_PM_WAKE_UP_CAPABILITIES structure in the virtual miniport attributes, the intermediate driver must specify a device power state of **NdisDeviceStateUnspecified** for each wake-up capability:

  - MinMagicPacketWakeUp
  - MinPatternWakeUp

    - MinLinkChangeWakeUp

  Such a setting indicates that the intermediate driver is power management-aware but cannot wake up the system.

- OID_PNP_QUERY_POWER and OID_PNP_SET_POWER

  The intermediate driver must always return NDIS_STATUS_SUCCESS to a query of OID_PNP_QUERY_POWER or a set of OID_PNP_SET_POWER. The intermediate driver must never propagate either of these OID requests to the underlying miniport driver.

- "Wake-up OIDs"

  If an underlying NIC is power management-aware, the intermediate driver must pass to the underlying miniport driver (by calling **NdisOidRequest** or **NdisCoOidRequest**) the following OID_PNP_*Xxx* that relate to wake-up events:

  OID_PNP_ENABLE_WAKE_UP

  OID_PNP_ADD_WAKE_UP_PATTERN

  OID_PNP_REMOVE_WAKE_UP_PATTERN

  OID_PNP_WAKE_UP_PATTERN_LIST

  OID_PNP_WAKE_UP_ERROR

  OID_PNP_WAKE_UP_OK

The intermediate driver must also propagate the underlying miniport driver's response to these OIDs to the overlying protocol drivers.

If the underlying miniport adapter is not power management-aware, the miniport driver sets the **PowerManagementCapabilities** member of **NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES** to **NULL** and NDIS sets the **PowerManagementCapabilities** member of **NDIS_BIND_PARAMETERS** to **NULL**.

If an underlying miniport adapter is not power management-aware, the intermediate driver should return NDIS_STATUS_NOT_SUPPORTED in response to a query or set of these OIDs.

Implementing a ProtocolNetPnPEvent Handler in an Intermediate Driver

Article • 12/15/2021

The implementation of a *ProtocolNetPnPEvent* function in intermediate drivers is nearly identical to the implementation in protocol drivers. For more information about implementing a *ProtocolNetPnPEvent* handler in an intermediate driver, see Handling PnP Events and PM Events in a Protocol Driver.

NDIS intermediate drivers pass on PnP events to higher layer drivers by calling the **NdisMNetPnPEvent** function.

Handling a Set Power Request

Article • 12/15/2021

An intermediate driver must handle requests to set power to the working state (a network device power state of D0) and to sleeping states (a network device power state of D1, D2, or D3). The intermediate driver should also maintain power state variables and a StandBy flag. These issues are discussed further in this topic.

For examples of intermediate driver power management, see the NDIS MUX Intermediate Driver and Notify Object driver sample in the Windows driver samples repository on GitHub.

Handling a Set Power Request to a Sleeping State

There are two cases where an intermediate driver must handle a set power request to a sleeping state:

- NDIS requests that the virtual miniport upper edge of the intermediate driver go to a sleeping state.
- The intermediate driver protocol lower edge handles the underlying miniport driver transition to a sleeping state when it receives a Plug and Play (PnP) event notification.

These events can happen in any order and one event does not necessarily accompany the other.

When the virtual miniport upper edge of the intermediate driver receives a request to set power to a sleeping state, the sequence of events for handling the request is as follows:

1. NDIS calls the *ProtocolNetPnPEvent* function of each protocol driver bound to the virtual miniport. The call to *ProtocolNetPnPEvent* specifies a **NetEventSetPower** event for a sleeping state. Protocol drivers that are bound to the intermediate driver stop sending network data and making OID requests to the intermediate driver virtual miniport. The protocol lower edge of the intermediate driver can continue to send network data and requests down until NDIS indicates that the underlying miniport driver is making the transition to a sleeping state.
2. NDIS pauses the overlying drivers and then the virtual miniport after issuing the **NetEventSetPower** event. The specified reason for the pause is a transition to a

low-power state. For more information about pausing a virtual miniport, see Pausing an Adapter.

Note No OID requests can be sent to the virtual miniport while it is in a low-power state, with the exception of OID_PNP_SET_POWER.

3. NDIS issues an OID_PNP_SET_POWER request to the virtual miniport of the intermediate driver. The intermediate driver accepts the request by returning NDIS_STATUS_SUCCESS. The intermediate driver must not propagate the OID_PNP_SET_POWER request to the underlying miniport driver. After the intermediate driver completes this request, it should not indicate any more received network data or indicate status, even if it keeps receiving network data and status indications from the underlying miniport driver.

When the protocol lower edge of the intermediate driver transitions the underlying miniport driver to a sleeping state, the sequence of events for handling the transition is as follows:

1. NDIS calls the *ProtocolNetPnPEvent* function of the intermediate driver protocol lower edge. The call to *ProtocolNetPnPEvent* specifies a **NetEventSetPower** event for a sleeping state. The intermediate driver must stop sending network data and making OID requests to the underlying miniport driver. If there are outstanding requests or sends, the intermediate driver should return NDIS_STATUS_PENDING from the call to *ProtocolNetPnPEvent*. The intermediate driver calls **NdisCompleteNetPnPEvent** to complete the call to *ProtocolNetPnPEvent*. The protocol edge of an intermediate driver can still get received packet and status indications from the underlying miniport driver. Received network data can be ignored. If an intermediate driver's implementation depends upon monitoring the status of the underlying miniport driver, status indications should still be monitored.

2. NDIS pauses the protocol edge of the intermediate driver and then pauses the underying miniport adapter after issuing the **NetEventSetPower** event. The specified reason for the pause is a transition to a low-power state. For more information about pausing a protocol binding, see Pausing a Binding.

   Note No OID requests can be sent to the underlying miniport adapter while it is in a low-power state, with the exception of OID_PNP_SET_POWER.

3. NDIS issues an OID_PNP_SET_POWER request to the underlying miniport driver. However, if the underlying miniport driver does not support power management, it will be halted. In this case, even though NDIS halts the underlying miniport driver, it does not request the intermediate driver protocol to unbind from the underlying

miniport driver and NIC. After the underlying miniport driver has successfully completed processing the OID (or the miniport driver is halted), it will not indicate any more network data or status.

Handling a Set Power Request to the Working State

There are two cases where an intermediate driver handles a set power request to the working state:

- NDIS requests that the virtual miniport upper edge of the intermediate driver go to the working state.
- The intermediate driver protocol lower edge handles the underlying miniport driver transition to the working state, when it receives a Plug and Play (PnP) event notification.

These events can occur in any order and one event does not necessarily accompany the other.

When the virtual miniport upper edge of the intermediate driver receives a request to set power to a working state, the sequence of events for handling the request is as follows:

1. NDIS issues an OID_PNP_SET_POWER to the virtual miniport of the intermediate driver. The intermediate driver returns NDIS_STATUS_SUCCESS to the set power request. The intermediate driver must not propagate the OID_PNP_SET_POWER request to the underlying miniport driver.
2. NDIS restarts the virtual miniport and then restarts the overlying drivers after issuing the set power OID. For more information about restarting a virtual miniport, see Starting an Adapter.
3. NDIS calls the *ProtocolNetPnPEvent* function of the overlying protocol drivers. The call to *ProtocolNetPnPEvent* specifies a **NetEventSetPower** event to set the working state (D0). Bound protocol drivers can start sending network data to the intermediate driver's virtual miniport.

When the protocol lower edge of the intermediate driver transitions the underlying miniport driver to a working state, the sequence of events for handling the transition is as follows:

1. NDIS issues an OID_PNP_SET_POWER to the underlying miniport driver or calls its *MiniportInitializeEx* handler if the underlying miniport driver was halted.

2. NDIS restarts the underlying miniport driver and then the protocol edge of the intermediate NDIS and the underlying miniport adapter after issuing the OID. For more information about pausing a protocol binding, see Restarting a Binding.

3. NDIS calls the *ProtocolNetPnPEvent* function of the intermediate driver. The call to *ProtocolNetPnPEvent* specifies a **NetEventSetPower** event to set the working state (D0). The intermediate driver can start sending network data to the underlying miniport driver.

Power States and the Standby Flag

The intermediate driver should maintain a separate power state variable for each virtual miniport instance and for each underlying miniport driver to which the driver is bound. The intermediate driver should also maintain a StandingBy flag for each virtual miniport that is:

- Set to **TRUE** when the power state of either the virtual miniport or the underlying miniport driver leaves D0.

- Set to **FALSE** when the power state of either the virtual miniport or the underlying miniport driver returns to D0.

Note For MUX intermediate drivers, there can be multiple virtual miniports that are associated with an underlying miniport driver or multiple underlying miniports that are associated with each virtual miniport. When the power state of any miniport adapter changes, the behavior of all of the associated miniports are also affected. How the behavior is affected is implementation-specific. For example, a driver that implements a Load Balancing Failover (LBFO) solution might not deactivate the virtual miniports when a single underlying miniport driver is deactivated. However, a driver implementation that depends on all underlying miniport drivers would require deactivation of virtual miniports when any underlying miniport driver is deactivated.

The intermediate driver should use the StandingBy flag and power state variables when processing requests as follows:

- The driver's *MiniportSendNetBufferLists* function should fail unless the virtual miniport and its underlying miniport adapter are both in D0.

- The driver's *MiniportOidRequest* function should always succeed OID_PNP_QUERY_POWER to ensure that the driver receives the subsequent OID_PNP_SET_POWER requests.

- The driver's *MiniportOidRequest* function should fail if the virtual miniport is not in D0 or if StandingBy is **TRUE**. Otherwise, it should queue a single request if the underlying miniport driver is not in D0. A queued request should be processed when the underlying miniport driver state becomes D0.

- The intermediate driver virtual miniport should report status only if both the underlying miniport driver and virtual miniport are in D0.

Intermediate Driver Reset Operations

Article • 12/15/2021

An intermediate driver must be prepared to handle the situation where its outstanding sends on a binding to an underlying driver can be dropped because the underlying NIC is reset.

An underlying driver typically resets a NIC because NDIS calls the miniport driver's *MiniportResetEx* function when NDIS times out queued sends or requests that are bound for the NIC. If an underlying NIC is reset, NDIS calls the **ProtocolStatusEx**(or **ProtocolCoStatusEx**) function of each bound protocol and intermediate driver with a status of NDIS_STATUS_RESET_START. When the miniport driver completes the reset, NDIS again calls *ProtocolStatusEx*(or *ProtocolCoStatusEx*) with a status of NDIS_STATUS_RESET_END.

When a NIC is reset, if a bound intermediate driver has any transmit network data that is pending to that NIC, NDIS completes those network data back to the intermediate driver with an appropriate status. The intermediate driver must resubmit these network data again when the reset is completed.

When an intermediate driver receives a status of NDIS_STATUS_RESET_START, it should:

- Hold any network data ready to be transmitted until *ProtocolStatusEx* or *ProtocolCoStatusEx* receives an NDIS_STATUS_RESET_END notification.

- Hold any received network data that are ready to be indicated up to the next higher driver until *ProtocolStatusEx*(or *ProtocolCoStatusEx*) receives an NDIS_STATUS_RESET_END notification.

- Clean up any internal state it maintains for in-progress operations and NIC status.

After *ProtocolStatusEx*(or *ProtocolCoStatusEx*) receives NDIS_STATUS_RESET_END, the intermediate driver can resume sending network data, making requests and making indications to higher-level drivers.

An intermediate driver does not provide a *MiniportResetEx* function.

Status Indications in an Intermediate Driver

Article • 12/15/2021

The implementation of status indications in intermediate drivers is nearly identical to the implementation in protocol drivers. For more information about intermediate driver status indications, see Status Indications in a Protocol Driver.

When an intermediate driver receives a status indication, it can indicate the status indication up to the higher-level drivers by calling **NdisMIndicateStatusEx**. An intermediate driver should indicate status changes to overlying drivers as appropriate for its specific design requirements.

Installing an Intermediate Driver

Article • 12/15/2021

Intermediate drivers require two INF files. One of the INF files defines the installation parameters for the protocol lower edge. The other INF file defines the installation parameters for the virtual miniport upper edge.

The protocol INF file is the primary INF file. After the protocol lower edge is installed, the virtual miniport upper edge is installed, based on references to the miniport driver INF file that are defined in the protocol INF file.

On Windows Vista, you can use a notify object or a custom setup application to copy the miniport driver INF file to the system INF directory. For Windows Vista and later operating system versions, you should use the **INF CopyINF directive** in the protocol INF file to copy the miniport driver INF file. For more information about the notify object and copying INF files, see Intermediate Driver Notify Object.

The system-supplied device setup class for the protocol lower edge is **NetService** for filter intermediate drivers and **NetTrans** for MUX intermediate drivers. The driver class for the virtual miniport is always **Net**.

In addition to the INF files, you must also provide a notify object with a MUX intermediate driver. The notify object is optional for filter intermediate drivers.

The virtual miniport device is always removed from the user interface by using the **ExcludeFromSelect** directive. Therefore, the user only sees the protocol and installs the protocol from the protocol INF file.

Note The **ExcludeFromSelect** directive does not remove the virtual device from the **Connections** dialog box. However, the NCF_HIDDEN flag in the miniport driver INF file *DDInstall* section's **Characteristics** entry prevents the virtual miniport from being displayed in any part of the user interface, including the **Connections** dialog box.

This section provides information about intermediate INF files and notify objects. This information is described in the following topics:

Intermediate Driver UpperRange And LowerRange INF File Entries

MUX Intermediate Driver Installation

Intermediate Driver Notify Object

Intermediate Driver UpperRange And LowerRange INF File Entries

Article • 12/15/2021

This topic describes how to use the **UpperRange** and **LowerRange** INF file entries to define NDIS intermediate driver binding relationships.

In a network driver INF file, the **UpperRange** entry lists the possible upper bindings and the **LowerRange** entry lists the possible lower bindings. There are various system-defined values for these lists.

For filter intermediate drivers, you must set the value of the **UpperRange** and **LowerRange** entries to **noupper** and **nolower**, respectively. You should define these entries only in the protocol INF file; they are not required in the miniport driver INF file. The following code example illustrates these entries for a filter intermediate driver.

INF

```
HKR, Ndi\Interfaces, UpperRange, , noupper
HKR, Ndi\Interfaces, LowerRange, , nolower
```

In a filter intermediate driver, the **FilterMediaTypes** entry in the protocol INF file defines the driver's bindings to other drivers. **FilterMediaTypes** specifies the media types serviced by the filter intermediate driver. For a list of possible media types, see the list of Microsoft-supplied **LowerRange** values in Specifying Binding Interfaces. The following code example illustrates this entry for a filter intermediate driver.

INF

```
HKR, Ndi\Interfaces, FilterMediaTypes, , "ethernet, tokenring, fddi, wan"
```

When a filter intermediate driver is initialized, it inserts itself into all existing protocol-to-miniport bindings, as appropriate to the media types listed in **FilterMediaTypes**.

For MUX intermediate drivers, you should always set **UpperRange** in the protocol INF file to **noupper**. Set **LowerRange** to a list of values taken from those values allowed for **LowerRange,** as specified in Specifying Binding Interfaces. The following code example illustrates these entries for a MUX intermediate driver's lower edge.

INF

```
HKR, Ndi\Interfaces, UpperRange, 0, "noupper"
HKR, Ndi\Interfaces, LowerRange, 0, "ndis5"
```

For MUX intermediate drivers, you should always set **LowerRange** in the miniport driver INF file to **nolower**. Set the **UpperRange** to a list of values taken from those values allowed for the **UpperRange**, as specified in Specifying Binding Interfaces. The following code example illustrates these entries for a MUX intermediate driver virtual miniport.

INF

```
HKR, Ndi\Interfaces, UpperRange, 0, "ndis5"
HKR, Ndi\Interfaces, LowerRange, 0, "nolower"
```

MUX Intermediate Driver Installation

Article • 12/15/2021

This topic provides an overview of MUX intermediate driver installation issues. For additional information about the structure of intermediate driver INF files, see Installation Requirements for Network MUX Intermediate Drivers.

A MUX intermediate driver requires two INF files. The protocol INF file defines the installation parameters for the protocol lower edge. The miniport INF file defines the installation parameters for the virtual miniport upper edge. Set the **Class** INF file entry to **Net** in the virtual miniport INF file and **NetTrans** in the protocol INF file. The following code example shows a **Class** entry for the protocol INF file.

INF

```
Class = NetTrans
```

The *DDInstall* section in a MUX intermediate driver INF file must have a **Characteristics** entry. Define the **Characteristics** entry in your protocol INF file as demonstrated in the following code example.

INF

```
Characteristics = 0x80
```

NCF_HAS_UI (0x80) is required to enable custom property pages, which in this case is the notify object

Define the **Characteristics** entry in your miniport INF file as demonstrated in the following code example.

INF

```
Characteristics = 0x21
```

The **Characteristics** value 0x21 indicates the NCF_VIRTUAL (0x1) and NCF_NOT_USER_REMOVABLE (0x20) flags are set. NCF_VIRTUAL specifies that the device is a virtual adapter. NCF_NOT_USER_REMOVABLE is optional and specifies that the user cannot remove the intermediate driver. If you want to hide the virtual miniport from the user (you should not do this if your user must install devices manually) you can define the NCF_HIDDEN (0x8) flag. The NCF_*Xxx* flags are defined in Netcfgx.h. For more information about the **Characteristics** entry and NCF_*Xxx* flags, see DDInstall Section.

The *DDInstall* section of the protocol INF file for a MUX intermediate driver must include an **Addreg** directive for an **Ndi** key. For more information, see Adding Service-Related Values to the Ndi Key and DDInstall.Services Section.

In addition to the INF files, you must also provide a notify object with a MUX Intermediate driver. The notify object is responsible for installation of virtual miniports. Reference the notify object with the **ComponentDll** entry in the protocol INF as follows:

INF

```
HKR, Ndi,            ComponentDll,   , mux.dll
```

The user installs the protocol INF file which defines configuration parameters, copies installation files and also installs the notify object DLL. The user adds virtual miniports through the user interface provided by the notify object. The miniport INF file should define the **ExcludeFromSelect** entry to prevent the user from installing the miniport INF file instead of the protocol INF file.

The protocol name that the driver registers must match the service name.

INF

```
HKR, Ndi, Service, 0, MUXP
```

The **UpperRange** and **LowerRange** INF file entries determine the bindings for a MUX intermediate driver. The protocol INF file must define the protocol edge bindings, as the following code example shows.

INF

```
HKR, Ndi\Interfaces, UpperRange,    0,          "noupper"
HKR, Ndi\Interfaces, LowerRange,    0,          "ndis5"
```

The miniport INF file must define the upper edge bindings, as the following code example shows.

INF

```
HKR, Ndi\Interfaces,    UpperRange, 0,  "ndis5"
HKR, Ndi\Interfaces,    LowerRange, 0,  "nolower"
```

You should replace "ndis5" in the preceding code examples with the protocol bindings required by your driver. For more information about intermediate driver bindings and the **UpperRange/LowerRange** entries, see Intermediate Driver UpperRange And LowerRange INF File Entries.

Intermediate Driver Notify Object

Article • 05/30/2023

An *intermediate driver notify object* is an extension of the network class installer. The network class installer loads and initializes your notify object and sends it notifications of events (such as virtual miniport removal notifications) related to your driver. If you want an overview of notify objects in general or more information about notify objects, see Notify Objects for Network Components.

To include the notify object in your installation, you must reference it in your intermediate driver protocol INF. Filter intermediate drivers do not require a notify object. You can include a notify object with your filter intermediate driver if you would like to provide more flexible configuration options to your user.

On Windows Vista, you can use the notify object or a custom setup application to copy the miniport INF file to the system INF directory. For either of these, you use **SetupCopyOEMInf** to copy the INF. For Windows Vista and later operating system versions, you should use the **INF CopyINF directive** in the protocol INF to copy the miniport INF. On older versions of Windows you can't create a driver package with a notify object that is executed from the Driver Store. To successfully install a driver package in this scenario, you need to have a minimum OS build number of 25341. For more information about copying INF files, see Copying INFs.

A MUX intermediate driver notify object must provide services to install and remove virtual miniports. This can be done automatically or by providing a user interface. It must manage the virtual miniports' device name list in the registry. The device name list defines the bindings between virtual miniports and physical devices. For example, the n-to-one MUX intermediate driver sample notify object maintains a list of virtual miniports bound to each physical device in an **UpperBindings** registry entry. The MUX sample driver reads the **UpperBindings** list and initializes a virtual miniport for each entry.

Your MUX intermediate driver should use the **UpperRange/LowerRange** entries to control external bindings. However, you can control external bindings from your notify object if necessary. For more information about bindings in intermediate drivers, see Intermediate Driver UpperRange And LowerRange INF File Entries

Your notify object can optionally provide a user interface that allows the user to change or view your driver's configuration. The MUX intermediate driver sample includes an example user interface for a notify object.

Connection-Oriented NDIS

Article • 03/14/2023

This section describes connection-oriented NDIS (CoNDIS). Most CoNDIS 6.0 and later driver operations have not changed from their CoNDIS 5.*x* versions. For more information about the differences between CoNDIS 5.x and CoNDIS 6.0, see Porting CoNDIS 5.x Drivers to CoNDIS 6.0.

Unless noted otherwise, CoNDIS drivers provide the same services as connectionless NDIS drivers. You should be familiar with connectionless NDIS drivers before you attempt to write CoNDIS drivers. For more information about connectionless NDIS drivers, see Writing NDIS Miniport Drivers, Writing NDIS Protocol Drivers, and Writing NDIS Intermediate Drivers.

The following sections describe connection-oriented NDIS:

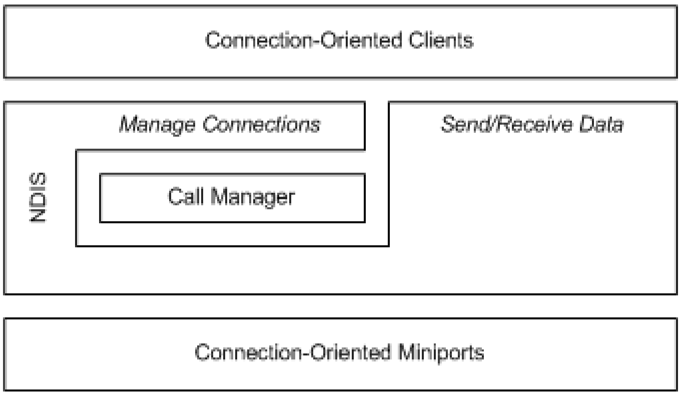
Connection-Oriented Environment

Article • 12/15/2021

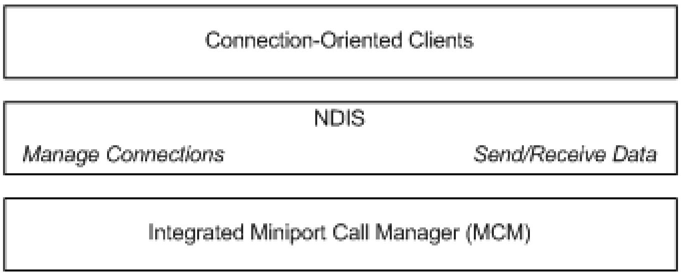
NDIS supports the following connection-oriented drivers:

- Connection-oriented client
- Call manager
- Integrated miniport call manager (MCM) driver
- Connection-oriented miniport driver

The following figure shows a configuration of connection-oriented clients, a call manager, and a miniport driver.



The following figure shows a configuration of connection-oriented clients and an integrated MCM driver.



Connection-Oriented Clients
NDIS
Manage Connections
Send/Receive Data
Integrated Miniport Call Manager (MCM)

A *connection-oriented miniport driver* controls one or more network interface cards (NICs) and provides an interface between connection-oriented protocol drivers (connection-oriented clients and call managers) and the NIC hardware.

For a summary of connection-oriented operations performed by a connection-oriented miniport driver, see Connection-Oriented Operations Performed by Miniport Drivers.

A *call manager* is an NDIS protocol driver that provides call setup and tear-down services for connection-oriented clients. A call manager:

- Uses the send and receive capabilities of a connection-oriented miniport driver to exchange signaling messages with network entities, such as network switches or remote peers.

- Supports one or more signaling protocol drivers. For a summary of connection-oriented operations performed by a call manager, see Connection-Oriented Operations Performed by Call Managers.

An *integrated MCM driver* is a connection-oriented miniport driver that also provides call manager services to connection-oriented clients. An MCM driver has the following characteristics:

- An MCM driver provides the same connection-oriented services to clients as a call manager that is paired with a connection-oriented miniport driver; however, the call manager-to-miniport driver interface is internal to the driver and therefore opaque to NDIS.

- Multiple call managers and MCM drivers can coexist in the same environment.

- Each call manager or MCM driver can support multiple signaling protocol drivers.

For a detailed comparison of MCM drivers and call managers, see How an MCM Driver Differs from a Call Manager.

A *connection-oriented client*:

- Uses the call setup and tear-down services of a call manager or MCM driver.

- Uses the send and receive capabilities of a connection-oriented miniport driver or an MCM driver to send and receive data.

- Can provide its own network and transport-layer services to a higher-layer application at its upper edge.

- Uses the services of a call manager and a connection-oriented miniport driver, or it uses the services of an MCM driver at its upper edge.

- Can be an adaptation layer, that resides between an old protocol and connection-oriented NDIS.

  Such adaptation layers use call management services to establish underlying connections but hide the connection-oriented nature of this interface from the connectionless protocols above it.

Note The definition of a connection-oriented client's upper-edge interface is beyond the scope of the NDIS documentation. If a client serves as an adaptation layer, its upper-edge interface is defined by the protocol that it adapts to connection-oriented NDIS.

For a summary of connection-oriented operations performed by a connection-oriented client, see Connection-Oriented Operations Performed by Clients.

Related topics

NDIS Miniport Drivers

Using AFs, VCs, SAPs, and Parties

Article • 12/15/2021

Connection-oriented drivers create and use entities including address families (AFs), virtual connections (VCs), service access points (SAPs), and parties.

When a connection-oriented driver registers an AF or creates a VC, SAP, or party, it passes a pointer to its local context area for that entity to NDIS. NDIS then returns to the driver (as well as to other appropriate connection-oriented drivers) a handle that represents the newly registered AF or the newly created VC, SAP, or party.

The following topics describe the entities that connection-oriented drivers create and use:

Address Families

Virtual Connections

Service Access Points

Parties

Address Families

Article • 12/15/2021

An *address family* (AF) represents an association between one of the following sets of drivers:

- A connection-oriented client, a call manager, and the underlying connection-oriented miniport driver.
- A connection-oriented client and an MCM driver for a specific signaling protocol.

An address family also specifies a particular signaling protocol.

A call manager or MCM driver advertises its call manager services for a specific signaling protocol by registering the address family with NDIS. NDIS then notifies each client on the binding of the newly registered address family. Before it can use the call manager services provided by a call manager or MCM driver, a connection-oriented client must open the address family with the call manager or MCM driver that advertised it.

For more information about operations on address families, see Registering and Opening an Address Family and Closing an Address Family.

Virtual Connections

Article • 12/15/2021

On a local computer, a *virtual connection (VC)* is an endpoint (or association) that can host a single call between a client, call manager or MCM driver, and a miniport driver. On the network, a VC refers to a connection between two communicating endpoints, such as two connection-oriented clients.

Many VCs can be active on a NIC at the same time, enabling the NIC to simultaneously service many calls. Each connection can be to different endpoints on different computers.

VCs on a network vary in the type of service that they provide to clients. For example, a VC can provide unidirectional or bidirectional service. Quality of service (QoS) parameters for each direction can guarantee specific performance thresholds, such as bandwidth and latency. Depending on the signaling protocol, the QoS for a VC may be negotiable. For more information about NDIS support of QoS, see Quality of Service.

A VC on a network can be a switched VC (SVC) or a permanent VC (PVC):

- An SVC is created as needed for a particular call. For example, a connection-oriented client initiates the creation of a VC for an outgoing call that it is going to make. Similarly, a call manager or MCM driver initiates the creation of a VC for an incoming call that it is going to indicate to a connection-oriented client. The call manager or MCM driver must communicate and sometimes negotiate the parameters for the VC with the remote party.

- A permanent VC is manually created and eventually deleted by an operator using a configuration utility, which is not supplied in NDIS. A client that monitors such manual creation and deletion of PVCs can use the OID_CO_ADD_PVC and OID_CO_DELETE_PVC OIDs to request that a call manager or MCM driver add or delete a PVC to or from its list of configured PVCs. The QoS for a PVC is configured by the operator and is not negotiable over the network.

In NDIS, a VC consists of resources that are allocated by a miniport driver to maintain state information about a VC on a network. These resources could include, but are not limited to, memory buffers, events, and data structures. The miniport driver is requested to create such a context for a VC by a connection-oriented client for an outgoing call or a call manager for an incoming call. For more information about the creation of VCs, see Creating a VC.

Before a created VC can be used for data transmission, it must be activated by a call manager or MCM driver. To activate a VC, a miniport driver or MCM driver sets up resources for the VC and communicates with a NIC as necessary to prepare the NIC to receive or transmit data on the VC. For more information about VC activation, see Activating a VC.

When tearing down a call, a call manager or MCM driver deactivates the VC used for the call.

After a call is torn down, the creator of the VC (a connection-oriented client, call manager, or MCM driver) can either initiate the deletion of the VC or use the VC for another call.

Service Access Points

Article • 12/15/2021

A *service access point* (SAP) identifies the characteristics of incoming calls of interest to a connection-oriented client. By registering a SAP with a call manager or MCM driver, a client indicates that the call manager or MCM driver should notify the client of all incoming calls addressed to that SAP.

A client does not always register a SAP, for example, if it does not handle incoming calls. A client can register multiple SAPs with a call manager or MCM driver.

For more information about SAPs, see Registering a SAP and Deregistering a SAP.

Parties

Article • 12/15/2021

A *party* represents one of possibly many leaves of a *point-to-multipoint connection*. When making an outgoing call, a connection-oriented client can specify a party. This makes the call a multipoint call, with the client acting as the *root* of the call and the remote party as a *leaf*. The client can then request that additional remote parties be added as *leaf nodes* to the call.

For more information about adding parties to a point-to-multipoint call, see Adding a Party to a Multipoint Call. For information about deleting parties from a point-to-multipoint call, see Dropping a Party from a Multipoint Call.

Quality of Service

Article • 12/15/2021

The originator of a call on an SVC can specify *quality of service* (QoS) parameters for the call that specify performance parameters for the call. Depending on the signaling protocol that is being used, a call manager or MCM driver that is setting up an outgoing or incoming call can negotiate the QoS with a network entity such as a network switch or a remote client. If allowed by the signaling protocol, a connection-oriented client might also request a change of QoS when determining whether to accept an incoming call.

The QoS parameters for a call are specified as call parameters in a **CO_CALL_PARAMETERS** structure. CO_CALL_PARAMETERS points to two other structures:

- **CO_CALL_MANAGER_PARAMETERS**, which specifies call manager parameters that a call manager or MCM driver use to set up a call.

- **CO_MEDIA_PARAMETERS**, which specifies media parameters that a miniport driver or MCM driver use to activate a VC.

Both CO_CALL_MANAGER_PARAMETERS and CO_MEDIA_PARAMETERS contain generic parameters (flags) that apply to all drivers that use the parameters. Each of these structures also points to a **CO_SPECIFIC_PARAMETERS** structure that specifies call manager-specific parameters (when pointed to by a CO_CALL_MANAGER_PARAMETERS structure) or media-specific parameters (when pointed to by a CO_MEDIA_PARAMETERS structure).

For more information about QoS operations, see Client-Initiated Request to Change Call Parameters and Incoming Request to Change Call Parameters.

MCM Drivers vs. Call Managers

Article • 12/15/2021

An integrated MCM driver is a connection-oriented miniport driver that also provides call manager services to connection-oriented clients. As such, an MCM driver performs all the connection-oriented functions of both a connection-oriented miniport driver and a call manager. Like all miniport drivers, MCM drivers must use **Ndis*Xxx*** calls to communicate with the underlying NIC hardware.

An MCM driver differs from a call manager in two major ways:

- A call manager is an NDIS connection-oriented *protocol driver* with added call manager functionality. An MCM driver is an NDIS connection-oriented *miniport driver* with added call manager functionality.

- The interface between a call manager and a connection-oriented miniport driver is fully exposed to NDIS--that is, all communication between the call manager and the miniport driver passes through NDIS. Except for the activation and deactivation of client VCs (VCs used for transmitting outgoing or incoming client data), the interface between the call manager part of an MCM driver and the miniport driver part of an MCM driver is opaque to NDIS. The activation and deactivation of client VCs must be accomplished through NDIS because NDIS keeps track of client VCs.

The differences between an MCM driver and a call manager are further described in the following sections:

Differences in Initialization

Differences in Calls to NdisXxx Functions

Differences in Virtual Connections

Differences in Initialization

Article • 12/15/2021

A call manager is an NDIS protocol; therefore, it follows the initialization sequence for a connection-oriented protocol, but with one additional step. In its *ProtocolBindAdapterEx* handler, immediately after completing the initialization steps for a connection-oriented protocol, a call manager must register an address family by calling **NdisCmRegisterAddressFamilyEx**. The call to **NdisCmRegisterAddressFamilyEx**, in which a call manager registers its call manager functions, identifies the protocol as a call manager. The call manager must register an address family for each NIC to which it binds itself.

An MCM driver is a miniport driver; therefore, it follows the initialization sequence for a connection-oriented miniport driver with the addition of the following step: an MCM driver must register an address family by calling **NdisMCmRegisterAddressFamilyEx** in its *MiniportInitializeEx* function, immediately after completing the miniport driver initialization sequence . The call to **NdisMCmRegisterAddressFamilyEx**, in which an MCM driver registers its call manager functions, distinguishes the MCM driver from a regular connection-oriented miniport driver. Although an MCM driver registers its miniport driver handlers only once during initialization by calling **NdisMRegisterMiniportDriver**, it must call **NdisMCmRegisterAddressFamilyEx** once for each NIC that it controls.

Differences in Calls to NdisXxx Functions

Article • 12/15/2021

A call manager calls a different set of call manager functions than an MCM driver. A call manager calls **NdisCm_Xxx_** functions, and an MCM driver calls **NdisMCm_Xxx_** functions.

An MCM driver does not call the **NdisCo_Xxx_** functions that both connection-oriented clients and call managers call. Instead, an MCM driver calls the following comparable **NdisMCm_Xxx_** functions:

- NdisMCmCreateVc instead of NdisCoCreateVc
- NdisMCmDeleteVc instead of NdisCoDeleteVc
- NdisMCmOidRequest instead of NdisCoOidRequest
- NdisMCmOidRequestComplete instead of NdisCoOidRequestComplete

An MCM driver does not require a call that is comparable to NdisCoSendNetBufferLists, because the send interface between the call manager and the miniport driver is internal to an MCM driver and therefore opaque to NDIS.

Differences in Virtual Connections

Article • 12/15/2021

A call manager uses *signaling VCs* to send and receive signaling messages to and from network entities, such as switches. A call manager's signaling VCs are visible to NDIS. The call manager must create, activate, deactivate, and delete all VCs with calls to NDIS. An MCM driver's signaling VCs, however, are opaque to NDIS. An MCM driver does not create, activate, deactivate, and delete signaling VCs with calls to NDIS. Instead, an MCM driver performs such operations internally. An MCM driver must call NDIS to perform operations on VCs that are used to send or receive client data. This is because NDIS must keep track of client VCs.

Because MCM driver is both a call manager and a miniport driver, certain connection-oriented functions are redundant. Specifically, MiniportCoCreateVc and MiniportCoDeleteVc are redundant and are therefore not supplied by an MCM driver. VC operations are handled by:

- An MCM driver's ProtocolCoCreateVc and ProtocolCoDeleteVc functions when a client requests the creation or deletion of a VC.
- NdisMCmCreateVc and NdisMCmDeleteVc when the MCM driver creates or deletes a VC.
- NdisMCmActivateVc and NdisCmDeactivateVc when the MCM driver activates or deactivates a VC.

An MCM driver must supply a MiniportCoOidRequest function for a client to use in querying or setting miniport driver information, and a MiniportCoSendNetBufferLists function to handle send operations from a client.

Connection-Oriented Timing Features

Article • 12/15/2021

Connection-oriented NDIS supports using a NIC's local time for scheduling the transmission of packets and for time-stamping send and receive packets.

Note These connection-oriented timing features are optional. These features are not supported by all CoNDIS NICs.

A connection-oriented protocol driver can call **NdisCoOidRequest** to query the local timing capabilities of a connection-oriented miniport driver or an MCM driver with OID_GEN_CO_GET_TIME_CAPS. In response to such a query, the miniport driver or MCM driver returns information about:

- Whether there is a readable clock on the NIC.
- Whether the NIC derives its time from the network connection.
- The precision of the local clock.
- Whether the NIC can timestamp received packets with its local time.
- Whether the NIC can schedule a send packet for transmission according to its local time.
- Whether the NIC can timestamp transmitted packets with its local time.

To obtain a NIC's local time, a connection-oriented protocol can call **NdisCoOidRequest** to query a connection-oriented miniport driver or MCM driver with OID_GEN_CO_GET_NETCARD_TIME. The connection-oriented miniport driver or MCM driver synchronously returns its local time, which the connection-oriented protocol can then use to schedule the transmission of packets.

Timing information for a send or receive packet is contained in the packet's out-of-band (OOB) data. For more information, see **NET_BUFFER_LIST**.

CoNDIS Miniport Driver Registration

Article • 03/14/2023

CoNDIS miniport drivers initialize like other miniport drivers and also must register additional CoNDIS entry points. For general information about miniport driver initialization, see Initializing a Miniport Driver.

To register CoNDIS entry points for *MiniportXxx* functions, CoNDIS miniport drivers call the **NdisSetOptionalHandlers** function from the *MiniportSetOptions* function. In *MiniportSetOptions*, the miniport driver initializes an **NDIS_MINIPORT_CO_CHARACTERISTICS** structure and passes it at the *OptionalHandlers* parameter of **NdisSetOptionalHandlers**.

Miniport call managers (MCMs) also register *ProtocolXxx* functions in *MiniportSetOptions*. For more information about MCM driver registration, see CoNDIS MCM Registration.

For more information about configuring optional miniport driver services, see Configuring Optional Miniport Driver Services.

CoNDIS Client Registration

Article • 03/14/2023

CoNDIS clients initialize like other protocol drivers and also must register additional CoNDIS entry points. For general information about protocol driver initialization, see Initializing a Protocol Driver.

To register CoNDIS entry points for *ProtocolXxx* functions, CoNDIS clients call the **NdisSetOptionalHandlers** function from the *ProtocolSetOptions* function. In *ProtocolSetOptions*, all CoNDIS protocol drivers initialize an **NDIS_PROTOCOL_CO_CHARACTERISTICS** structure and pass it at the *OptionalHandlers* parameter of **NdisSetOptionalHandlers**.

To specify entry points for a CoNDIS client, a protocol driver initializes an **NDIS_CO_CLIENT_OPTIONAL_HANDLERS** structure and passes it at the *OptionalHandlers* parameter of **NdisSetOptionalHandlers**.

For more information about configuring optional protocol driver services, see Configuring Optional Protocol Driver Services.

CoNDIS Call Manager Registration

Article • 03/14/2023

CoNDIS stand-alone call managers initialize like other protocol drivers and also must register additional CoNDIS entry points. For general information about protocol driver initialization, see Initializing a Protocol Driver.

To register CoNDIS entry points for *ProtocolXxx* functions, call managers call the **NdisSetOptionalHandlers** function from the *ProtocolSetOptions* function. In *ProtocolSetOptions*, all CoNDIS protocol drivers initialize an **NDIS_PROTOCOL_CO_CHARACTERISTICS** structure and pass it at the *OptionalHandlers* parameter of **NdisSetOptionalHandlers**.

To specify entry points for a call manager, a protocol driver initializes an **NDIS_CO_CALL_MANAGER_OPTIONAL_HANDLERS** structure and passes it at the *OptionalHandlers* parameter of **NdisSetOptionalHandlers**.

Miniport call managers (MCMs) also register call manager *ProtocolXxx* functions. For more information about MCM driver registration, see CoNDIS MCM Registration.

For more information about configuring optional protocol driver services, see Configuring Optional Protocol Driver Services.

CoNDIS MCM Registration

Article • 03/14/2023

CoNDIS miniport call managers (MCMs) initialize like other miniport drivers and also must register additional CoNDIS entry points. For general information about miniport driver initialization, see Initializing a Miniport Driver.

To register CoNDIS entry points for *MiniportXxx* functions and *ProtocolXxx* functions, CoNDIS MCMs call the **NdisSetOptionalHandlers** function from the *MiniportSetOptions* function. In *MiniportSetOptions*, an MCM initializes an **NDIS_MINIPORT_CO_CHARACTERISTICS** structure and passes it at the *OptionalHandlers* parameter of **NdisSetOptionalHandlers**.

To register call manager entry points, MCMs initialize an **NDIS_CO_CALL_MANAGER_OPTIONAL_HANDLERS** structure and pass it at the *OptionalHandlers* parameter of **NdisSetOptionalHandlers**.

For more information about configuring optional miniport driver services, see Configuring Optional Miniport Driver Services.

Connection-Oriented Operations Performed by Clients

Article • 12/15/2021

A connection-oriented client:

- **Opens and closes an address family.**

  On receiving notification from NDIS that a call manager or MCM driver has registered an address family, a connection-oriented driver can open that address family with the call manager or MCM driver. The client can then use the call manager services provided by the call manager or MCM driver. A client releases the association between itself and a call manager or MCM driver by closing the address family.

- **Registers and deregisters SAPs.**

  After opening an address family with a call manager or an MCM driver, a connection-oriented client can register one or more SAPs with the call manager or MCM driver. The call manager or MCM driver will then indicate to the client any incoming calls addressed to the registered SAPs. A client releases an SAP by deregistering the SAP.

- **Adds and deletes PVCs.**

  A connection-oriented client can monitor when an operator manually configures or deconfigures a permanent VC (PVC). In response to such an action, the client can request a call manager or MCM driver to add a PVC to its list of configured PVCs or to delete a PVC from such a list (see OID_CO_ADD_PVC and OID_CO_DELETE_PVC).

- **Makes outgoing calls.**

  Before making an outgoing call, a client must initiate the creation of a VC for the call. A client can then make an outgoing call. To make a point-to-multipoint call, a client specifies a party when making the call.

- **Adds a party to or drops a party from a point-to-multipoint call.**

  A client can add a party to a point-to-multipoint call and delete a party from a point-to-multipoint call. A client can also respond to an incoming request to drop a party from a point-to-multipoint call.

- **Accepts or rejects an incoming call.**

  A client can accept or reject an incoming call that is addressed to a SAP that the client previously registered with a call manager or MCM driver.

- **Negotiates the call parameters for an active VC.**

  Depending on what is allowed by the signaling protocol, a client can negotiate the call parameters for an active VC. A client can request a change in quality of service (QoS) and respond to an incoming request to change the QoS for an active VC. A client can also respond to a request from the remote party to change the QoS for a call.

- **Sends and receives packets.**

  A client can send packets through a connection-oriented miniport driver or MCM driver. A client can also receive packets through a connection-oriented miniport driver or MCM driver.

- **Initiates the deletion of a VC.**

  A client can initiate the deletion of a VC that it created.

- **Initiates the tear-down of a call.**

  A client can initiate the tear-down of a outgoing call that it made or an incoming call that it accepted.

- **Queries or sets information.**

  A client can query or set information maintained by a bound call manager or the call manager portion of an MCM driver. A client can also respond to queries and sets from a bound call manager or MCM driver.

  In addition, a client can query or set information maintained by a bound miniport driver or the miniport driver portion of a bound MCM driver.

- **Inputsminiport driver status indications.**

  A client can input status indicated by a connection-oriented miniport driver or an MCM driver.

Connection-Oriented Operations Performed by Call Managers

Article • 12/15/2021

A call manager performs:

- **Registers and deregisters one or more address families (AFs).**

  A call manager registers one or more address families with NDIS . By registering an address family, a call manager advertises its call manager services (specifically, a signaling protocol) to bound connection-oriented clients. For information about registering entry points with NDIS, see CoNDIS Registration.

- **Registers and deregisters SAPs at the request of a connection-oriented client.**

  A call manager receives a bound connection-oriented client's requests to register SAPs and to deregister SAPs. The call manager sends signaling messages over the network to register or deregister SAPs on behalf of clients.

- **Sets up an outgoing call at the request of a connection-oriented client.**

  When a connection-oriented client makes an outgoing call, the call manager communicates (exchanges signaling messages) with network control devices, as necessary, to make a connection. If the call is accepted by the remote party, the call manager activates the VC that is created for the call.

- **Sets up and indicates an incoming call to a connection-oriented client.**

  A call manager indicates to a bound connection-oriented client all calls that are addressed to a SAP registered by that client. Before indicating the incoming call to the client, the call manager initiates creation of a VC for the call then initiates activation of the VC.

- **Communicates requests for a change in QoS.**

  Depending on the signaling protocol, the call manager can communicate a request from the local client to change the QoS for an outgoing or incoming call or a request from the remote party to change the QoS for a call.

- **Communicates requests to add and drop parties.**

  A call manager communicates a local client's request to add a party to or drop a party from a point-to-multipoint call. A call manager also communicates a remote party's incoming request to drop itself from a point-to-multipoint call.

- **Tears down a call.**

  At the request of a connection-oriented client, a call manager closes a call by communicating with network control devices to terminate a connection. At the request of a remote party, a call manager indicates to a local connection-oriented client a remote party's request to close a call. In the process of tearing down a call, the call manager deactivates the VC that is used for the call. If the call manager created the VC (for an incoming call), the call manager can also delete the VC.

- **Queries or sets information.**

  A call manager can query or set information maintained by a bound connection-oriented client. A call manager can also respond to query and set operations from a bound connection-oriented client.

  In addition, a call manager can query or set information maintained by a bound miniport driver or by the miniport driver portion of a bound MCM driver.

- **Inputsminiport driver status indications.**

  A call manager inputs status indications from a bound connection-oriented miniport driver.

Connection-Oriented Operations Performed by Miniport Drivers

Article • 12/15/2021

In addition to controlling NIC hardware, a connection-oriented miniport driver:

- **Sends and receives packets.**

  A connection-oriented miniport driver sends and receives packets on behalf of connection-oriented clients or call managers.

- **Creates (sets up) VCs.**

  At the request of a connection-oriented client, a connection-oriented miniport driver allocates and initializes the resources for a VC for an outgoing call. At the request of a call manager, a connection-oriented miniport driver allocates and initializes the resources for a VC for an incoming call or on which the call manager will send or receive signaling messages.

- **Activates VCs.**

  At the request of a call manager, a connection-oriented miniport driver communicates with a NIC to prepare the NIC to receive or transmit data across a VC (see Activating a VC).

- **Deactivates VCs.**

  At the request of a call manager, a connection-oriented miniport driver communicates with a NIC to terminate all communication across a VC (see Deactivating a VC).

- **Deletes VCs.**

  At the request of a connection-oriented client, a connection-oriented miniport driver deallocates the resources for a VC whose creation was initiated by that client (see Deleting a VC). At the request of a call manager, a connection-oriented miniport driver deallocates the resources for a VC whose creation was initiated by that call manager.

- **Responds to information queries or sets.**

  A connection-oriented miniport driver responds to query and set operations by a bound connection-oriented client or call manager.

- **Indicates status.**

  A connection-oriented miniport driver can indicate changes in its status or the status of a NIC to bound connection-oriented clients and call managers.

- **Resets the NIC.**

  At the request of NDIS, a connection-oriented miniport driver resets a NIC.

Operations on Address Families and SAPs

Article • 12/15/2021

A call manager or MCM driver must register its call manager entry points with NDIS and advertise its call manager services to connection-oriented clients. For more information about registering entry points with NDIS, see CoNDIS Registration.

To use the call manager services of a call manager or MCM driver, a connection-oriented client must open an address family with that call manager or MCM driver. To receive incoming calls, the client must also register one or more SAPs with the call manager or MCM driver.

The following connection-oriented operations pertain to address families and SAPs:

Registering and Opening an Address Family

Registering a SAP

Deregistering a SAP

Closing an Address Family

Registering and Opening an Address Family

Article • 12/15/2021

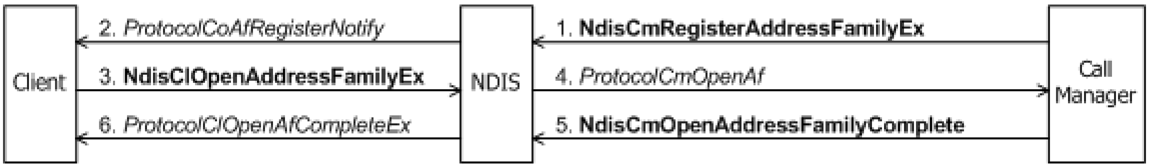
A call manager must register an address family for each NIC on which it provides call manager services to connection-oriented clients. Similarly, an MCM driver must register an address family for the NIC that it manages.

By registering an address family, a call manager or MCM driver causes NDIS to advertise the call manager's or MCM driver's services to all connection-oriented clients that bind to the adapter.

If a connection-oriented client can use the services advertised by a call manager or MCM driver, it can open an address family with the call manager or MCM driver.

Registering an Address Family from a Call Manager

After its *ProtocolBindAdapterEx* function binds to an underlying miniport driver with **NdisOpenAdapterEx**, a call manager calls **NdisCmRegisterAddressFamilyEx** to register an address family for the binding (see the following figure).



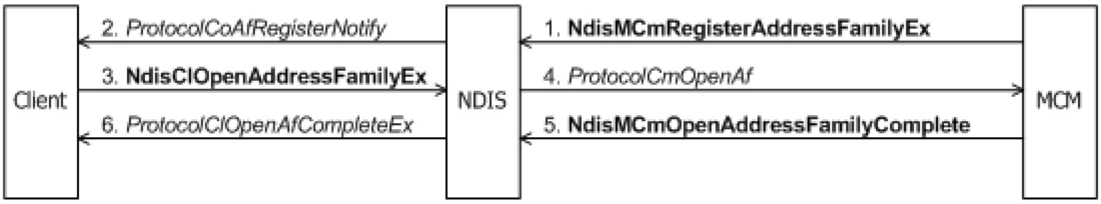
Client
2. ProtocolCoAfRegisterNotify
3. NdisClOpenAddressFamilyEx
6. ProtocolClOpenAfCompleteEx
NDIS
1. NdisCmRegisterAddressFamilyEx
4. ProtocolCmOpenAf
5. NdisCmOpenAddressFamilyComplete
Call Manager

The call to **NdisCmRegisterAddressFamilyEx** advertises the call manager's specific signaling services. A call manager must register an address family each time that its *ProtocolBindAdapterEx* function and is called and successfully binds to a NIC with **NdisOpenAdapterEx**.

The call manager can support more than one address family across all the miniport drivers to which it is bound. The call manager can also support more than one address family on a single NIC to which it is bound. The call manager must register the same entry points for each address family on the binding. Only one call manager can support a particular type of address family for clients bound to any particular miniport driver. For more information about registering entry points for a call manager, see CoNDIS Registration.

Registering an Address Family from an MCM Driver

An MCM driver calls **NdisMCmRegisterAddressFamilyEx** from its *MiniportInitializeEx* function after registering its miniport driver entry points with **NdisMRegisterMiniportDriver**. For more information about regsitering entry points see, CoNDIS Registration. An MCM driver calls **NdisMCmRegisterAddressFamilyEx** once to advertise its services to connection-oriented clients (see the following figure).



Client
2. ProtocolCoAfRegisterNotify
3. NdisClOpenAddressFamilyEx
6. ProtocolClOpenAfCompleteEx
NDIS
1. NdisMCmRegisterAddressFamilyEx
4. ProtocolCmOpenAf
5. NdisMCmOpenAddressFamilyComplete
MCM

A miniport driver of a NIC that has on-board connection-oriented signaling support can register itself as an MCM driver even though a call manager may be available. By doing so, such an MCM driver preempts the call manager as the call manager for that NIC.

Opening an Address Family

A call manager's or MCM driver's call to **Ndis(M)CmRegisterAddressFamily** causes NDIS to call the **ProtocolCoAfRegisterNotify** function of each connection-oriented client on the binding (as shown in two previous figures).

ProtocolCoAfRegisterNotify examines the address-family data to determine whether the client can use the services of this particular CM or MCM driver. Whether the client can make modifications in the (M)CM-supplied address-family data depends on the particular signaling-protocol support of the call manager or MCM driver.

If the client finds the offered call-management services acceptable, *ProtocolCoAfRegisterNotify* allocates a per-AF context area for the client and calls **NdisClOpenAddressFamilyEx**. **NdisClOpenAddressFamilyEx** does not register the client's connection-oriented entry points with NDIS. For more information about registering connection-oriented entry points with NDIS, see CoNDIS Registration.

The call to **NdisClOpenAddressFamilyEx** causes NDIS to call the call manager's or MCM driver's **ProtocolCmOpenAf** function (as shown already in the two earlier figures). *ProtocolCmOpenAf* ensures that the client passed in a valid address family and allocates and initializes the resources necessary to perform operations on behalf of the client that is opening this instance of the address family. *ProtocolCmOpenAf* also stores an NDIS-supplied *NdisAfHandle* that represents the association between the call manager and client for the open address family.

ProtocolCmOpenAf can complete synchronously or asynchronously. To complete asynchronously, the *ProtocolCmOpenAf* function of a call manager calls **NdisCmOpenAddressFamilyComplete**; the *ProtocolCmOpenAf* function of an MCM driver calls **NdisMCmOpenAddressFamilyComplete**. The call to **Ndis(M)CmOpenAddressFamilyComplete** causes NDIS to call the *ProtocolOpenAfComplete* function of the client that originally called **NdisClOpenAddressFamilyEx**.

If the client's call to **NdisClOpenAddressFamilyEx** is successful, NDIS returns to the client an *NdisAfHandle* that represents the association between the call manager and client for the open address family.

If a client accepts incoming calls, it usually registers one or more SAPs from its *ProtocolClOpenAfCompleteEx* function by calling **NdisClRegisterSap** following its successful call to **NdisClOpenAddressFamilyEx**.

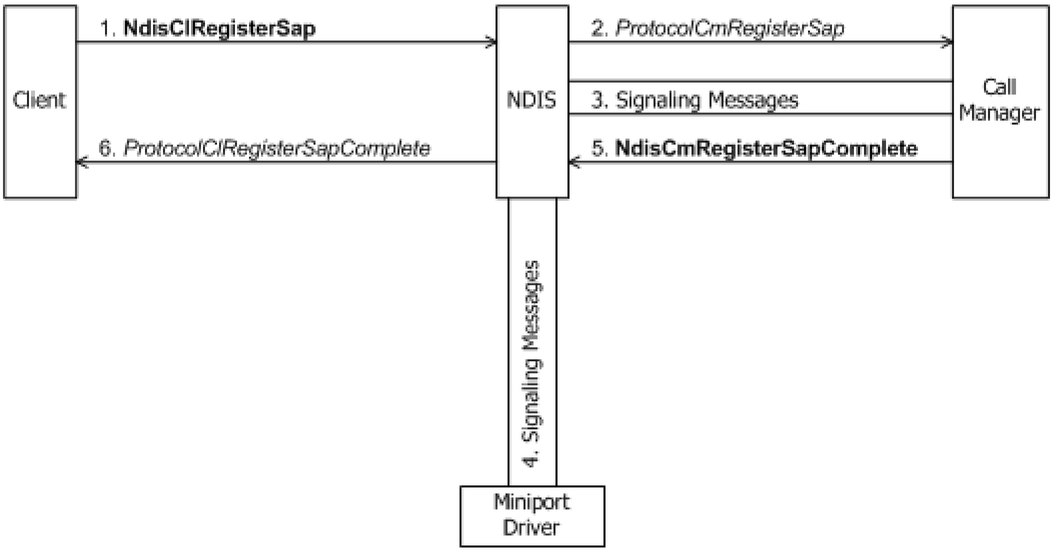
If a client makes outgoing calls, it could create one or more VCs in its *ProtocolClOpenAfCompleteEx* function in anticipation of a request by one or more its clients to make an outgoing call.

Registering a SAP

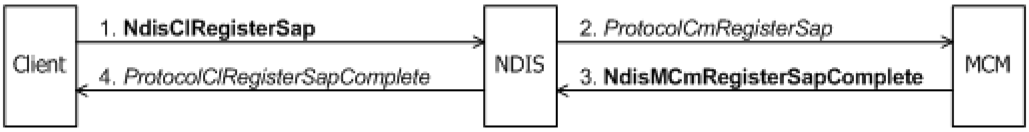
Article • 12/15/2021

If a client accepts incoming calls, its ProtocolClOpenAfCompleteEx function usually registers one or more SAPs with the call manager by calling NdisClRegisterSap.

The following figure shows a client of a call manager registering a SAP.



The following figure shows a client of an MCM driver registering a SAP.



Client
1. NdisClRegisterSap
NDIS
2. ProtocolCmRegisterSap
MCM
4. ProtocolClRegisterSapComplete
3. NdisMCmRegisterSapComplete

With the call to **NdisClRegisterSap**, a client requests notifications of incoming calls on a particular SAP. NDIS forwards the SAP information supplied by the client to the call manager's or MCM driver's ProtocolCmRegisterSap function for validation. If the given SAP is already in use or if the call manager or MCM driver does not recognize the client-supplied SAP specification, the call manager or MCM driver fails this request.

In *ProtocolCmRegisterSap*, the call manager or MCM driver might communicate with network control devices or other media-specific agents to register the SAP on the network for a connection-oriented client. *ProtocolCmRegisterSap* also stores an NDIS-supplied *NdisSapHandle* that represents the SAP.

ProtocolCmRegisterSap can complete synchronously or asynchronously. To complete asynchronously, the *ProtocolCmRegisterSap* function of a call manager calls NdisCmRegisterSapComplete. The *ProtocolCmRegisterSap* function of an MCM driver calls NdisMCmRegisterSapComplete. The call to **Ndis(M)CmRegisterSapComplete** causes NDIS to call the client's *ProtocolClRegisterSapComplete* function.

If the client's call to **NdisClRegisterSap** is successful, NDIS returns to the client an NdisSapHandle that represents the SAP.

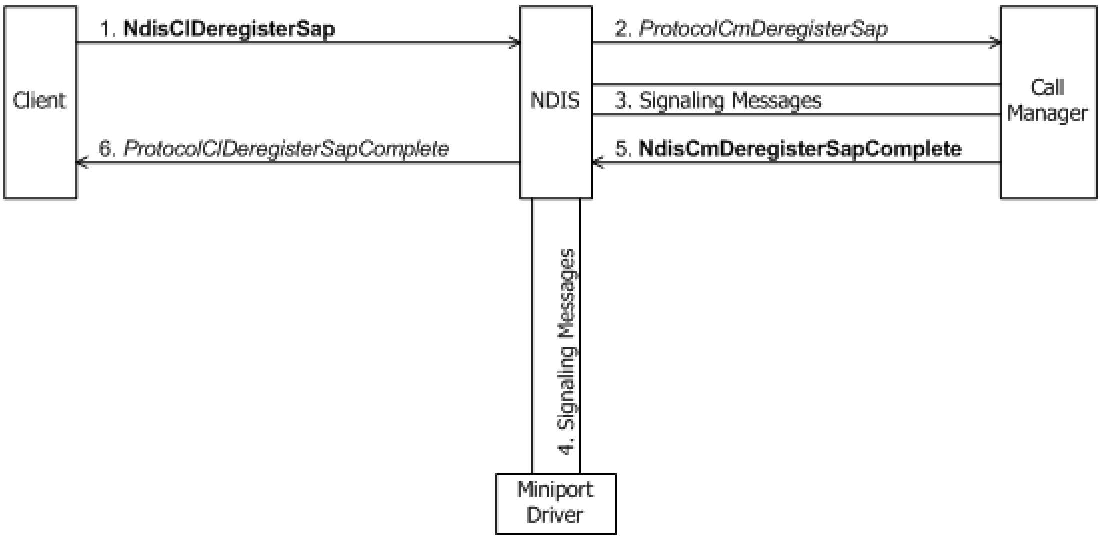
After a call manager registers a SAP on behalf of a connection-oriented client, it notifies that client of an incoming call offer directed to that SAP by calling **NdisCmDispatchIncomingCall**. An MCM driver calls **NdisMCmDispatchIncomingCall**(see Indicating an Incoming Call). A client can receive incoming calls on a SAP even while SAP registration is still pending; that is, before its *ProtocolClRegisterSapComplete* function is called.

Deregistering a SAP

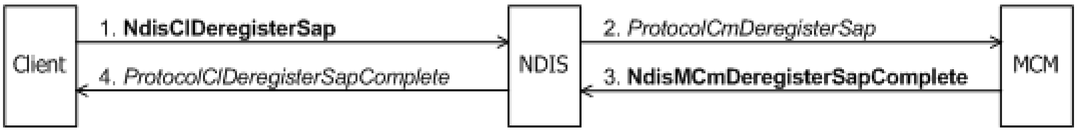
Article • 12/15/2021

A connection-oriented client deregisters a SAP with NdisClDeregisterSap.

The following figure shows a client of a call manager deregistering a SAP.



The following figure shows a client of an MCM driver deregistering a SAP.



Client
1. NdisClDeregisterSap
4. ProtocolClDeregisterSapComplete
NDIS
2. ProtocolCmDeregisterSap
3. NdisMCmDeregisterSapComplete
MCM

The call to **NdisClDeregisterSap** causes NDIS to call the call manager's or MCM driver's ProtocolCmDeregisterSap function. In *ProtocolCmDeregisterSap*, the call manager or MCM driver might communicate with network control devices or other media-specific agents to deregister the SAP on the network. In addition, *ProtocolCmDeregisterSap* must free any resources that it dynamically allocated for the SAP.

ProtocolCmDeregisterSap can complete synchronously or asynchronously. To complete asynchronously, the *ProtocolCmDeregisterSap* function of a call manager calls NdisCmDeregisterSapComplete. The *ProtocolCmDeregisterSap* function of an MCM driver calls NdisMCmDeregisterSapComplete. **Ndis(M)CmDegisterSapComplete** notifies both NDIS and the client that the call manager has completed the SAP-deregistration request for which its *ProtocolCmDeregisterSap* function previously returned NDIS_STATUS_PENDING.

A call to **Ndis(M)CmDeregisterSapComplete** causes NDIS to call the client's ProtocolClDeregisterSapComplete function. A call to *ProtocolClDeregisterSapComplete* indicates that the client's preceding call to **NdisClDeregisterSap** has been processed by the call manager or MCM driver.

Note that a client can deregister a SAP without affecting an incoming call that has already been received on that SAP and without affecting the VC for that incoming call.

Closing an Address Family Overview

Article • 12/15/2021

A connection-oriented client calls **NdisClCloseAddressFamily** to delete the association between itself, a call manager, and a particular underlying NIC.

When a CoNDIS stand-alone call manager is closing a binding to an underlying miniport adapter, or a miniport call manager (MCM) is halting a miniport adapter, the call manager or the MCM must notify NDIS if an associated address family (AF) should be closed. NDIS then notifies each CoNDIS client that has the AF open that the client should close the AF.

This section includes the following topics:

Closing a CoNDIS Call Manager or MCM

Closing an Address Family in a CoNDIS Client

Closing a CoNDIS Call Manager or MCM

Article • 03/14/2023

When a stand-alone call manager is unbinding from an underlying miniport adapter, the call manager must notify all of the affected CoNDIS clients that they must close the associated AF. To notify each client, NDIS stand-alone call managers call the **NdisCmNotifyCloseAddressFamily** function.

If a CoNDIS miniport adapter that an MCM manages is halting, the MCM must notify all of the affected clients that they must close the associated AF. To notify each client, the MCMs call the **NdisMCmNotifyCloseAddressFamily** function.

If a stand-alone call manager or MCM calls **NdisCmNotifyCloseAddressFamily** or **NdisMCmNotifyCloseAddressFamily**, respectively, NDIS calls the **ProtocolClNotifyCloseAf** function of the CoNDIS client that is associated with the handle in the *NdisAfHandle* parameter of **NdisCmNotifyCloseAddressFamily** or **NdisMCmNotifyCloseAddressFamily**. This call notifies the client to close the AF. If **NdisCmNotifyCloseAddressFamily** or **NdisMCmNotifyCloseAddressFamily** returns NDIS_STATUS_PENDING, NDIS will call the call manager's **ProtocolCmNotifyCloseAfComplete** function when the close notification operation is complete.

For more information about closing an address family in a CoNDIS client, see Closing an Address Family in a CoNDIS Client.

Closing an Address Family in a CoNDIS Client

Article • 03/14/2023

To close AFs, a CoNDIS client must provide a ProtocolClNotifyCloseAf function. NDIS calls *ProtocolClNotifyCloseAf* when a stand-alone call manager or MCM calls the NdisCmNotifyCloseAddressFamily function or the NdisMCmNotifyCloseAddressFamily function, respectively.

From within *ProtocolClNotifyCloseAf*, the client finishes closing the specified AF, or it returns NDIS_STATUS_PENDING and calls the NdisClNotifyCloseAddressFamilyComplete function to complete the operation. After the client calls **NdisClNotifyCloseAddressFamilyComplete**, NDIS calls the ProtocolCmNotifyCloseAfComplete function to notify the call manager that the client closed the AF.

To close the AF, the client should:

1. If the client has active multipoint connections, call the NdisClDropParty function as many times as necessary until only a single party remains active on each multipoint virtual connection (VC).

2. Call the NdisClCloseCall function as many times as necessary to close all of the calls that are still open and are associated with the address family.

3. Call the NdisClDeregisterSap function as many times as necessary to deregister all of the service access points (SAPs) that the client registered with the call manager.

4. Call the NdisClCloseAddressFamily function to close the AF.

Creating a VC

Article • 12/15/2021

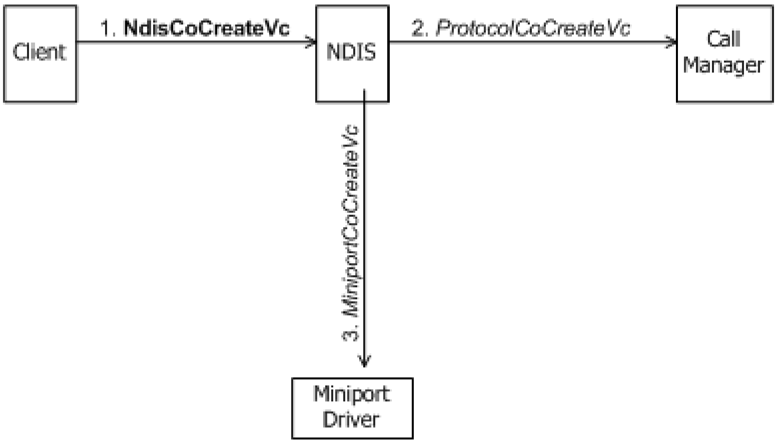
Before making an outgoing call, a connection-oriented client initiates the creation a virtual connection (VC). Before indicating an incoming call to a connection-oriented client, a call manager or an MCM driver initiates the creation of a VC . After the VC has been set up and activated, client data can be transmitted or received on the VC.

A call manager or an MCM driver can also initiate the creation of a VC on which signaling messages are exchanged with network components, such as a network switch.

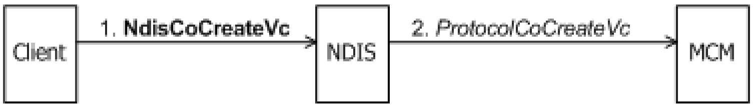
Client-Initiated Creation of a VC

Before making a call with **NdisClMakeCall**, a connection-oriented client calls **NdisCoCreateVc** to initiate the creation of a VC.

The following figure shows a client of a call manager initiating the creation of a VC.



The following figure shows a client of an MCM driver initiating the creation of a VC.



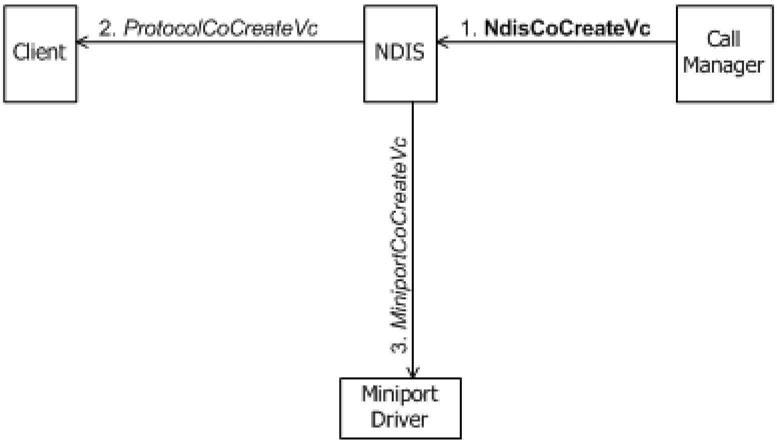
When a connection-oriented client of a call manager calls **NdisCoCreateVc**, NDIS calls, as a synchronous operation, the **ProtocolCoCreateVc** function of the call manager and the **MiniportCoCreateVc** function of the underlying miniport driver (see the first figure in this topic). NDIS passes an *NdisVcHandle* that represents the VC to both *ProtocolCoCreateVc* and *MiniportCoCreateVc*. If the call to **NdisCoCreateVc** is successful, NDIS returns the *NdisVcHandle* to **NdisCoCreateVc**.

ProtocolCoCreateVc allocates and initializes any dynamic resources and structures that the call manager requires to perform subsequent operations on a VC that will be activated. *MiniportCoCreateVc* allocates and initializes any resources that the miniport driver requires to maintain state information about the VC. Both *ProtocolCoCreateVc* and *MiniportCoCreateVc* store the *NdisVcHandle* .

When a connection-oriented client of an MCM driver, the call to **NdisCoCreateVc** causes NDIS to call the MCM driver's *ProtocolCoCreateVc* function (see Client-Initiated Creation of a VC (MCM Driver Present)). In this case, *ProtocolCoCreateVc* performs the necessary allocation and initialization of resources for the VC. There is no call (internal or otherwise) to *MiniportCoCreateVc*, because an MCM driver does not supply such a function.

Call Manager-Initiated Creation of a VC

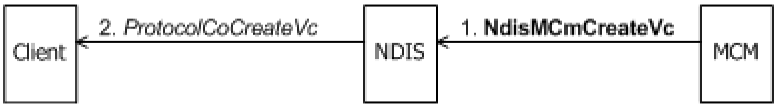
Before indicating an incoming call to a connection-oriented client with **NdisCmDispatchIncomingCall**, a call manager calls **NdisCoCreateVc** to initiate the creation of a VC (see the following figure).



When a call manager calls **NdisCoCreateVc**, NDIS calls, as a synchronous operation, the **ProtocolCoCreateVc** function of the connection-oriented client that registered the SAP on which the call is being received, as well as the **MiniportCoCreateVc** function of the underlying miniport. NDIS passes an *NdisVcHandle* that represents the VC to both *ProtocolCoCreateVc* and *MiniportCoCreateVc*. If the call to **NdisCoCreateVc** is successful, NDIS returns the *NdisVcHandle* to **NdisCoCreateVc**.

MCM Driver-Initiated Creation of a VC

Before indicating an incoming call to a connection-oriented client with **NdisMCmDispatchIncomingCall**, an MCM driver calls **NdisMCmCreateVc** to initiate the creation of a VC (see the following figure).



When an MCM driver calls **NdisMCmCreateVc**, NDIS calls, as a synchronous operation before **NdisMCmCreateVc** returns, the **ProtocolCoCreateVc** function of the connection-oriented client that registered the SAP on which the call is being received. NDIS passes an *NdisVcHandle* that represents the VC to *ProtocolCoCreateVc*. If the call to **NdisMCmCreateVc** is successful, NDIS returns the *NdisVcHandle* to **NdisMCmCreateVc**.

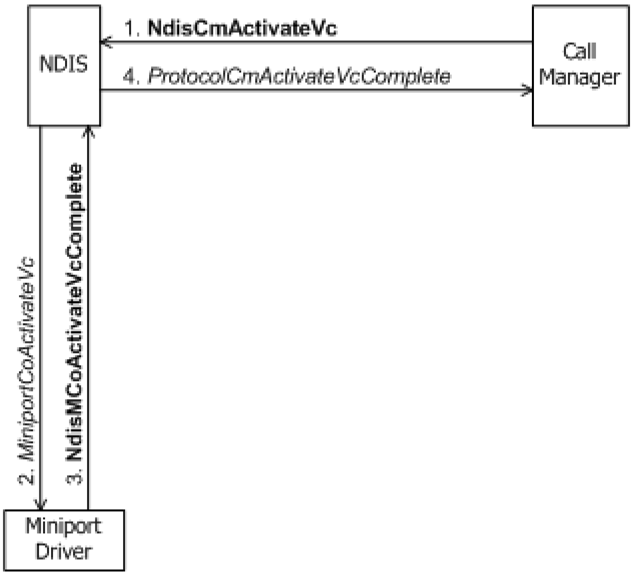
ProtocolCoCreateVc allocates and initializes any dynamic resources and structures that the client requires to perform subsequent operations on the VC. *ProtocolCoCreateVc* also stores the *NdisVcHandle* .

Note that when an MCM driver creates a VC for exchanging signaling messages with a network component, it does not use **Ndis*Xxx*** calls to create a VC. In fact, an MCM driver does not use **Ndis*Xxx*** calls to create, activate, deactivate, or delete such VCs. Instead, an MCM driver performs these operations internally. Such VCs are therefore opaque to NDIS.

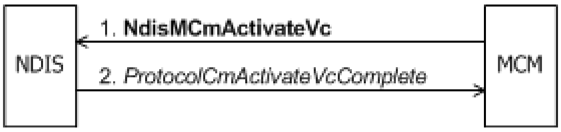
Activating a VC

Article • 12/15/2021

After a virtual connection (VC) has been created (see Creating a VC), it must be activated before data can be transmitted or received on it. A call manager initiates the activation of a VC by calling **NdisCmActivateVc**(see the following figure).



An MCM driver initiates the activation of a VC by calling **NdisMCmActivateVc**(see the following figure).



A call manager or MCM driver could initiate reactivation of an active VC if the local client or a remote party successfully negotiates a change in call parameters on that VC (see Client-Initiated Request to Close a Call and Incoming Request to Change Call Parameters). The call manager or MCM driver can call **Ndis(M)CmActivateVc** many times for a single VC to change the call parameters for an already active call.

For a client-initiated outgoing call, a call manager or an MCM driver usually calls **Ndis(M)CmActivateVc** immediately following the packet exchange confirming a negotiated agreement with the remote target of the call or successful call-setup at the switch. The call manager or MCM driver calls **Ndis(M)CmActivateVc** before it notifies NDIS (and the client) of outgoing call completion with **Ndis(M)CmMakeCallComplete**(see Making a Call). For an incoming call, a call manager or MCM driver usually calls **Ndis(M)CmActivateVc** after it has called **NdisCo(MCm)CreateVc** successfully and before it calls **Ndis(M)CmDispatchIncomingCall**(see Indicating an Incoming Call).

A call manager's call to **NdisCmActivateVc** causes NDIS to call the MiniportCoActivateVc function of the underlying miniport driver. *MiniportCoActivateVc* must validate the call parameters for this VC to verify that the adapter can support the requested call. If the call parameters are acceptable, *MiniportCoActivateVc* communicates with its adapter as necessary to prepare the adapter to receive or transmit data across the virtual connection (for example, programming receive buffers). If the requested call parameters cannot be supported, the miniport driver fails the request.

MiniportCoActivateVc can complete synchronously or asynchronously. The call to NdisMCoActivateVcComplete causes NDIS to call the call manager's ProtocolCmActivateVcComplete function. *ProtocolCmActivateVcComplete* must check the status returned by **NdisMCoActivateVcComplete** to ensure that the virtual connection has been activated successfully. If the miniport driver did not successfully activate the VC, the call manager must not attempt to communicate over the VC. *ProtocolCmActivateVcComplete* must also complete any processing required by the network media to ensure that the virtual connection is ready for data transmission before returning control to NDIS.

An MCM driver's call to **NdisMCmActivateVc** informs NDIS that it has set up call and media parameters on a newly created VC or changed the call parameters on an established VC. This action notifies NDIS that the MCM driver has made a NIC ready for transfers on the VC. NDIS completes the activation sequence by calling the MCM driver's *ProtocolCmActivateVcComplete* function.

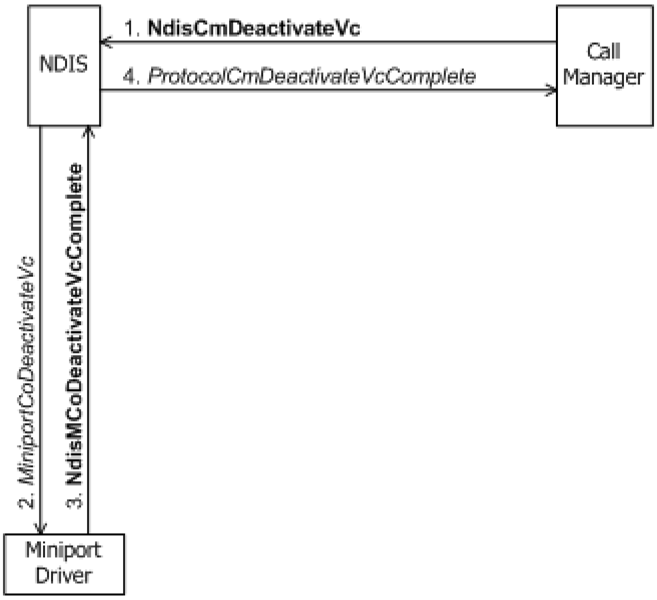
An MCM driver calls **NdisMCmActivateVc** to activate only VCs used for transmitting and/or receiving client data, but not to activate VCs used for exchanging signaling messages between the MCM driver and network components such as a switch. An MCM driver activates a signaling VC internally without calling any **Ndis*Xxx*** function. Any VC that an MCM driver sets up for its own signaling purposes is therefore opaque to NDIS.

Deactivating a VC

Article • 12/15/2021

A call manager calls **NdisCmDeactivateVc** as an essential step in closing either an outgoing or incoming call, typically after the packet exchange with network components that tears down the call (see Client-Initiated Request to Close a Call and Incoming Request to Close a Call). An MCM driver does the same thing by calling **NdisMCmDeactivateVc**.

The call to **NdisCmDeactivateVc** causes NDIS to call the underlying miniport driver's **MiniportCoDeactivateVc** function (see the following figure). *MiniportCoDeactivateVc* communicates with its network adapter to terminate all communication across this VC (for example, clearing receive or send buffers on the adapter).



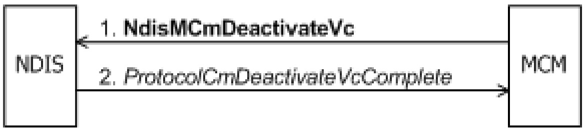
NDIS
1. NdisCmDeactivateVc
4. ProtocolCmDeactivateVcComplete
Call Manager
2. MiniportCoDeactivateVc
3. NdisMCoDeactivateVcComplete
Miniport Driver

Before it deactivates a VC, the miniport driver must complete any pending transfers on the VC. That is, the miniport driver must wait until it has completed all sends in progress and until all receive packets that it has indicated are returned to it. After deactivating the VC, the miniport driver cannot indicate receives or transmit sends on the VC.

Note that *MiniportCoDeactivateVc* does not delete the VC. The creator (client, call manager, or MCM driver) of a particular VC that will not be reused calls **NdisCoDeleteVc** to destroy that VC. A deactivated VC can be reactivated by a connection-oriented client, a call manager, or an MCM driver.

MiniportCoDeactivateVc can complete synchronously or asynchronously. A call to **NdisMCoDeactivateVcComplete**. causes NDIS to call the **ProtocolCmDeactivateVcComplete** function of the call manager that originally requested the VC deactivation. Completion of the deactivation means that all call parameters for the VC used on activation are no longer valid. Any further use of the VC is prohibited except to reactivate it with a new set of call parameters.

An MCM driver's call to **NdisMCmDeactivateVc** informs NDIS that it has deactivated a VC or changed the call parameters on an established VC (see the following figure). NDIS completes the deactivation sequence by calling the MCM driver's *ProtocolCmDeactivateVcComplete* function.



An MCM driver does not call **NdisMCmDeactivateVc** to deactivate VCs used for exchanging signaling messages between the MCM driver and network components such as a switch. An MCM driver deactivates a signaling VC internally without calling any **Ndis*Xxx*** function.

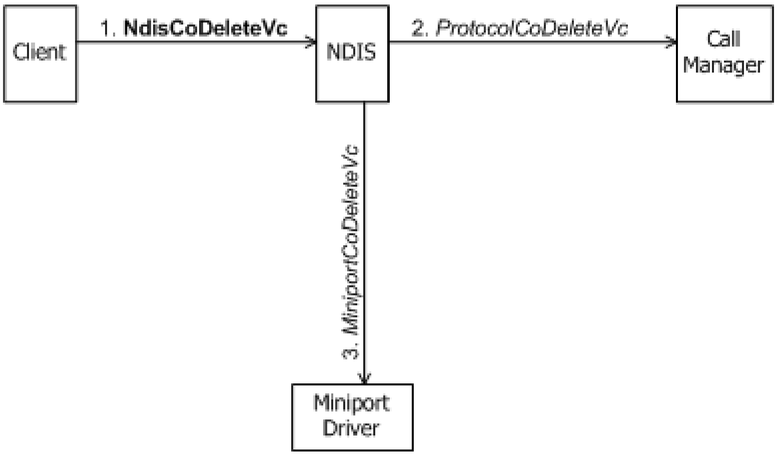
Deleting a VC

Article • 12/15/2021

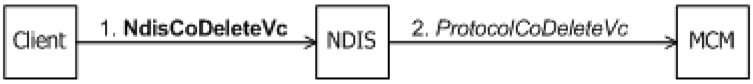
Only the connection-oriented client, call manager, or MCM driver that initiated the creation of a virtual circuit (VC) can initiate the deletion of that VC. A client therefore deletes a VC that it previously created for an outgoing call, a call manager or MCM driver deletes a VC that it previously created for an incoming call over the network, and a call manager deletes a VC that it previously created for exchanging signaling messages over the network. (An MCM driver does not call NDIS to delete a VC that it created for exchanging signaling messages. The MCM driver deletes such a VC with an internal operation that is opaque to NDIS.)

A connection-oriented client or call manager initiates the deletion of a VC with NdisCoDeleteVc.

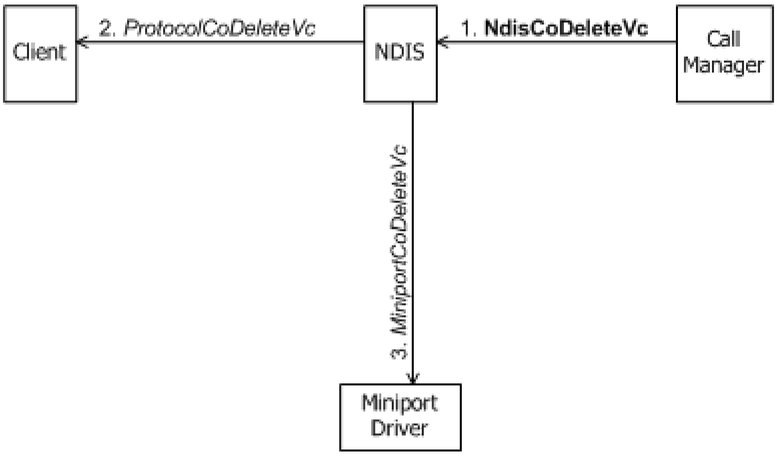
The following figure shows a client of a call manager initiating the deletion of a VC.



The following figure shows a client of an MCM driver initiating the deletion of a VC.



The following figure shows a call manager initiating the deletion of a VC.



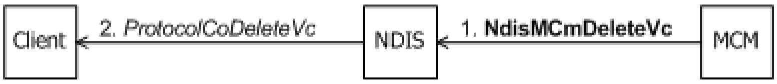
When a client or call manager calls **NdisCoDeleteVc** or when an MCM driver calls **NdisMCmDeleteVc**, there must be no outstanding calls on the given VC and that VC must already have been deactivated. To meet these requirements implies that the following conditions are satisfied:

- The client has already called **NdisClCloseCall** with the given *NdisVcHandle* and its close-call request has completed successfully.
- The call manager has already called **NdisCmDeactivateVc** or the MCM driver has already called **NdisMCmDeactivateVc** with the given *NdisVcHandle* and the deactivation request has completed successfully (see Incoming Request to Close a Call).

A client's or call manager's call to **NdisCoDeleteVc** causes NDIS to call both the underlying miniport driver's **MiniportCoDeleteVc** function and the **ProtocolCoDeleteVc** function of the client or call manager with which the caller shares the *NdisVcHandle* (see the three preceding figures).

MiniportCoDeleteVc frees any resources allocated for the VC, as well as the miniport driver's context for the VC. *ProtocolCoDeleteVc* releases any resources that the client or call manager used to perform operations on and track state for the VC. Both *MiniportCoDeleteVc* and *ProtocolCoDeleteVc* are synchronous functions that cannot return NDIS_STATUS_PENDING.

An MCM driver initiates the deletion of a VC with **NdisMCmDeleteVc**(see the following figure).



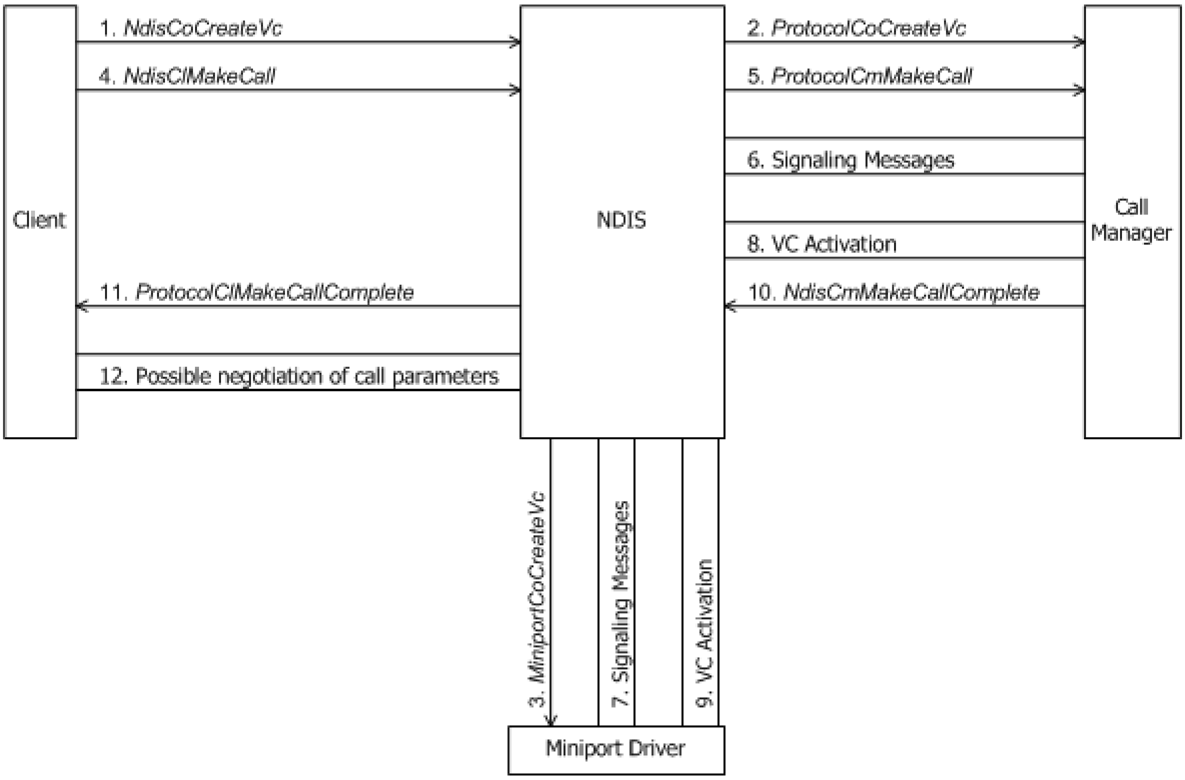
An MCM driver's call to **NdisMCmDeleteVc** causes NDIS to call the **ProtocolCoDeleteVc** function of the client with which the MCM driver shared the *NdisVcHandle* .

When **NdisCoDeleteVc** or **NdisMCmDeleteVc** returns control, the *NdisVcHandle* is no longer valid.

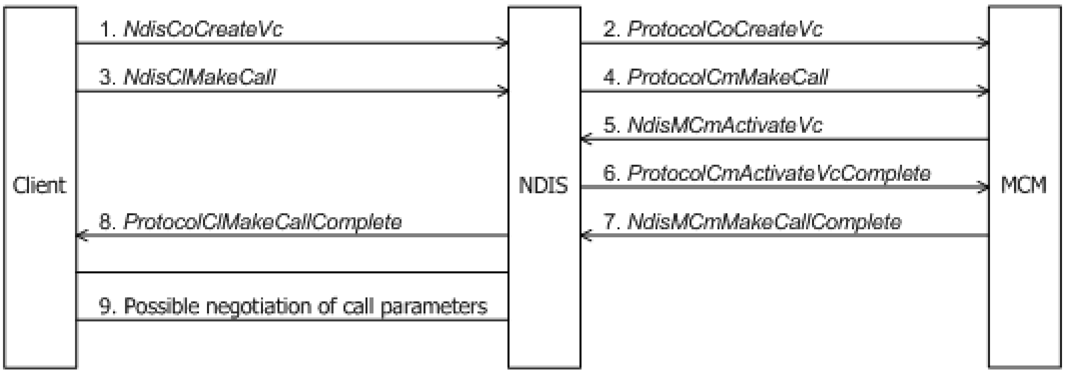
Making a Call

Article • 12/15/2021

The following figure shows a client making an outgoing call through a call manager.



The following figure shows a client making an outgoing call through an MCM driver.



Client
1. NdisCoCreateVc
3. NdisClMakeCall
NDIS
2. ProtocolCoCreateVc
4. ProtocolCmMakeCall
5. NdisMCmActivateVc
6. ProtocolCmActivateVcComplete
MCM
7. NdisMCmMakeCallComplete
8. ProtocolClMakeCallComplete
9. Possible negotiation of call parameters

Before making an outgoing call, a connection-oriented client must:

- Initialize call parameters in a structure of type CO_CALL_PARAMETERS. The call manager or MCM driver typically uses the call parameters the client specifies to set up the call and to derive media parameters for use by the miniport driver.
- Initiate the creation of a VC with NdisCoCreateVc.

On the successful return of **NdisCoCreateVc**, the client calls NdisClMakeCall to initiate the call (see the two figures in this section).

In its call to **NdisClMakeCall**, the client passes a pointer to the CO_CALL_PARAMETERS structure initialized previously. The client also passes an *NdisVcHandle* (returned by **NdisCoCreateVc**) that identifies the VC on which the client will transmit (and perhaps receive) data for the call. If the client is making a multipoint call (a call to more than one remote party), it also passes a *ProtocolPartyContext* that specifies a handle to a client-allocated resident context area in which the client will maintain per-party state for the initial party on the multipoint VC.

The call to **NdisClMakeCall** causes NDIS to forward this request to the **ProtocolCmMakeCall** function of the call manager or MCM driver with which the client shares the given *NdisVcHandle* . *ProtocolCmMakeCall* must validate the input call parameters that were set up by the client.

ProtocolCmMakeCall communicates (exchanges signaling messages) with network control devices to make a connection. A call manager calls **NdisCoSendNetBufferLists** to initiate such an exchange (see Sending NET_BUFFER Structures from CoNDIS Drivers). An MCM driver never calls **NdisCoSendNetBufferLists**. Instead, it transmits the data directly across the network.

The call manager or MCM driver can modify the client-supplied call parameters while negotiating with relevant network components and can return different traffic parameters than the client originally gave to **NdisClMakeCall**(see Incoming Request to Change Call Parameters).

An explicit *NdisPartyHandle* passed to *ProtocolCmMakeCall* indicates that the VC created by the client will be used for a multipoint call. The call manager or MCM driver must allocate and initialize any necessary resources required to maintain per-party state information and control the multipoint call.

After a call manager has done all the necessary communication with its networking hardware as required by its medium, it must call **NdisCmActivateVc** to initiate the activation of the VC on which call data will be sent and perhaps received. An MCM driver must call **NdisMCmActivateVc**.

When the underlying miniport driver is ready to make data transfers on the VC (that is, after the VC has been activated), a call manager calls **NdisCmMakeCallComplete**, and an MCM driver calls **NdisMCmMakeCallComplete**. At this point, the call manager or MCM driver should have negotiated with the network to establish call parameters for the VC, and the underlying miniport driver should have completed activation of the VC.

In the call to **Ndis(M)CmMakeCallComplete**, the call manager or MCM driver passes the call parameters for the VC as a pointer to a structure of type CO_CALL_PARAMETERS. If the call manager has modified the call parameters as originally specified by the client, it can notify the client by setting the CALL_PARAMETERS_CHANGED flag in the CO_CALL_PARAMETERS structure.

A call to **Ndis(M)CmMakeCallComplete** causes NDIS to call the **ProtocolClMakeCallComplete** function of the client that originated the outgoing call. A call to *ProtocolClMakeCallComplete* indicates that the call manager has completed processing the client's request to establish a virtual connection with **NdisClMakeCall**.

If the client's attempt to establish an outgoing call was successful, *ProtocolClMakeCallComplete* should check the CALL_PARAMETERS_CHANGED flag to determine whether the call parameters originally specified by the client were modified. If the flag is set, indicating that the call parameters were changed, *ProtocolClMakeCallComplete* should examine the returned call parameters to determine whether they are acceptable for this connection.

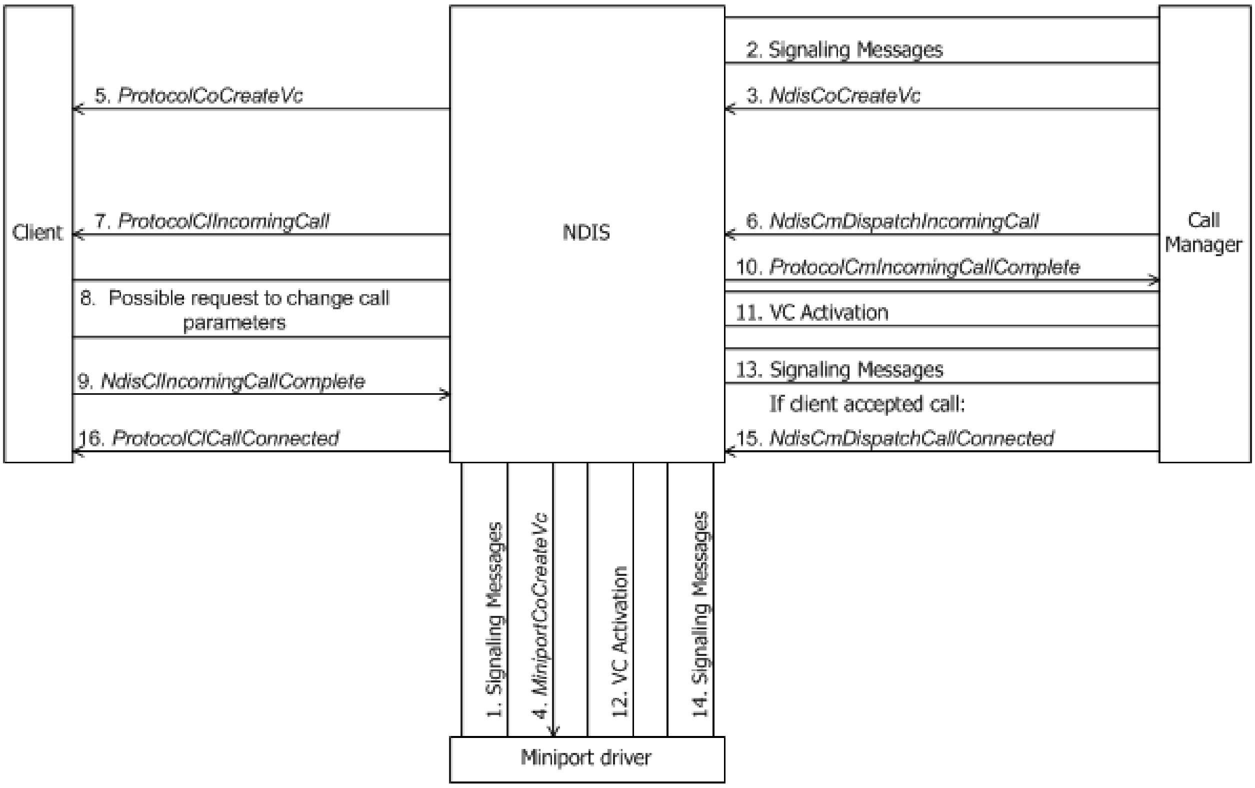
If the call parameters are acceptable, *ProtocolClMakeCallComplete* simply returns control. If the call parameters are not acceptable and if the signaling protocol allows renegotiation at this point, the client can call **NdisClModifyCallQoS** to request a change in call parameters (see Client-Initiated Request to Close a Call). If the signaling protocol does not allow renegotiation of unacceptable call parameters, *ProtocolClMakeCallComplete* must tear down the call with **NdisClCloseCall**(see Client-Initiated Request to Close a Call).

Indicating an Incoming Call

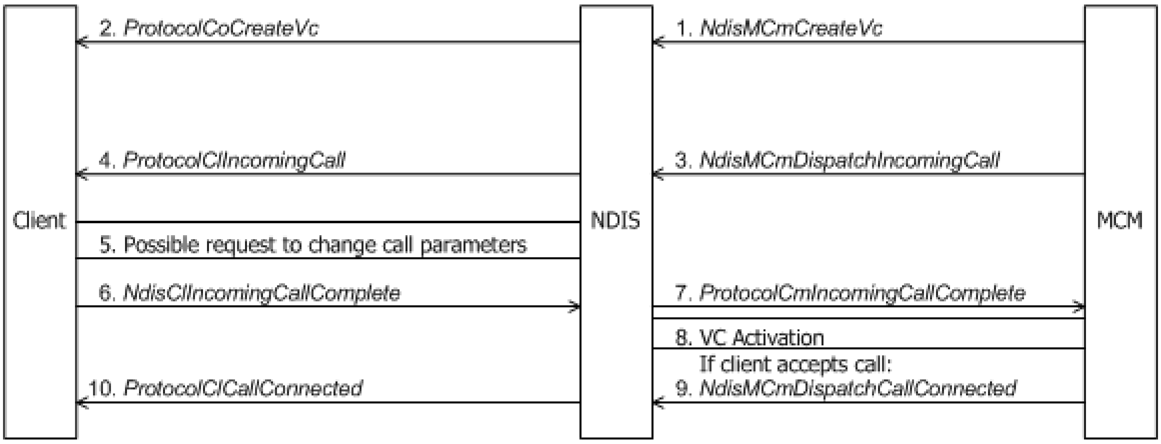
Article • 12/15/2021

A call manager or MCM driver is alerted to an incoming call by signaling messages from the network. From these signaling messages, the call manager or MCM driver extracts the call parameters for the call, including the SAP to which the incoming call is addressed.

The following figure shows an MCM driver indicating an incoming call.



The following figure shows a call manager indicating an incoming call.



Client
NDIS
MCM
1. NdisMCmCreateVc
2. ProtocolCoCreateVc
3. NdisMCmDispatchIncomingCall
4. ProtocolClIncomingCall
5. Possible request to change call parameters
6. NdisClIncomingCallComplete
7. ProtocolCmIncomingCallComplete
8. VC Activation
If client accepts call:
9. NdisMCmDispatchCallConnected
10. ProtocolClCallConnected

If the incoming call parameters are unacceptable to the call manager or MCM driver, it can attempt to negotiate a change in these parameters with the remote party if such negotiation is allowed by the signaling protocol. Alternatively, the client to which the incoming call is directed could attempt to negotiate the call parameters after receiving the call indication from the call manager or MCM driver (see Client-Initiated Request to Change Call Parameters). If the call manager or MCM driver cannot negotiate acceptable call parameters for the call with the remote party, it might refuse the call. The signaling protocol determines what is possible in such cases.

Before indicating an incoming call to a client, the call manager or MCM driver must identify the SAP to which the call is directed. The SAP must have been previously registered by a client. The call manager or MCM driver must also initiate the creation of a VC and initiate the activation of this VC.

The call manager or MCM driver then indicates the incoming call to the client that registered the SAP to which the incoming call is directed. A call manager indicates an incoming call with **NdisCmDispatchIncomingCall**. An MCM driver indicates an incoming call with **NdisMCmDispatchIncomingCall**.

In the call to **Ndis(M)CmDispatchIncomingCall**, the call manager or MCM driver passes the following:

- An *NdisSapHandle* that identifies the SAP to which the incoming call is addressed.

- An *NdisVcHandle* that identifies the virtual circuit for the incoming call.

- A pointer to a structure of type **CO_CALL_PARAMETERS**, which contains the call parameters for the call.

The call to **Ndis(M)CmDispatchIncomingCall** causes NDIS to call the client's **ProtocolClIncomingCall** function, within which the client either accepts or rejects the requested connection. *ProtocolClIncomingCall* should validate the SAP, VC, and call parameters.

ProtocolClIncomingCall can complete synchronously or it can return NDIS_STATUS_PENDING and complete asynchronously with **NdisClIncomingCallComplete**. A call to **NdisClIncomingCallComplete** causes NDIS to call the call manager's or MCM driver's **ProtocolCmIncomingCallComplete** function.

The NDIS_STATUS code that is returned by a synchronous completion of *ProtocolClIncomingCall* or supplied to **NdisClIncomingCallComplete** indicates the client's acceptance or rejection of the incoming call. The client also returns the call parameters for the call in a buffered CO_CALL_PARAMETERS structure. If the client finds the call parameters unacceptable, it can, if allowed by the signaling protocol, request a change in the call parameters by setting the **Flags** member in the CO_CALL_PARAMETERS structure with CALL_PARAMETERS_CHANGED and by supplying the revised call parameters in a buffered CO_CALL_PARAMETERS structure.

If the client accepts the incoming call, the call manager or MCM driver should send signaling messages to indicate to the calling entity that the call has been accepted. Otherwise, the call manager or MCM driver should send signaling messages to indicate that the call has been rejected. If the client is requesting a change in call parameters, the call manager or MCM driver sends signaling messages to request a change in call parameters.

If the client accepted the call, or if the client's requested change in call parameters was accepted by the remote party, a call manager calls **NdisCmDispatchCallConnected**, and an MCM driver calls **NdisMCmDispatchCallConnected**. The call to **Ndis(M)CmDispatchCallConnected** causes NDIS to call the client's *ProtocolClCallConnected* function.

If the client rejected the call and the call manager or MCM driver has already activated a VC for the incoming call, the call manager or MCM driver calls **Ndis(M)CmDeactivateVc** to deactivate the VC if the VC is activated. The call manager or MCM driver can then initiate deletion of the VC by calling **NdisCoDeleteVc** in the case of the call manager or **NdisMCmDeleteVc** in the case of the MCM driver.

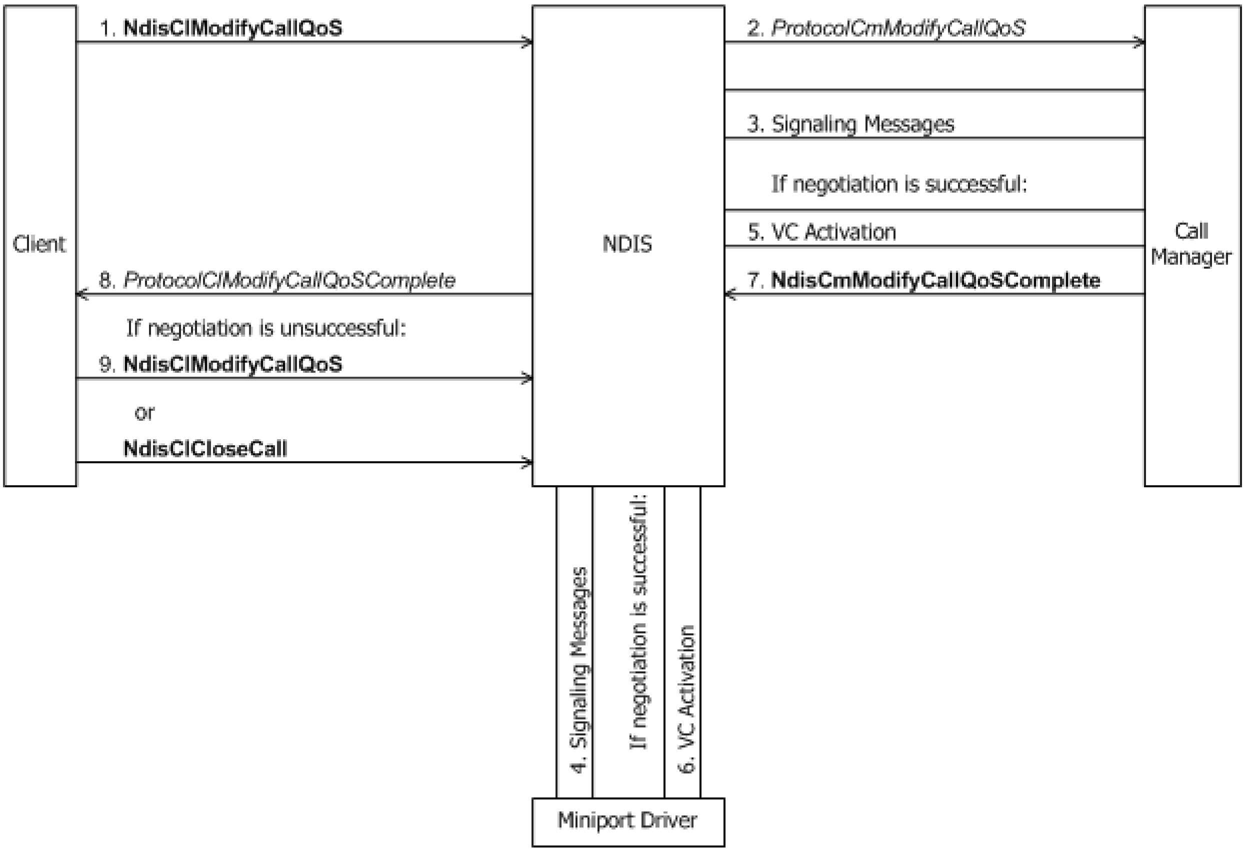
If the client accepted the call but the end-to-end connection was not successfully established (because, for example, the remote party tore down the call), the call manager or MCM driver will not call **Ndis(M)CmDispatchCallConnected**. Instead, it will call **Ndis(M)CmDispatchIncomingCloseCall**, which causes NDIS to call the client's *ProtocolClIncomingCloseCall* function. The client must then call **NdisClCloseCall** to complete the teardown of the call. The call manager or MCM driver then calls **Ndis(M)CmDeactivateVC** to deactivate the VC that it created for the incoming call. The call manager or MCM driver can then initiate deletion of the VC by calling **NdisCoDeleteVc** in the case of the call manager or **NdisMCmDeleteVc** in the case of the MCM driver.

Client-Initiated Request to Change Call Parameters

Article • 12/15/2021

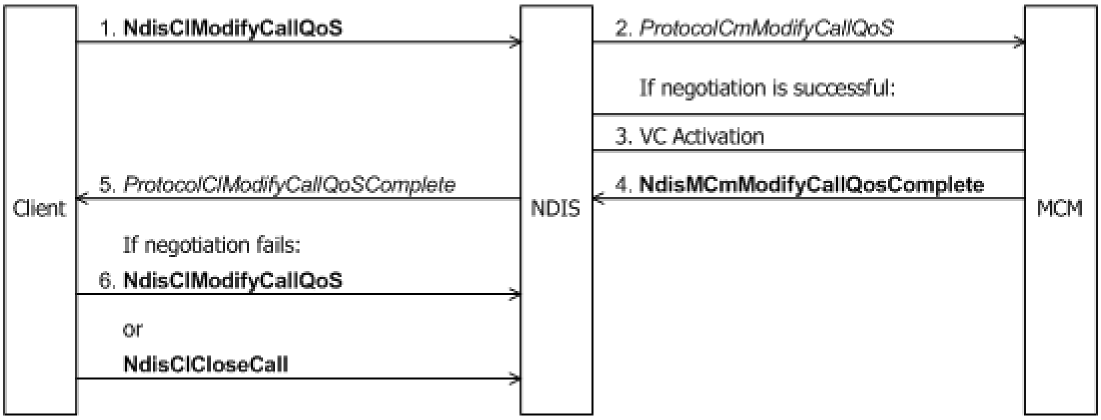
A client requests a change in quality of service (QoS) on an active virtual connection (VC) with NdisClModifyCallQoS.

The following figure shows the client of a call manager requesting a change in quality of service.



Client
NDIS
Call Manager
Miniport Driver
1. NdisClModifyCallQoS
2. ProtocolCmModifyCallQoS
3. Signaling Messages
If negotiation is successful:
5. VC Activation
7. NdisCmModifyCallQoSComplete
8. ProtocolClModifyCallQoSComplete
If negotiation is unsuccessful:
9. NdisClModifyCallQoS
or
NdisClCloseCall
4. Signaling Messages
If negotiation is successful:
6. VC Activation

The following figure shows the client of an MCM driver requesting a change in quality of service.



Client
NDIS
MCM
1. NdisClModifyCallQoS
2. ProtocolCmModifyCallQoS
If negotiation is successful:
3. VC Activation
4. NdisMCmModifyCallQosComplete
5. ProtocolClModifyCallQoSComplete
If negotiation fails:
6. NdisClModifyCallQoS
or
NdisClCloseCall

In the call to **NdisClModifyCallQoS**, the client supplies:

- An *NdisVcHandle* parameter that identifies the VC.

- A pointer to a CO_CALL_PARAMETERS structure that contains the call parameters the client is requesting.

The circumstances under which a client can request a change in QoS are determined by the signaling protocol.

The call to **NdisClModifyCallQoS** causes NDIS to call the call manager's or MCM driver's ProtocolCmModifyCallQoS function, which inputs the *NdisVcHandle* and buffered CO_CALL_PARAMETERS structure that the client passes to **NdisClModifyCallQoS**. **ProtocolCmModifyQoS** communicates with network control devices or other media-specific agents, as necessitated by its media, to modify the media-specific call parameters for an established virtual connection.

After communicating with the network and determining that the changes were successful, a call manager must call NdisCmActivateVc(and an MCM driver must call NdisMCmActivateVc) to activate the specified VC with the new call parameters.

If the network does not accept the new call parameters or if the underlying miniport driver cannot accept the parameters, the call manager or MCM driver must restore the VC to the state that existed before any modifications were attempted, and return NDIS_STATUS_FAILURE.

To indicate the status of the client's request to change QoS, a call manager calls NdisCmModifyCallQoSComplete, and an MCM driver calls NdisMCmModifyCallQoSComplete. In this call, the call manager or MCM driver passes:

- An NDIS_STATUS that indicates the status of the request.

- An *NdisVcHandle* that identifies the VC.

- A pointer to a CO_CALL_PARAMETERS structure that contains the call parameters for the VC.

If allowed by the signaling protocol, the call manager or MCM driver can pass modified call parameters back to the client. These modifications can be the product of negotiation with the network or they can be supplied by the call manager or MCM driver itself. A call manager or MCM driver should indicate that the call parameters have been modified by setting the CALL_PARAMETERS_CHANGED flag in the CO_CALL_PARAMETERS structure.

The call to **Ndis(M)CmModifyCallQoSComplete** causes NDIS to call the client's ProtocolClModifyCallQoSComplete function. NDIS passes the following to *ProtocolClModifyCallQoSComplete*:

- An NDIS_STATUS that indicates the status of the client's request to change the QoS.
- A *ProtocolVcContext* handle that identifies the VC.
- A pointer to a CO_CALL_PARAMETERS structure that contains the call parameters that are passed by the call manager or MCM driver to **Ndis(M)CmModifyCallQoSComplete**.

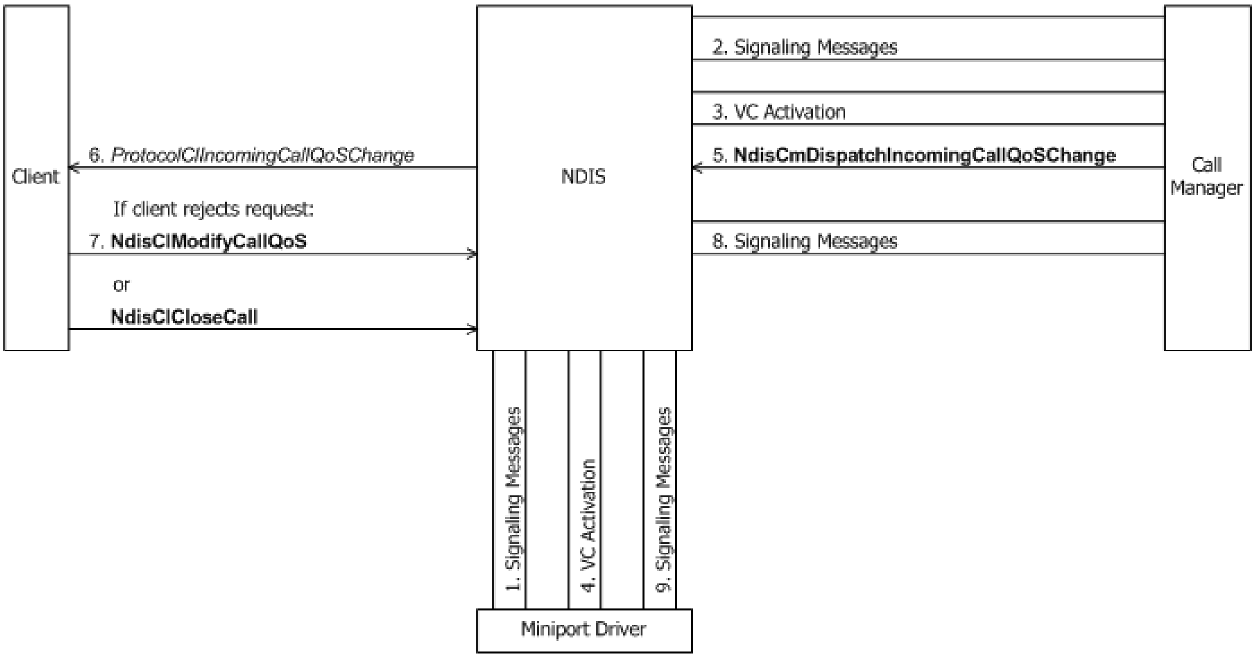
If the CALL_PARAMETERS_CHANGED flag is set in the CO_CALL_PARAMETERS structure, the client must examine the returned call parameters and determine whether the modifications are acceptable. If the client's call to **NdisClModifyCallQoS** succeeds, *ProtocolClModifyCallQoSComplete* can accept the QoS change by simply returning control. Otherwise, *ProtocolClModifyCallQoSComplete* can engage in further negotiation with the call manager if allowed by the signaling protocol and as long as the client's developer places some reasonable limit on the number of possible renegotiations. Alternatively, *ProtocolClModifyCallQoSComplete* can simply tear down the call with **NdisClCloseCall**(see Client-Initiated Request to Close a Call) whenever the call manager rejects a request to change the QoS and the previously established QoS has become unacceptable to the client.

Incoming Request to Change Call Parameters

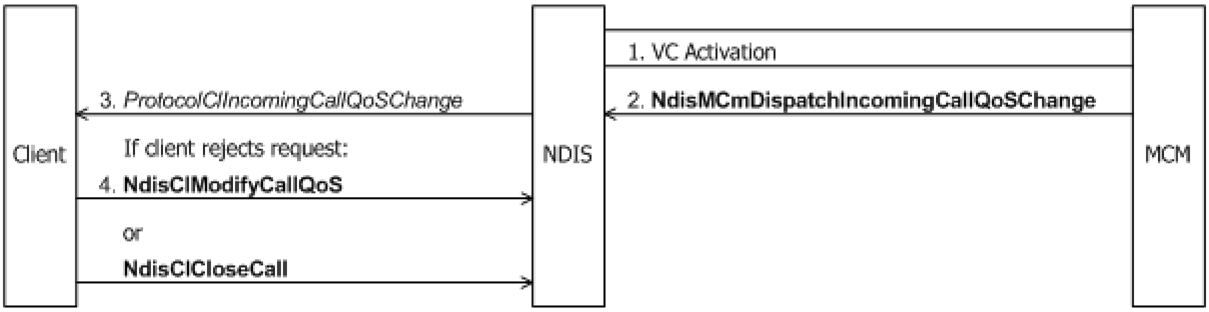
Article • 12/15/2021

A call manager or MCM driver is alerted to an incoming request from a remote party to change the call parameters on an active VC by signaling messages from the network. Whether a call manager or MCM driver supports dynamic QoS changes on active calls depends on the signaling protocol.

The following figure shows an incoming request through a call manager to change call parameters.



The following figure shows an incoming request through an MCM driver to change call parameters.



Client
NDIS
MCM
1. VC Activation
2. NdisMCmDispatchIncomingCallQoSChange
3. ProtocolClIncomingCallQoSChange
If client rejects request:
4. NdisClModifyCallQoS
or
NdisClCloseCall

After receiving an incoming request to change call parameters, a call manager passes appropriately modified call parameters to NdisCmActivateVc to notify the underlying miniport driver of the proposed QoS change. An MCM driver passes modified call parameters to NdisMCmActivateVc(see Activating a VC). If the underlying miniport driver accepts the changed call parameters, a call manager then calls

NdisCmDispatchIncomingCallQosChange(see Incoming Request to Change Call Parameters). An MCM driver calls **NdisMCmDispatchIncomingCallQosChange**(see Incoming Request to Change Call Parameters). The call manager or MCM driver passes an *NdisVcHandle* and a buffered **CO_CALL_PARAMETERS** structure to **Ndis(M)CmDispatchIncomingCallQoSChange**.

A call to **Ndis(M)CmDispatchIncomingCallQoSChange** causes NDIS to call the client's *ProtocolClIncomingCallQoSChange* function. NDIS passes a *ProtocolVcContext* handle that identifies the VC and the modified call parameters in a buffered CO_CALL_PARAMETERS structure to *ProtocolClIncomingCallQoSChange*.

The client accepts the proposed modifications to the call parameters for the VC by doing nothing, except possibly updating any state it maintains about the QoS for the VC, and returning control. If the proposed modifications are unacceptable, the client can attempt to renegotiate the call parameters with **NdisClModifyCallQoS** if allowed by the signaling protocol (see Client-Initiated Request to Change Call Parameters). Otherwise, the client rejects the proposed QoS change by tearing down the call with **NdisClCloseCall**(see Client-Initiated Request to Close a Call).

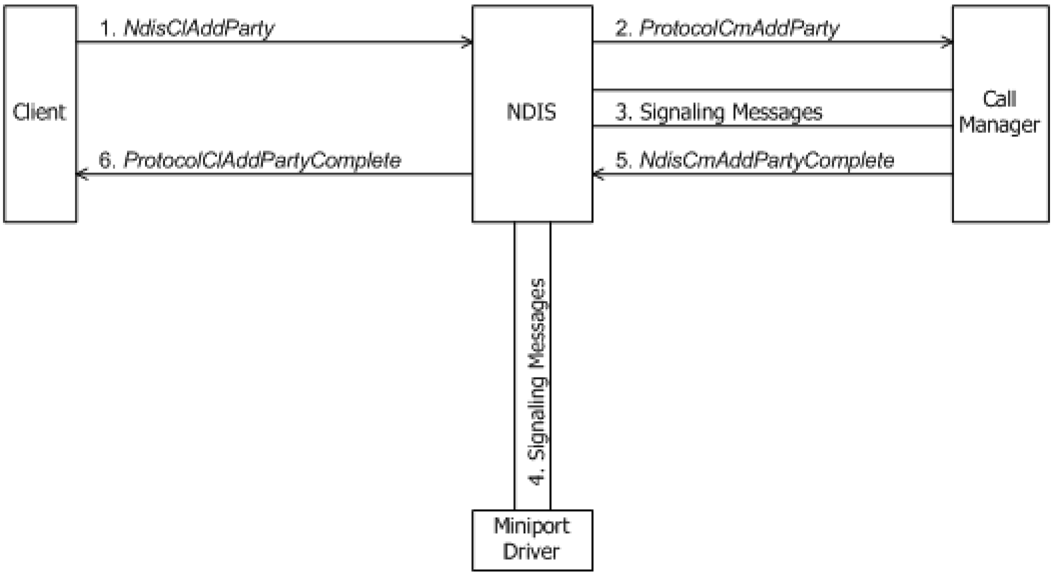
After **ProtocolClIncomingCallQoS** returns, the call manager or MCM driver communicates the client's acceptance or rejection of the proposed change to the remote party that originated the request.

Adding a Party to a Multipoint Call

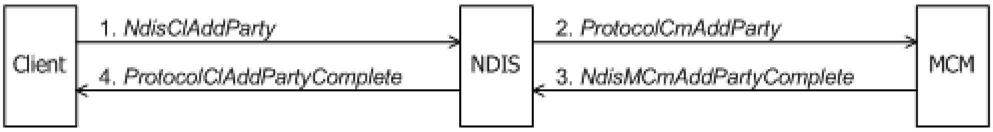
Article • 12/15/2021

A client requests to add a party to a multipoint call with **NdisClAddParty**. A client can add a party only to an existing multipoint call--that is, a call for which the client supplied a *ProtocolPartyContext* to **NdisClMakeCall**(see Making a Call).

The following figure shows a client of a call manager requesting to add a party to multipoint call.



The following figure shows a client of an MCM driver requesting to add a party to multipoint call.



Before it calls **NdisClAddParty**, a client must allocate and initialize its context area for the party to be added. Clients commonly pass a pointer to such a context area as the *ProtocolPartyContext* and a pointer to a variable within that context area as the *NdisPartyHandle* parameters when they call **NdisClAddParty**.

In addition to an *NdisVcHandle* and a *ProtocolPartyContext*, the client passes call parameters (a buffered **CO_CALL_PARAMETERS** structure) to **NdisClAddParty**. The underlying network medium determines whether a client can specify per-party traffic parameters on a multipoint VC.

The call to **NdisClAddParty** causes NDIS to forward this request to the **ProtocolCmAddParty** function of the call manager or MCM driver with which the client shares the given *NdisVcHandle* . NDIS passes the following to the *ProtocolCmAddParty*:

- A *CallMgrVcContext* that indicates the VC for the call.
- A pointer to a CO_CALL_PARAMETERS structure that contains the call parameters that the client passes to **NdisClAddParty**.
- An *NdisPartyHandle* that identifies the party to be added.

ProtocolCmAddParty allocates and initializes any dynamic resources needed for the party being added to the call. From *ProtocolCmAddParty*, a call manager or MCM driver communicates with network control devices or other media-specific agents, as necessary, to add the specified party to the multipoint call.

If the client passed in call parameters that did not match those already established for the multipoint VC, the call manager or MCM driver can, for example:

- Set up the per-party traffic parameters if the underlying network medium supports this feature on multipoint VCs.
- Reset the client-supplied traffic parameters to those originally established for the VC.
- Change the call parameters for the VC and for every party currently connected on it.
- Fail the client's attempt to add a party.

ProtocolCmAddParty can complete synchronously or, more probably, asynchronously with **NdisCmAddPartyComplete**, in the case of a call manager, or **NdisMCmAddPartyComplete**, in the case of an MCM driver. Whether the call manager or MCM driver completes the operation synchronously or asynchronously, it passes the buffered call parameters to NDIS.

The call to **Ndis(M)CmAddPartyComplete** causes NDIS to call the client's **ProtocolClAddPartyComplete** function. If the client's request to add the party succeeded and if the signaling protocol allows the call manager or MCM driver to modify the call parameters, *ProtocolClAddPartyComplete* should test the CALL_PARAMETERS_CHANGED flag in the buffered CO_CALL_PARAMETERS structure to determine whether the call parameters were modified. The signaling protocol determines what the client can do if it finds the modifications to CO_CALL_PARAMETERS unacceptable. Usually, a client calls **NdisClDropParty** in this case (see Dropping a Party from a Multipoint Call).

Dropping a Party from a Multipoint Call

Article • 12/15/2021

A connection-oriented client that serves as the root of a multipoint call must eventually drop each party from that call with **NdisClDropParty** or **NdisClCloseCall**.

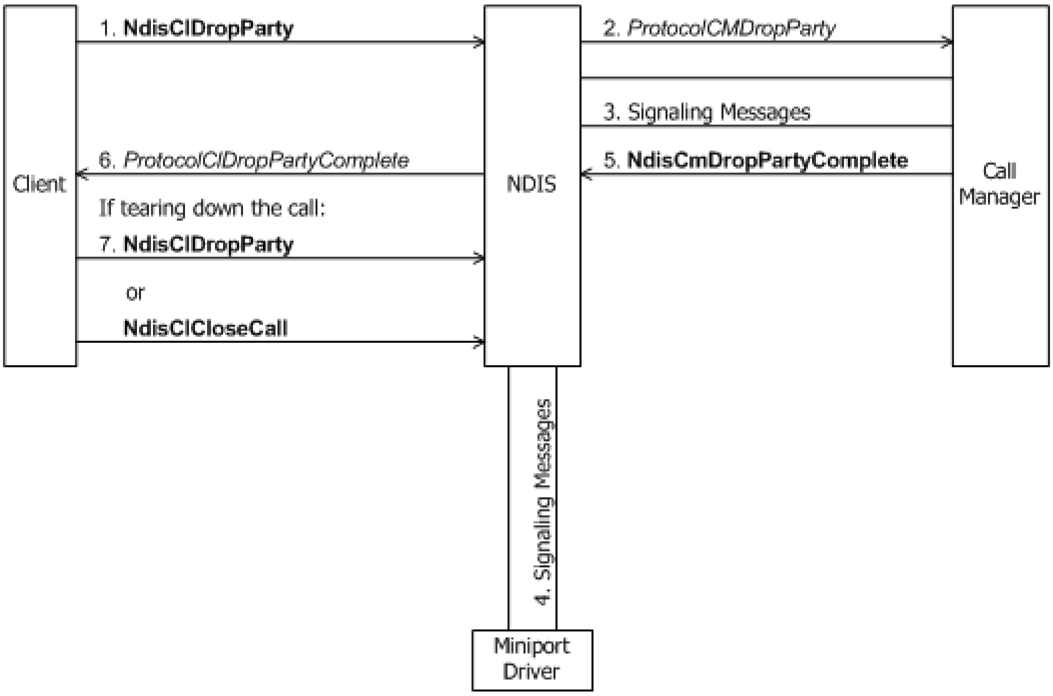
A client drops a party from a call in the following situations:

- Before initiating the tear down of a multipoint call with **NdisClCloseCall**(see Client-Initiated Request to Close a Call), a client must drop all but the last party with successive calls to **NdisClDropParty**. The client specifies the last party to drop from the call with **NdisClCloseCall**.

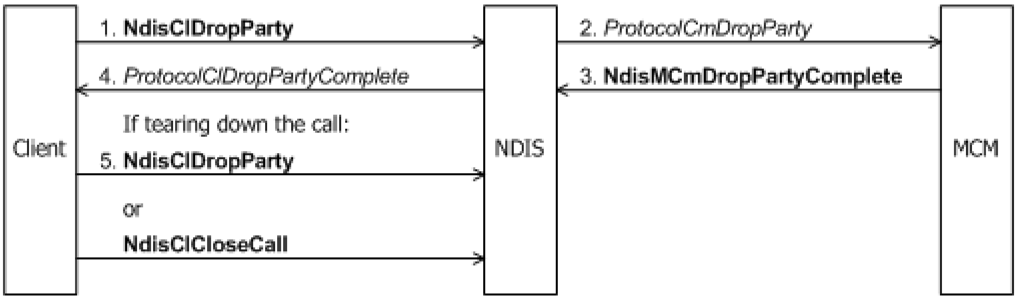
- In response to a remote party's request to be dropped from a multipoint call (see Incoming Request to Drop a Party from a Multipoint Call), a client, from its **ProtocolClIncomingDropParty** function, calls **NdisClDropParty**.

A client's call to **NdisClDropParty** causes NDIS to call the **ProtocolCmDropParty** function of the call manager or MCM driver that shares the same *NdisVcHandle* to the multipoint VC.

The following figure shows the client of a call manager requesting to drop a party from a multipoint call.



The next figure shows the client of an MCM driver requesting to drop a party from a multipoint call.



ProtocolCmDropParty communicates with network control devices to drop a party from an existing multipoint call. NDIS can pass to *ProtocolCmDropParty* a pointer to a buffer that contains data (supplied to the client in the call to **NdisClDropParty**). *ProtocolCmDropParty* must send any such data across the network before the connection is dropped.

ProtocolCmDropParty can complete synchronously, or more probably, asynchronously with **NdisCmDropPartyComplete**, in the case of a call manager, or **NdisMCmDropPartyComplete**, in the case of an MCM driver.

The call to **Ndis(M)CmDropPartyComplete** causes NDIS to call the client's **ProtocolClDropPartyComplete** function. If the client is in the process of tearing down a multipoint VC that it created, *ProtocolClDropPartyComplete* can call **NdisClDropParty** with any valid *NdisPartyHandle* to one of the remaining parties on the client's active multipoint VC. If only one party remains on its multipoint VC, the client should drop that party by passing its *NdisPartyHandle* to **NdisClCloseCall**(see Client-Initiated Request to Close a Call).

Incoming Request to Drop a Party from a Multipoint Call

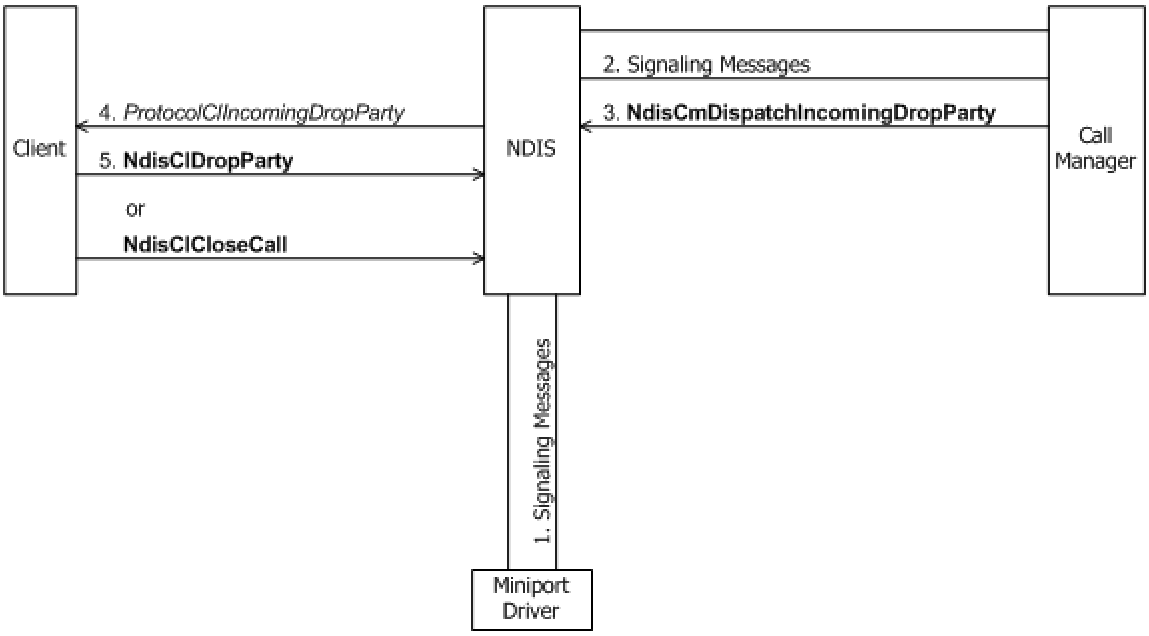
Article • 12/15/2021

A call manager or MCM driver is alerted to an incoming request from a remote party to drop that party from a multipoint call by signaling messages from the network. A call manager or MCM driver can also signal an incoming request to drop a party if it detects network problems that prevent further data transfers on the VC.

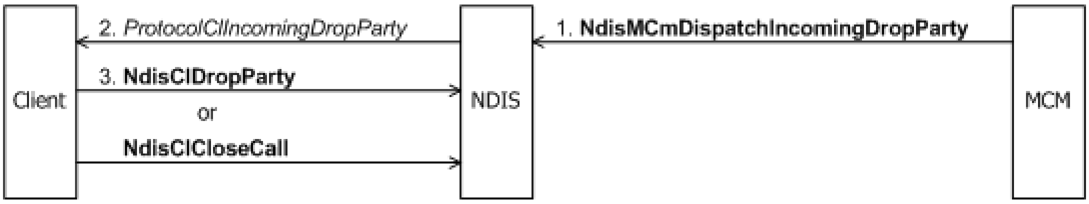
If the party that is being dropped from the call is not the last party on the VC, a call manager calls **NdisCmDispatchIncomingDropParty**. An MCM driver calls **NdisMCmDispatchIncomingDropParty**. If the party that is being dropped is the last party on the VC, a call manager calls **NdisCmDispatchIncomingCloseCall**, and an MCM driver calls **NdisMCmDispatchIncomingCloseCall**(see Incoming Request to Close a Call).

A call to **Ndis(M)CmDispatchIncomingDropParty** causes NDIS to call the client's **ProtocolClIncomingDropParty** function.

The following shows an incoming request through a call manager to drop a party through a multipoint call.



The next figure shows an incoming request through an MCM driver to drop a party through a multipoint call.



Client
2. *ProtocolClIncomingDropParty*
3. **NdisClDropParty**
or
NdisClCloseCall
NDIS
1. **NdisMCmDispatchIncomingDropParty**
MCM

ProtocolClIncomingDropParty should carry out any protocol-determined operations for dropping the party from the client's multipoint VC. If the party that is being dropped is not the last party on the VC, *ProtocolClIncomingDropParty* must call **NdisClDropParty**(see Dropping a Party from a Multipoint Call). If the party being dropped is the last party on the VC, *ProtocolClIncomingDropParty* must call **NdisClCloseCall**(see Client-Initiated Request to Close a Call).

Sending and receiving data in CoNDIS

Article • 03/14/2023

Transferring data involves sending or receiving packets over an established and activated VC.

Note Protocol drivers must not call **NdisCoSendNetBufferLists** to send data to a VC after calling **NdisClCloseCall** for that VC.

The CoNDIS send and receive functions are similar to connectionless send and receive functions. The primary difference between the CoNDIS and connectionless interfaces is the management of virtual connections (VCs). For more information about connectionless send and receive operations, see Send and Receive Operations.

In a single function call, CoNDIS drivers can send multiple **NET_BUFFER_LIST** structures with multiple **NET_BUFFER** structures on each NET_BUFFER_LIST structure. Also, CoNDIS drivers can indicate completed send operations for multiple NET_BUFFER_LIST structures with multiple NET_BUFFER structures on each NET_BUFFER_LIST structure.

In the receive path, CoNDIS miniport drivers can provide a list of NET_BUFFER_LIST structures to indicate receives. Each NET_BUFFER_LIST that a miniport driver provides contains one NET_BUFFER structure. Because a different protocol binding can process each NET_BUFFER_LIST structure, NDIS can independently return each NET_BUFFER_LIST structure to the miniport driver.

To support NDIS 5.*x* and earlier drivers, CoNDIS provides a translation layer between legacy **NDIS_PACKET** structures and the NET_BUFFER-based structures. CoNDIS performs the necessary conversion between NET_BUFFER structures and NDIS_PACKET structures. To avoid degrading performance because of the translation, CoNDIS drivers must be updated to support NET_BUFFER structures and should support multiple NET_BUFFER_LIST structures in all data paths.

This section includes the following topics:

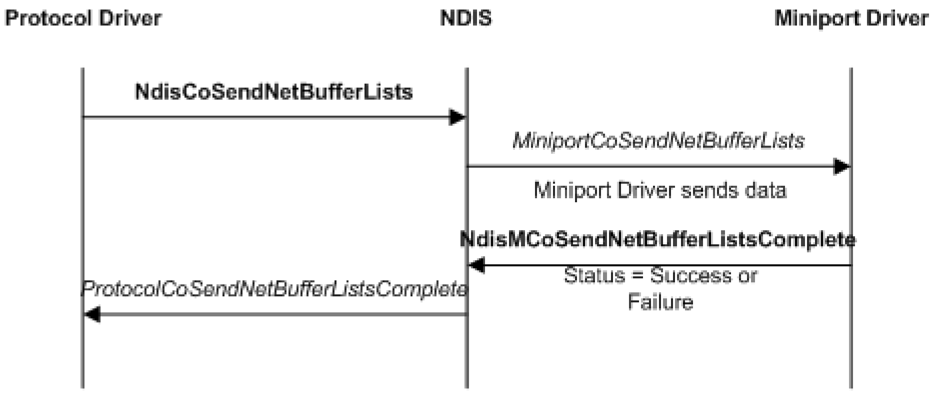
Sending NET_BUFFER Structures from CoNDIS Drivers

Receiving NET_BUFFER Structures in CoNDIS Drivers

Sending NET_BUFFER Structures from CoNDIS Drivers

Article • 03/14/2023

The following figure illustrates a basic CoNDIS send operation, which involves a protocol driver, NDIS, and a miniport driver.



Protocol Driver
NDIS
Miniport Driver
NdisCoSendNetBufferLists
MiniportCoSendNetBufferLists
Miniport Driver sends data
NdisMCoSendNetBufferListsComplete
Status = Success or Failure
ProtocolCoSendNetBufferListsComplete

As the preceding figure shows, protocol drivers call the NdisCoSendNetBufferLists function to send NET_BUFFER_LIST structures on a virtual connection (VC). NDIS then calls the miniport driver's MiniportCoSendNetBufferLists function to forward the NET_BUFFER_LIST structures to an underlying miniport driver.

All NET_BUFFER-based send operations are asynchronous. Therefore, the miniport driver always calls the NdisMCoSendNetBufferListsComplete function and provides an appropriate status code when it is done sending the data. The miniport driver can complete the send operation for each NET_BUFFER_LIST structure independent of other NET_BUFFER_LIST structures. NDIS calls the protocol driver's ProtocolCoSendNetBufferListsComplete function each time the miniport driver calls **NdisMCoSendNetBufferListsComplete**.

Protocol drivers can reclaim the ownership of the NET_BUFFER_LIST structures and all associated structures and data as soon as NDIS calls the protocol driver's *ProtocolCoSendNetBufferListsComplete* function.

The miniport driver or NDIS can return the NET_BUFFER_LIST structures in any order. But protocol drivers are guaranteed that the list of NET_BUFFER structures that are attached to each NET_BUFFER_LIST structure has not been modified.

Protocols drivers set the **SourceHandle** member in the NET_BUFFER_LIST structure to the same value as the *NdisVcHandle* parameter of **NdisCoSendNetBufferLists**. NDIS uses the **SourceHandle** member to return the NET_BUFFER_LIST structures to the protocol driver that sent the NET_BUFFER_LIST structures.

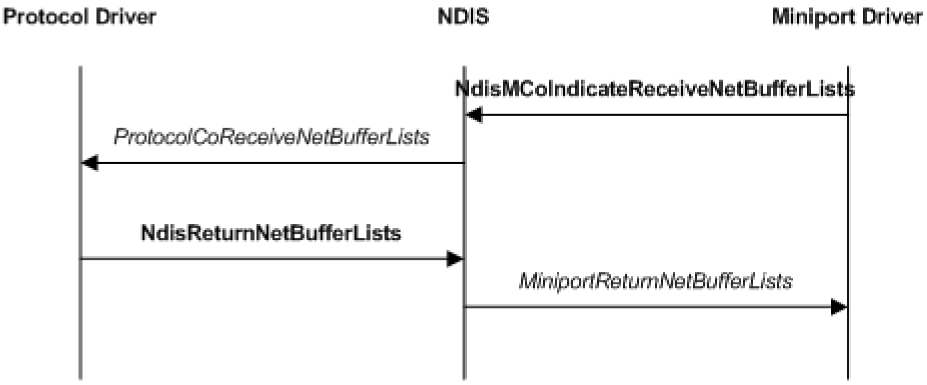
Intermediate drivers also set the **SourceHandle** member in the NET_BUFFER_LIST structure to the *NdisVcHandle* value. If an intermediate driver forwards a send request, the driver must save the **SourceHandle** value that the overlying driver provided before it writes to the **SourceHandle** member. When NDIS returns a forwarded NET_BUFFER_LIST structure to the intermediate driver, the intermediate driver must restore the **SourceHandle** that it saved.

Protocol drivers can cancel send requests by using the same mechanisms as connectionless drivers. For more information about canceling send requests, see Canceling a Send Operation.

Receiving NET_BUFFER Structures in CoNDIS Drivers

Article • 03/14/2023

The following figure illustrates a basic CoNDIS receive operation, which involves a protocol driver, NDIS, and a miniport driver.



Protocol Driver
NDIS
Miniport Driver
NdisMCoIndicateReceiveNetBufferLists
ProtocolCoReceiveNetBufferLists
NdisReturnNetBufferLists
MiniportReturnNetBufferLists

As the preceding figure shows, miniport drivers call the **NdisMCoIndicateReceiveNetBufferLists** function to indicate **NET_BUFFER** structures to overlying drivers. In most miniport drivers, each NET_BUFFER structure is attached to a separate **NET_BUFFER_LIST** structure, so protocol drivers can create a subset of the original list of NET_BUFFER_LIST structures and forward them to different clients. However, the number of NET_BUFFER structures that are attached to a NET_BUFFER_LIST depends on the driver.

After the miniport driver links all the NET_BUFFER_LIST structures, the miniport driver passes a pointer to the first NET_BUFFER_LIST structure in the list to the **NdisMCoIndicateReceiveNetBufferLists** function. NDIS examines the NET_BUFFER_LIST structures and calls the **ProtocolCoReceiveNetBufferLists** function of the protocol driver that is associated with the specified virtual connection (VC). NDIS passes a subset of the list that includes only the NET_BUFFER_LIST structures that are associated with the correct binding to each protocol driver.

If the NDIS_RECEIVE_FLAGS_STATUS_RESOURCES flag is set in the *CoReceiveFlags* parameter for a protocol driver's *ProtocolCoReceiveNetBufferLists* function, NDIS regains ownership of the **NET_BUFFER_LIST** structures immediately after *ProtocolCoReceiveNetBufferLists* returns.

If the NDIS_RECEIVE_FLAGS_STATUS_RESOURCES flag is not set in the *CoReceiveFlags* parameter for a protocol driver's **ProtocolCoReceiveNetBufferLists** function, the protocol driver can retain ownership of the NET_BUFFER_LIST structures. In this case, the protocol driver must return the NET_BUFFER_LIST structures by calling the NdisReturnNetBufferLists function.

If a miniport driver runs low on receive resources, it can set the NDIS_RECEIVE_FLAGS_STATUS_RESOURCES flag in the *CoReceiveFlags* parameter for the NdisMCoIndicateReceiveNetBufferLists function. In that case, the driver can reclaim ownership of all of the indicated NET_BUFFER_LIST structures and embedded NET_BUFFER structures as soon as **NdisMCoIndicateReceiveNetBufferLists** returns. If a miniport driver indicates NET_BUFFER structures with the NDIS_RECEIVE_FLAGS_RESOURCES flag set, the protocol drivers must copy the data, so you should avoid using NDIS_RECEIVE_FLAGS_RESOURCES in this way. A miniport driver should detect when it has low receive resources and should complete any steps that are necessary to avoid this situation.

NDIS calls a miniport driver's *MiniportReturnNetBufferLists* function after the protocol driver calls **NdisReturnNetBufferLists**.

Note If a miniport driver indicates a NET_BUFFER_LIST structure with a given status, NDIS is not required to indicate the NET_BUFFER_LIST structure to the overlying drivers with the same status. For example, NDIS could copy a NET_BUFFER_LIST structure with the NDIS_RECEIVE_FLAGS_RESOURCES flag set and indicate the copy to the overlying drivers with this flag cleared.

NDIS can return NET_BUFFER_LIST structures to the miniport driver in any arbitrary order and in any combination. That is, the linked list of NET_BUFFER_LIST structures that NDIS returns to a miniport driver by calling *MiniportReturnNetBufferLists* can have NET_BUFFER_LIST structures from different previous calls to NdisMCoIndicateReceiveNetBufferLists.

Miniport drivers must set the **SourceHandle** member in the NET_BUFFER_LIST structures to the same value as the *NdisVcHandle* parameter of **NdisMCoIndicateReceiveNetBufferLists**. so that NDIS can return the NET_BUFFER_LIST structures to the correct miniport driver.

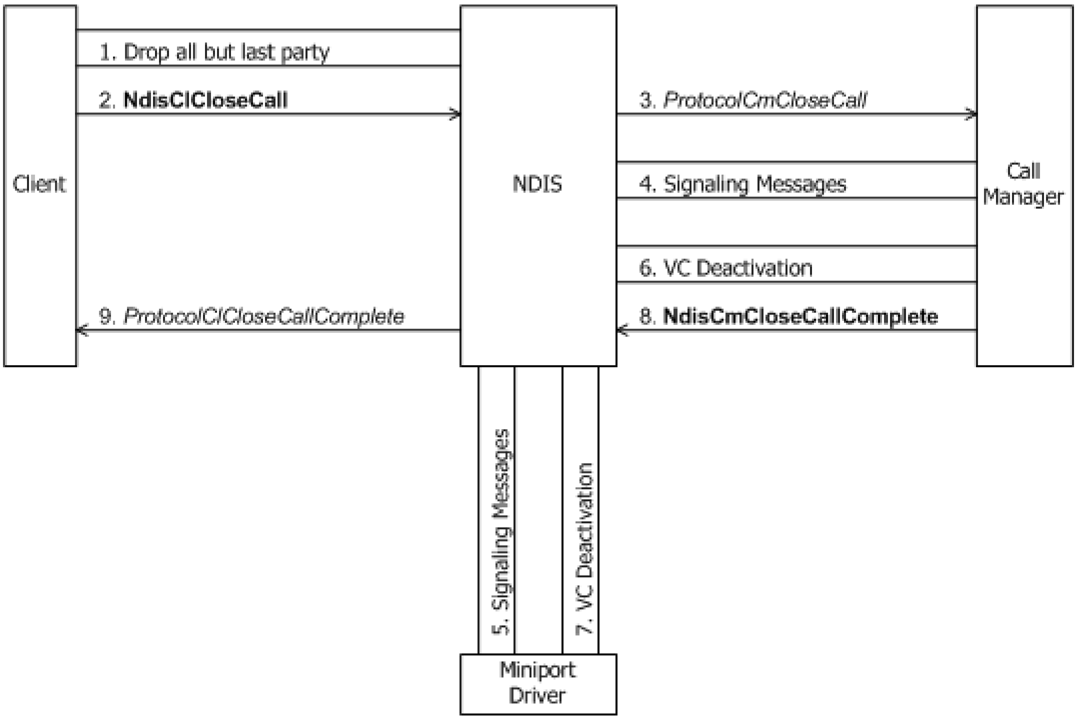
Intermediate drivers also set the **SourceHandle** member in the NET_BUFFER_LIST structure to the *NdisVcHandle* value. If an intermediate driver forwards a receive indication, the driver must save the **SourceHandle** value that the underlying driver provided before it writes to the **SourceHandle** member. When NDIS returns a forwarded NET_BUFFER_LIST structure to the intermediate driver, the intermediate driver must restore the **SourceHandle** that it saved.

Client-Initiated Request to Close a Call

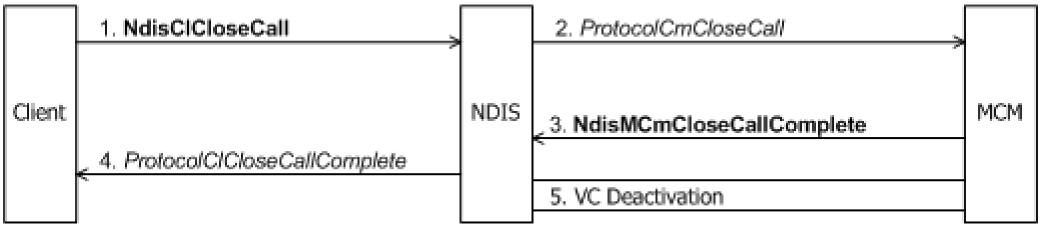
Article • 12/15/2021

If a client is closing a multipoint call to which more than one party is still connected, it must first call **NdisClDropParty** as many times as necessary to drop all but the last party from the call (see Dropping a Party from a Multipoint Call).

A client initiates the closing of a call with **NdisClCloseCall**. The following figure shows a client initiating the closing of a call through a call manager.



The next figure shows a client initiating the closing of a call through an MCM driver.



A connection-oriented client typically calls **NdisClCloseCall** in any one of the following circumstances:

- To close an established outgoing or incoming call.
- From the **ProtocolClIncomingCloseCall** function to tear down an established call (see Incoming Request to Close a Call).
- From the *ProtocolClIncomingCallQoSChange* function to tear down an established call if a QoS change that the remote party proposes is unacceptable (see Incoming

Request to Change Call Parameters).

- From the **ProtocolClModifyCallQoSComplete** function to tear down an established call if a QoS change that the client proposes is unacceptable to the remote party (see Client-Initiated Request to Change Call Parameters).

A client's call to **NdisClCloseCall** causes NDIS to call the call manager's or MCM driver's **ProtocolCmCloseCall** function. *ProtocolCmCloseCall* must communicate with network control devices to terminate a connection between the local node and a remote node.

If *ProtocolCmCloseCall* is passed an explicit *CallMgrPartyContext*, the call that is being terminated is a multipoint call. The call manager or MCM driver must perform any necessary network communication with its networking hardware, as appropriate to its media type, to terminate the call as a multipoint call.

NDIS can pass *ProtocolCmCloseCall* a pointer to a buffer containing data supplied by the client in the call to **NdisClClose**. This data can be diagnostic data that indicates why the call was closed or any other data that is required by the signaling protocol. *ProtocolCmCloseCall* must send any such data across the network before completing the call termination. If sending data concurrent with a connection being terminated is not supported, a call manager or MCM driver should return NDIS_STATUS_INVALID_DATA.

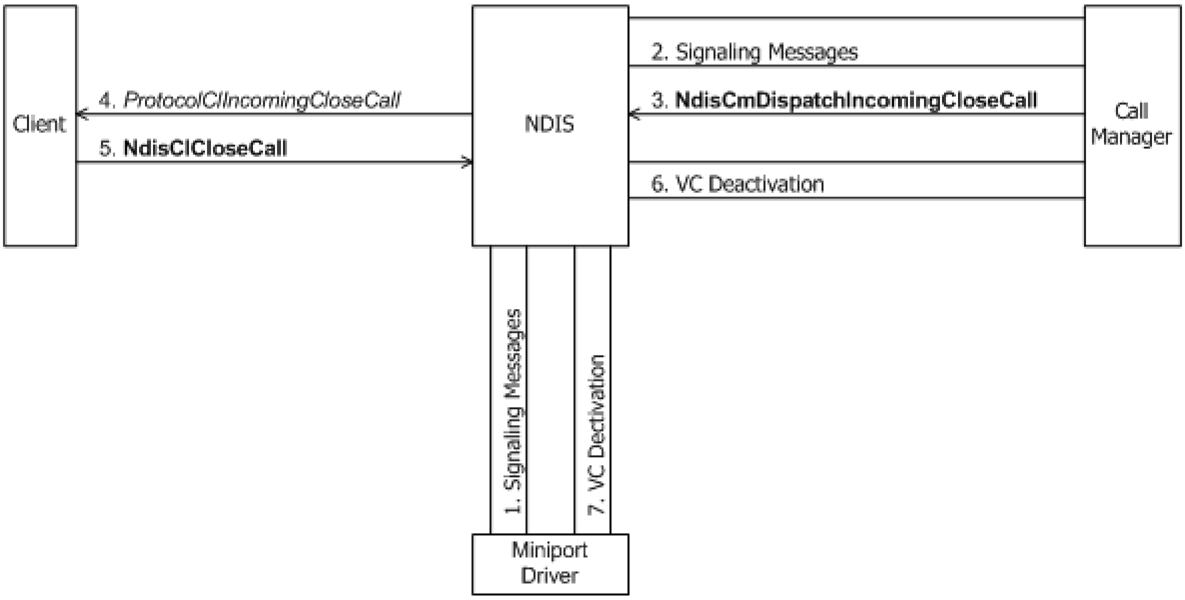
ProtocolCmCloseCall can complete synchronously or, more probably, asynchronously with **NdisCmCloseCallComplete**(in the case of a call manager) or **NdisMCmCloseCallComplete**(in the case of an MCM driver). A call to **Ndis(M)CmCloseCallComplete** causes NDIS to call the client's **ProtocolClCloseCallComplete** function.

The call manager or MCM driver must then initiate deactivation of the VC used for the call by respectively calling **NdisCmDeactivateVc** or **NdisMCmDeactivateVc**(see Deactivating a VC). The creator of the VC (client, call manager, or MCM driver) can then optionally initiate deletion of the VC (see Deleting a VC).

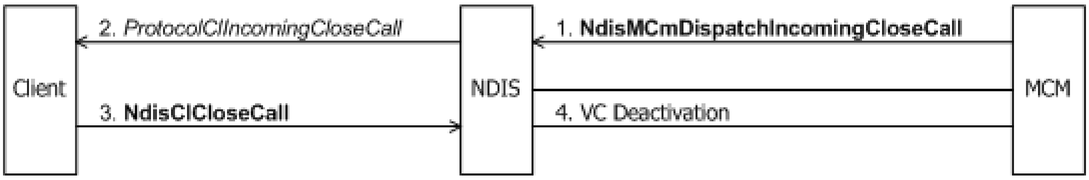
Incoming Request to Close a Call

Article • 12/15/2021

When the remote client closes a call, the local call manager or MCM driver must indicate this incoming request to the local client. To indicate such a request, a call manager calls **NdisCmDispatchIncomingCloseCall** with the *CloseStatus* set to NDIS_STATUS_SUCCESS (see the following figure).



An MCM driver calls **NdisMCmDispatchIncomingCloseCall** to indicate an incoming request to close a call (see the following figure).



Client
2. ProtocolClIncomingCloseCall
3. NdisClCloseCall
NDIS
1. NdisMCmDispatchIncomingCloseCall
4. VC Deactivation
MCM

A call manager or MCM driver also can call **Ndis(M)CmDispatchIncomingCloseCall**:

- From its **ProtocolCmIncomingCallComplete** function if it determines that the connection-oriented client is requesting an unacceptable change in call parameters in response to an incoming call previously that is indicated by the call manager or MCM driver (see Incoming Request to Change Call Parameters).

- If abnormal network conditions force the call manager to tear down active calls.

The call to **Ndis(M)CmDispatchIncomingCloseCall** causes NDIS to call the **ProtocolClIncomingCloseCall** function of the connection-oriented client on that connection. *ProtocolClIncomingCloseCall* should carry out any protocol-determined operations, such as notifying its own client or clients that the connection is being broken. If the call to be closed is a multipoint VC created by the client, *ProtocolClIncomingCloseCall* must call **NdisClDropParty** one or more times until only a single party remains on the VC (see Dropping a Party from a Multipoint Call).

ProtocolClIncomingCloseCall must then call **NdisClCloseCall**(with the handle to the last party on the VC if the VC is a multipoint VC created by the client) to acknowledge that the client will no longer attempt to send or expect to receive data on this particular VC. If the call manager or MCM driver created this VC, *ProtocolClIncomingCloseCall* should return control after it calls **NdisClCloseCall**. The call manager or MCM driver must also deactivate the VC (see Deactivating a VC).

If the client originally created this VC for an outgoing call and *CloseStatus* is NDIS_STATUS_SUCCESS, *ProtocolClIncomingCloseCall* can optionally tear down the VC with **NdisCoDeleteVc**(see Deleting a VC) or reuse the VC for another call. If *CloseStatus* is not NDIS_STATUS_SUCCESS, *ProtocolClIncomingCloseCall* must call **NdisCoDeleteVc**.

If the call manager or MCM driver originally created this VC for an incoming call, the call manager or MCM driver can optionally delete the VC by respectively calling **NdisCoDeleteVc** or **NdisMCmDeleteVc**.

Querying or Setting Information

Article • 12/15/2021

CoNDIS protocol drivers and NDIS can send OID requests to underlying drivers. CoNDIS protocol drivers and miniport call managers (MCMs) can also send OID requests to other protocol drivers.

A connection-oriented client or call manager calls **NdisCoOidRequest** to query or set information that is maintained by another protocol driver on a binding or by the underlying miniport driver.

Before it calls **NdisCoOidRequest**, a client or call manager allocates a buffer for its request and initializes an **NDIS_OID_REQUEST** structure. This structure specifies the type of request (query or set), identifies the information (OID) that is being queried or set, and points to buffers that are used for passing OID data.

If the connection-oriented client or call manager passes a valid *NdisAfHandle* (see Address Families), NDIS calls the **ProtocolCoOidRequest** function of each protocol driver on the binding.

NDIS defines object identifier (OID) values to identify adapter parameters, including operating parameters such as device characteristics, configurable settings, and statistics. For more information about OIDs, see NDIS OIDs.

This section includes the following topics:

CoNDIS Miniport Driver OID Requests

CoNDIS Protocol Driver OID Requests

CoNDIS MCM OID Requests

CoNDIS Miniport Driver OID Requests

Article • 03/14/2023

NDIS calls a CoNDIS miniport driver's **MiniportCoOidRequest** function to submit an OID request to query or set information in the driver. NDIS calls *MiniportCoOidRequest* either on its own behalf or on behalf of an overlying driver that called the **NdisCoOidRequest** function.

NDIS passes *MiniportCoOidRequest* a pointer to an **NDIS_OID_REQUEST** structure that contains the request information. The request structure contains an OID_*Xxx* identifier that indicates the type of request and other members to define the request data.

The **Timeout** member specifies a time-out, in seconds, for the request. NDIS can reset the driver or cancel the request if the time-out expires before the driver completes the request.

The **RequestId** member specifies an optional identifier for the request. Miniport drivers can set the **RequestId** member of a status indication to the value that the driver obtained from the **RequestId** member of an associated OID request. Typically, miniport drivers can ignore this member. If a driver must set this member, the driver must use one of the required values, which are specified in the reference page for the particular OID. For more information about status indications, see CoNDIS Miniport Driver Status Indications.

A miniport driver can complete an OID request synchronously by returning a success or failure status. The driver can complete an OID request asynchronously by returning NDIS_STATUS_PENDING. In this case, the driver must call the **NdisMCoOidRequestComplete** function to complete the operation.

If the *MiniportCoOidRequest* function returns NDIS_STATUS_PENDING, NDIS can call *MiniportCoOidRequest* with another request for the adapter before the pending request is completed. You should note that this is different from the connectionless NDIS interface where all OID requests are serialized.

NDIS can call a miniport driver's *MiniportCancelOidRequest* function to cancel a CoNDIS OID request.

CoNDIS Protocol Driver OID Requests

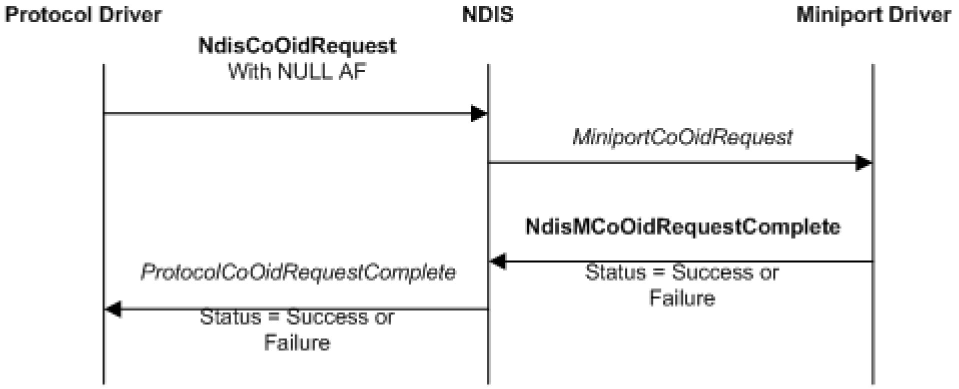
Article • 03/14/2023

CoNDIS protocol drivers, either clients or call managers, can query or set the operating parameters of miniport drivers and other protocol drivers. CoNDIS protocol drivers can also query or set information in miniport call managers (MCMs). For more information about OID requests and MCMs, see CoNDIS MCM OID Requests.

To originate an OID request to an underlying driver, a protocol driver calls the **NdisCoOidRequest** function and sets the address family (AF) handle, at the *NdisAfHandle* parameter, to **NULL**. To originate an OID request to another CoNDIS protocol driver, a protocol driver calls **NdisCoOidRequest** and provides a valid AF handle.

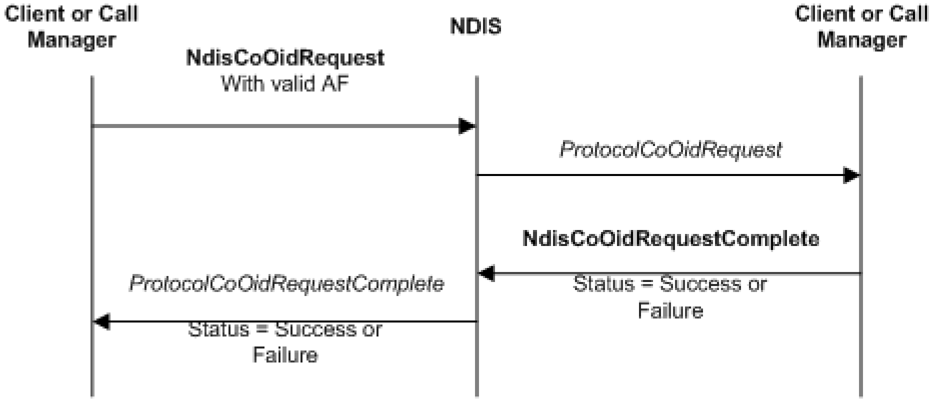
After a protocol driver calls the **NdisCoOidRequest** function, NDIS calls the OID request function of the other driver (an underlying driver or another CoNDIS protocol driver). For miniport drivers, NDIS calls the **MiniportCoOidRequest** function. For protocol drivers, NDIS calls the **ProtocolCoOidRequest** function.

The following figure illustrates an OID request that is directed to a miniport driver.



Protocol Driver
NDIS
Miniport Driver
NdisCoOidRequest
With NULL AF
MiniportCoOidRequest
NdisMCoOidRequestComplete
Status = Success or Failure
ProtocolCoOidRequestComplete
Status = Success or Failure

The following figure illustrates an OID request that is directed to a protocol driver.



To complete synchronously, NdisCoOidRequest returns NDIS_STATUS_SUCCESS or an error status. To complete asynchronously, **NdisCoOidRequest** returns NDIS_STATUS_PENDING.

If **NdisCoOidRequest** returns NDIS_STATUS_PENDING, NDIS calls the ProtocolCoOidRequestComplete function after the other driver completes the OID request by calling the NdisMCoOidRequestComplete function or the NdisCoOidRequestComplete function. In this case, NDIS passes the results of the request at the *OidRequest* parameter of *ProtocolCoOidRequestComplete*. NDIS passes the final status of the request at the *Status* parameter of *ProtocolCoOidRequestComplete*.

If NdisCoOidRequest returns NDIS_STATUS_SUCCESS, it returns the results of a query request in the NDIS_OID_REQUEST structure at the *OidRequest* parameter points. In this case, NDIS does not call the *ProtocolCoOidRequestComplete* function.

If an underlying driver should associate the OID request with a subsequent status indication, the protocol driver should set the **RequestId** and **RequestHandle** members in the NDIS_OID_REQUEST structure. If the underlying driver makes a status indication, the driver sets the **RequestId** member in the NDIS_STATUS_INDICATION structure to the value from the **RequestId** member of the NDIS_OID_REQUEST structure and the **DestinationHandle** member in the NDIS_STATUS_INDICATION structure to the value from the **RequestHandle** member of the NDIS_OID_REQUEST structure.

A driver can call NdisCoOidRequest when a binding is in the *Restarting*, *Running*, *Pausing*, or *Paused* state.

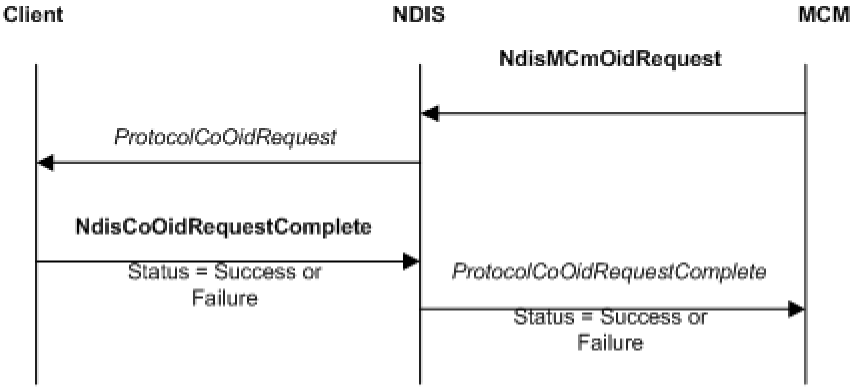
CoNDIS MCM OID Requests

Article • 03/14/2023

Like other CoNDIS call managers, miniport call managers (MCMs) can query or set the operating parameters of CoNDIS client drivers. CoNDIS client drivers can query or set the call manager parameters or the miniport driver parameters of an MCM.

To originate an OID request to a CoNDIS client driver, an MCM calls the NdisMCmOidRequest function.

The following figure illustrates an OID request that an MCM originated.



Client
NDIS
MCM
NdisMCmOidRequest
ProtocolCoOidRequest
NdisCoOidRequestComplete
Status = Success or Failure
ProtocolCoOidRequestComplete
Status = Success or Failure

After an MCM driver calls the NdisMCmOidRequest function, NDIS calls the ProtocolCoOidRequest function of the client driver.

To complete synchronously, **NdisMCmOidRequest** returns NDIS_STATUS_SUCCESS or an error status. To complete asynchronously, **NdisMCmOidRequest** returns NDIS_STATUS_PENDING.

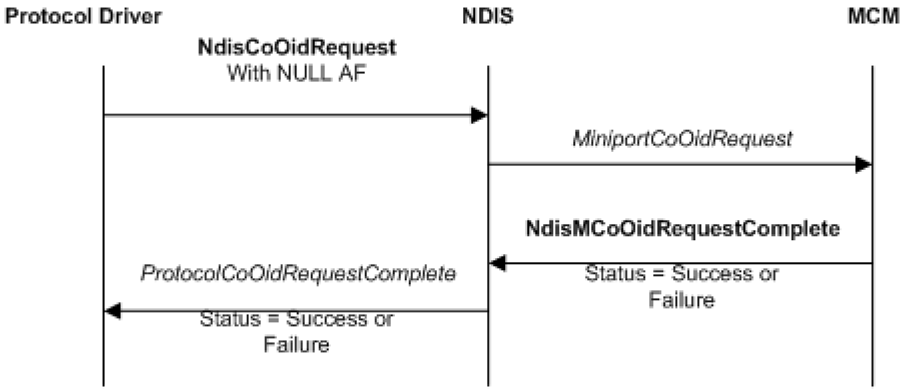
If NdisMCmOidRequest returns NDIS_STATUS_PENDING, NDIS calls the ProtocolCoOidRequestComplete function of the MCM after the client drivers complete the OID request by calling the NdisCoOidRequestComplete function. In this case, NDIS passes the results of the request at the *OidRequest* parameter of *ProtocolCoOidRequestComplete*. NDIS passes the final status of the request at the *Status* parameter of *ProtocolCoOidRequestComplete*.

If **NdisMCmOidRequest** returns NDIS_STATUS_SUCCESS, it returns the results of a query request in the NDIS_OID_REQUEST structure at the *OidRequest* parameter. In this case, NDIS does not call the *ProtocolCoOidRequestComplete* function of the MCM.

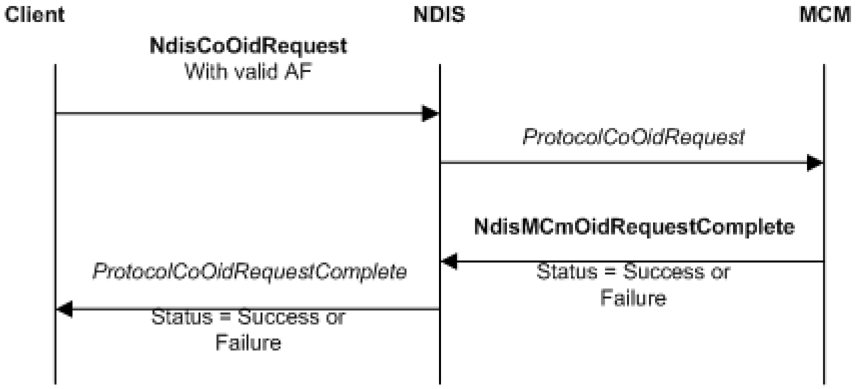
CoNDIS client drivers can query or set the call manager operating parameters or miniport operating parameters of MCMs. To originate an OID request for MCM call manager parameters, a client calls the NdisCoOidRequest function and provides a valid address family (AF) handle at the *NdisAfHandle* parameter. To originate an OID request for MCM miniport parameters, a client calls the **NdisCoOidRequest** function and sets the AF handle to **NULL**.

After a client calls the **NdisCoOidRequest** function, NDIS calls either the MiniportCoOidRequest function or the ProtocolCoOidRequest function of the MCM driver.

The following figure illustrates an OID request for the miniport parameters of the MCM.



The following figure illustrates an OID request for the call manager parameters of the MCM.



To complete synchronously, NdisCoOidRequest returns NDIS_STATUS_SUCCESS or an error status. To complete asynchronously, ProtocolCoOidRequest or MiniportCoOidRequest returns NDIS_STATUS_PENDING.

If *ProtocolCoOidRequest* or **MininportCoOidRequest** returns NDIS_STATUS_PENDING, NDIS calls the ProtocolCoOidRequestComplete function of the client after the MCM completes the OID request by calling the NdisMCoOidRequestComplete or NdisMCmOidRequestComplete function. In this case, NDIS passes the results of the request at the *OidRequest* parameter of *ProtocolCoOidRequestComplete*. NDIS passes the final status of the request at the *Status* parameter of *ProtocolCoOidRequestComplete*.

If NdisCoOidRequest returns NDIS_STATUS_SUCCESS, it returns the results of a query request in the NDIS_OID_REQUEST structure at the *OidRequest* parameter. In this case, NDIS does not call the client's *ProtocolCoOidRequestComplete* function.

Indicating Miniport Driver Status

Article • 12/15/2021

Miniport drivers provide status indications to overlying drivers. The CoNDIS status indication functions are similar to the connectionless status indication functions.

To report a change in the status of a connection-oriented NIC or a change in the status of a particular VC active on the NIC, a connection-oriented miniport driver calls **NdisMCoIndicateStatusEx**. If the miniport driver is reporting a change in the status of a particular VC, it supplies an *NdisVcHandle* that identifies the VC.

This section includes the following topics:

CoNDIS Miniport Driver Status Indications

Handling Status Indications in a CoNDIS Protocol Driver

CoNDIS Miniport Driver Status Indications

Article • 03/14/2023

Miniport drivers call the NdisMCoIndicateStatusEx function to report a change in the status of a miniport adapter. The miniport driver passes **NdisMCoIndicateStatusEx** a pointer to an NDIS_STATUS_INDICATION structure that contains the status information.

The status indication includes information to identify the type of status and a reason for the status change.

The miniport driver should set the **SourceHandle** member of the NDIS_STATUS_INDICATION structure to the handle that NDIS passed to the *MiniportAdapterHandle* parameter of the *MiniportInitializeEx* function. If the status indication is associated with an OID request, the miniport driver can set the **DestinationHandle** and **RequestId** members of NDIS_STATUS_INDICATION so that NDIS can provide the status indication to a specific protocol binding. For more information about OID requests, see CoNDIS Miniport Driver OID Requests.

Handling Status Indications in a CoNDIS Protocol Driver

Article • 03/14/2023

Protocol drivers must supply a **ProtocolCoStatusEx** function that NDIS calls when an underlying driver reports status.

NDIS calls a protocol driver's *ProtocolCoStatusEx* function after an underlying driver calls a status indication function (for example, **NdisMCoIndicateStatusEx**). For more information about indicating status from a miniport driver, see CoNDIS Miniport Driver Status Indications.

If the status indication is associated with an OID request, the underlying driver can set the **DestinationHandle** and **RequestId** members of the **NDIS_STATUS_INDICATION** structure that contains the status information so that NDIS can provide the status indication to a specific protocol binding. For more information about OID requests, see CoNDIS Protocol Driver OID Requests.

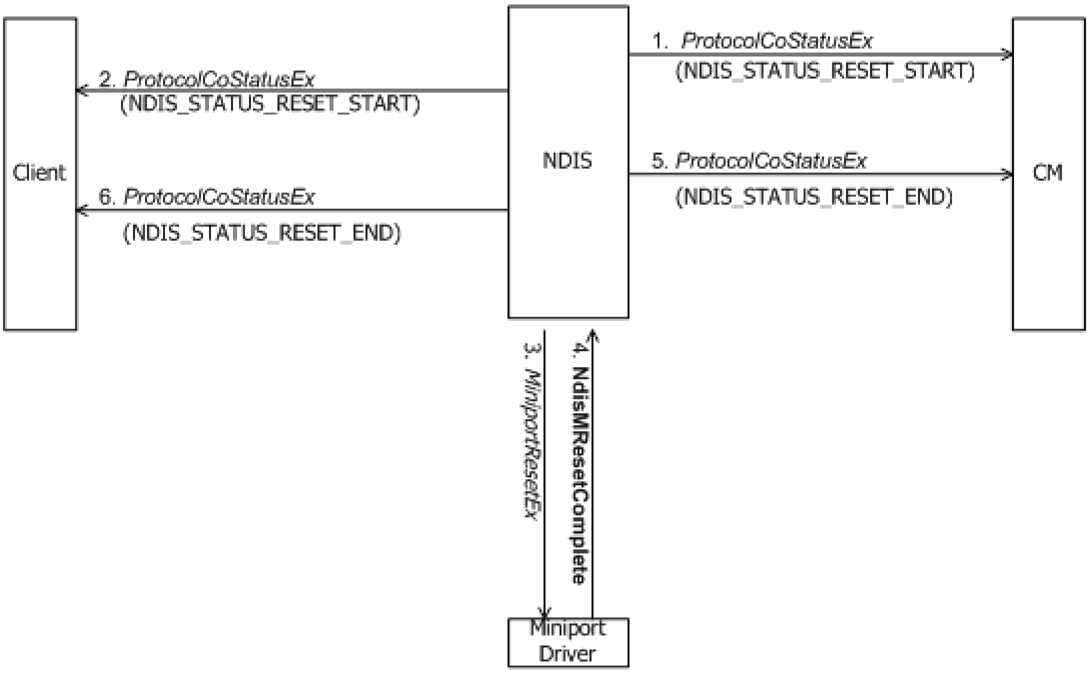
Reset

Article • 12/15/2021

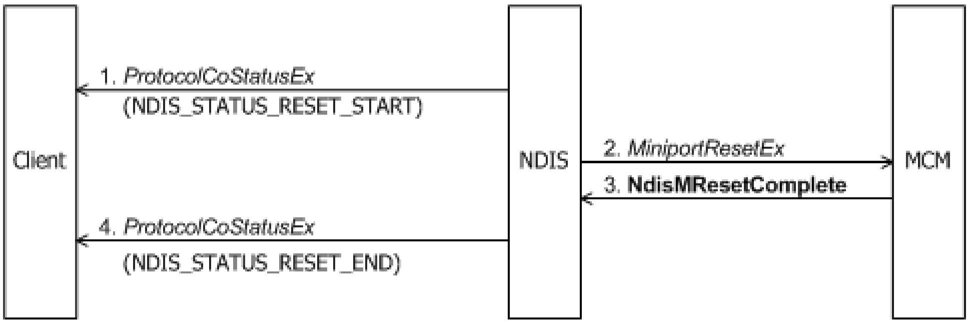
NDIS might call a miniport driver's or MCM driver's *MiniportResetEx* function to reset a NIC.

Note AF, SAP, and VC handles that are active and valid before a reset are active and valid after the reset.

The following figure shows a client issuing a reset request to a miniport driver.



The next figure shows a client issuing a reset request to an MCM driver.



When an underlying connection-oriented driver is resetting a NIC, NDIS notifies each bound protocol by calling the protocol's **ProtocolCoStatusEx** function with NDIS_STATUS_RESET_START.

NDIS will not accept protocol-initiated sends and requests to a miniport driver or MCM driver while the miniport driver's or MCM driver's NIC is being reset. While a reset is in progress, a protocol driver must not attempt to send packets to the miniport driver with

NdisCoSendNetBufferLists or request information from the miniport driver with NdisCoOidRequest.

MiniportResetEx performs any device-dependent actions that are required to reset the NIC. *MiniportResetEx* can complete synchronously, or it can complete asynchronously with a call to NdisMResetComplete:

- If the reset completes synchronously, NDIS calls each bound protocol's *ProtocolCoStatusEx* function with NDIS_STATUS_RESET_END.

- If the reset completes asynchronously, NDIS calls each bound protocol's *ProtocolCoStatusEx* function with NDIS_STATUS_RESET_END.

Introduction to NDIS Network Interfaces

Article • 03/14/2023

To support the management information base (MIB), NDIS manages a collection of network interface information for the local computer. NDIS interface providers provide information about some network interfaces to NDIS. NDIS provides a proxy interface provider that registers interfaces and handles interface provider requests for miniport adapters and filter modules. Therefore, no NDIS drivers are required to be network interface providers.

However, all NDIS network driver types can register as interface providers. Such drivers register network interfaces and provide callback functions to respond to interface OID requests. NDIS interface providers typically provide information about interfaces that are not directly accessible to NDIS and are not supported by the NDIS proxy interface provider. For example, a MUX intermediate driver can have internal interfaces between its virtual miniports and underlying adapters.

This section includes:

Overview of NDIS Network Interfaces

Registering as an Interface Provider

Handling OID Query and Set Requests in an NDIS Interface Provider

Mapping of NDIS Network Interfaces to NDIS OIDs

Overview of NDIS Network Interfaces

Article • 03/14/2023

NDIS network interfaces provide a consistent representation for all of the various network interfaces that Microsoft Windows supports. Without the NDIS network interface services, all network interfaces are not visible to the computer administrator, and the interfaces that are visible do not necessarily support the management information base (MIB). Also, NDIS network interface services enable the layering relationships between interfaces to be visible to the administrator.

This section includes:

NDIS Network Interface Services

NDIS Network Interface Architecture

NDIS Interface Provider Operations

NDIS Interface Types

ⓘ **Note**

The NDIS 6.0 Network Interfaces section refers to many Request for Comments (RFCs) from the Internet Engineering Task Force (IETF). To view an IETF RFC, visit the **IETF Request for Comments** Web site, and search for the RFC in the **RFC number** box under **IETF repository retrieval**.

NDIS Network Interface Services

Article • 03/14/2023

The NDIS network interfaces programming interface provides services to:

- Generate a locally unique identifier (NET_LUID) for each interface. NET_LUID values:
  - Must persist when the computer restarts. Interface providers must make NET_LUIDs persistent even if the associated interface is not persistent. For example, this persistence allows the interface provider to free the NET_LUID index if there is a computer power failure.
  - Must be associated with an interface type (*IfType* in RFC 2863).
  - Must be unique on a local computer.
  - Can be converted to a text representation because a NET_LUID is equivalent to the interface name (*ifName* in RFC 2863).

- Generate a locally unique interface index (a 24-bit value that is also referred to as *IfIndex*) for each interface. *IfIndex* values have the following properties:
  - Low numbers are preferred. For example, NDIS reuses the lowest available interface index.
  - *IfIndex* values do not persist when the computer restarts.
  - There is a one-to-one correspondence between a NET_LUID value and an *IfIndex* value.

- Map between interface indexes, NET_LUID values, and "friendly names" (For example, a friendly name as displayed in the network connections folder).

- Define the layering order of interfaces in a driver stack.

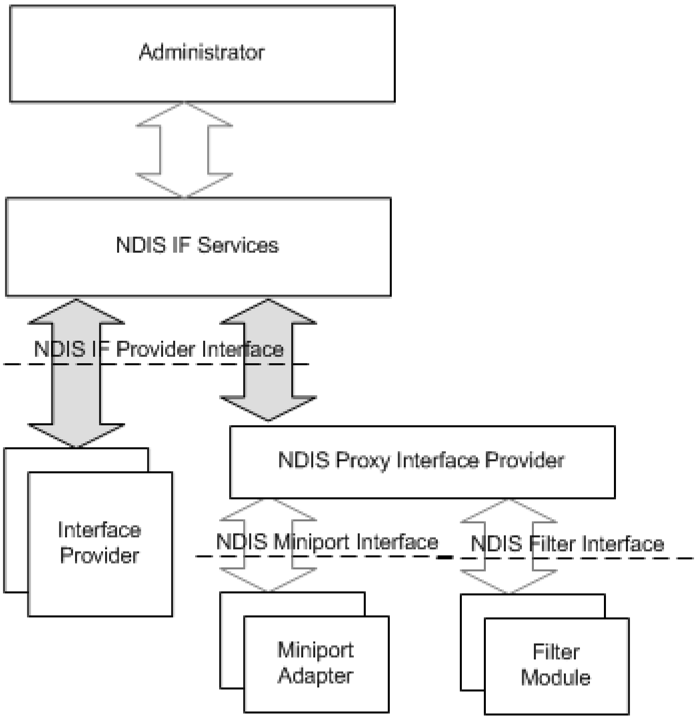
- Query and set interface properties and tables that NDIS drivers manage and that RFCs 2863 and 2864 specify.

NDIS Network Interface Architecture

Article • 03/14/2023

NDIS provides a set of services to support network interfaces and interface stacks. In the WDK, this set of services is referred to as *NDIS network interface (NDISIF)* services.

The following figure shows the NDISIF architecture for NDIS 6.0 and later.



The NDISIF components of the architecture include:

- *NDIS IF Services*
  An NDIS component that handles registration of interface providers and interfaces, implements OID query and set services for interface providers, and supplies other NDISIF services.
- *NDIS IF provider interface*
  An interface that the *NDIS IF Services* component supplies to enable NDIS drivers to implement interface providers.
- *NDIS proxy interface provider*
  An NDIS component that implements the NDISIF provider services on behalf of NDIS miniport drivers (for each miniport adapter) and filter drivers (for each filter module).
- *Interface provider*
  An NDIS driver that provides the NDISIF provider services for interfaces that the *NDIS proxy interface provider* component cannot serve. For example, a MUX intermediate driver can have internal interfaces between its virtual miniports and underlying adapters.

The NDIS proxy interface provider uses the standard NDIS miniport driver and NDIS filter driver interfaces to provide NDISIF services for miniport adapters and filter modules. Therefore, miniport drivers and filter drivers are not required to register as interface providers.

NDIS Interface Provider Operations

Article • 03/14/2023

All NDIS drivers can register as interface providers. Whenever a driver (or the NDIS proxy interface provider) detects a new interface that is being introduced to the computer, it allocates a **NET_LUID** index, registers the interface, and retains the associated NET_LUID value in persistent storage (such as the registry). The following list describes several examples of how a new interface can be introduced to a computer:

- Installing a network adapter, either a virtual adapter for an intermediate driver or a physical adapter. In this case, the NDIS proxy interface provider manages the interface.

- Attaching a filter module. In this case, the NDIS proxy interface provider manages the interface.

- MUX intermediate driver internal bindings. The MUX intermediate driver should implement NDIS provider services to handle this case because the internal interfaces are not visible to NDIS.

When the computer subsequently restarts, the interface provider should not allocate a new **NET_LUID** for the same interface if the interface is persistent; instead, the interface provider should use the previously stored NET_LUID value to register the same interface. Also, even if the interface is not persistent, the interface provider must free the NET_LUID index if there is a computer power failure. Therefore, the interface provider should store the NET_LUID in persistent storage (for example, the registry).

If an interface provider detects that an interface is being shut down, it should deregister the interface.

Note The NDIS proxy provider deregisters interfaces for miniport adapters when they are uninstalled and filter modules when they are detached.

If an interface provider detects that an interface is being removed completely (for example, the NDIS proxy provider is notified that a miniport adapter is being uninstalled), the interface provider deregisters the interface and releases the NET_LUID index. The NDIS proxy provider also releases the NET_LUID index when a filter module is detached.

During run time, interface providers handle OID requests for the interfaces that they registered. The NDIS proxy interface provider might issue OID requests to underlying drivers to obtain interface information.

NDIS Interface Types

Article • 03/14/2023

NDIS interface types correspond to the *IfType* object that is defined in the management information base (MIB). These interface types are used in the **IfType** members and *IfType* parameters for many NDIS structures and functions.

NDIS interface types are registered with the Internet Assigned Numbers Authority (IANA), which publishes a list of interface types periodically in the Assigned Numbers RFC, or in a derivative of it that is specific to Internet network management number assignments. For more information about the IANA IfType *definitions*, see IANA ifType MIB Definitions. For more information about the IANA, see the IANA Web site.

The following table describes IfType values.

Name	Value	Comment
IF_TYPE_OTHER	1	Use this value if none of the other IF_TYPE_*Xxx* types applies.
IF_TYPE_REGULAR_1822	2	
IF_TYPE_HDH_1822	3	
IF_TYPE_DDN_X25	4	
IF_TYPE_RFC877_X25	5	
IF_TYPE_ETHERNET_CSMACD	6	
IF_TYPE_IS088023_CSMACD	7	
IF_TYPE_ISO88024_TOKENBUS	8	
IF_TYPE_ISO88025_TOKENRING	9	
IF_TYPE_ISO88026_MAN	10	
IF_TYPE_STARLAN	11	
IF_TYPE_PROTEON_10MBIT	12	
IF_TYPE_PROTEON_80MBIT	13	
IF_TYPE_HYPERCHANNEL	14	
IF_TYPE_FDDI	15	
IF_TYPE_LAP_B	16	

IF_TYPE_SDLC	17	
IF_TYPE_DS1	18	DS1-MIB
IF_TYPE_E1	19	Obsolete. See DS1-MIB.
IF_TYPE_BASIC_ISDN	20	
IF_TYPE_PRIMARY_ISDN	21	
IF_TYPE_PROP_POINT2POINT_SERIAL	22	Proprietary serial
IF_TYPE_PPP	23	
IF_TYPE_SOFTWARE_LOOPBACK	24	
IF_TYPE_EON	25	CLNP over IP
IF_TYPE_ETHERNET_3MBIT	26	
IF_TYPE_NSIP	27	XNS over IP
IF_TYPE_SLIP	28	Generic Slip
IF_TYPE_ULTRA	29	ULTRA Technologies
IF_TYPE_DS3	30	DS3-MIB
IF_TYPE_SIP	31	SMDS and coffee
IF_TYPE_FRAMERELAY	32	DTE only
IF_TYPE_RS232	33	
IF_TYPE_PARA	34	Parallel port
IF_TYPE_ARCNET	35	
IF_TYPE_ARCNET_PLUS	36	
IF_TYPE_ATM	37	ATM cells
IF_TYPE_MIO_X25	38	
IF_TYPE_SONET	39	SONET or SDH
IF_TYPE_X25_PLE	40	
IF_TYPE_ISO88022_LLC	41	
IF_TYPE_LOCALTALK	42	
IF_TYPE_SMDS_DXI	43	

IF_TYPE_FRAMERELAY_SERVICE	44	FRNETSERV-MIB
IF_TYPE_V35	45	
IF_TYPE_HSSI	46	
IF_TYPE_HIPPI	47	
IF_TYPE_MODEM	48	Generic modem
IF_TYPE_AAL5	49	AAL5 over ATM
IF_TYPE_SONET_PATH	50	
IF_TYPE_SONET_VT	51	
IF_TYPE_SMDS_ICIP	52	SMDS InterCarrier interface
IF_TYPE_PROP_VIRTUAL	53	Proprietary virtual/internal
IF_TYPE_PROP_MULTIPLEXOR	54	Proprietary multiplexing
IF_TYPE_IEEE80212	55	100BaseVG
IF_TYPE_FIBRECHANNEL	56	
IF_TYPE_HIPPIINTERFACE	57	
IF_TYPE_FRAMERELAY_INTERCONNECT	58	Obsolete. Use 32 or 44 instead.
IF_TYPE_AFLANE_8023	59	ATM-emulated LAN-for 802.3
IF_TYPE_AFLANE_8025	60	ATM-emulated LAN for 802.5
IF_TYPE_CCTEMUL	61	ATM-emulated circuit
IF_TYPE_FASTETHER	62	Fast Ethernet (100BaseT)
IF_TYPE_ISDN	63	ISDN and X.25
IF_TYPE_V11	64	CCITT V.11/X.21
IF_TYPE_V36	65	CCITT V.36
IF_TYPE_G703_64K	66	CCITT G703 at 64Kbps
IF_TYPE_G703_2MB	67	Obsolete. See DS1-MIB.
IF_TYPE_QLLC	68	SNA QLLC

Registering as an Interface Provider

Article • 05/20/2024

An NDIS interface provider is a software component that provides and manages information for NDIS network interfaces. For example, protocol drivers, MUX intermediate drivers, and NDIS are interface providers. (NDIS provides a proxy interface provider for miniport drivers and filter drivers. However, miniport drivers and filter drivers can also be interface providers.) Each interface provider calls the **NdisIfRegisterProvider** function to register as a network interface provider.

If the call to **NdisIfRegisterProvider** succeeds, **NdisIfRegisterProvider** returns a handle at the address that the *pNdisProviderHandle* parameter specifies. The caller uses this handle in subsequent calls (for example, to register interfaces). The *ProviderCharacteristics* parameter points to an **NDIS_IF_PROVIDER_CHARACTERISTICS** structure that contains the provider's entry points to handle OID query and set requests. NDIS_IF_PROVIDER_CHARACTERISTICS includes the following query and set functions:

- **ProviderQueryObject**
- **ProviderSetObject**

For more information about interface provider query and set handlers, see Handling OID Query and Set Requests in an NDIS Interface Provider.

NDIS drivers can call the **NdisIfDeregisterProvider** function to deregister as a network interface provider. For example, NDIS drivers should deregister as an interface providers when they are unloaded. An interface provider must ensure that it does not have any interfaces registered before it calls **NdisIfDeregisterProvider**. The provider must not use the provider handle that it passed at the *NdisProviderHandle* parameter of **NdisIfDeregisterProvider** after it calls **NdisIfDeregisterProvider**.

Managing NDIS Network Interfaces

Article • 03/14/2023

NDIS network interface providers register network interfaces with NDIS. Before registering an interface, an interface provider obtains a **NET_LUID** value for that interface. NDIS assigns an interface index (*IfIndex* in RFC 2863) to an interface when it is registered.

NDIS also provides services that drivers can use to manage entries in the interface stack table (*ifStackTable* in RFC 2863).

This section includes:

NET_LUID Value

Using a NET_LUID Index

Registering a Network Interface

Deregistering a Network Interface

Mapping a NET_LUID Value to an Interface Index

NET_LUID Values for Miniport Adapters and Filter Modules

Maintaining a Network Interface Stack

NET_LUID Value

Article • 12/15/2021

A **NET_LUID** value is a 64-bit value that identifies an NDIS network interface. The NET_LUID data type is a union that can provide access to the NET_LUID value as a single 64-bit value or as a structure that contains a NET_LUID index and an interface type.

The **NetLuidIndex** member of the NET_LUID union is a 24-bit NET_LUID index that NDIS allocates when an interface provider calls the **NdisIfAllocateNetLuidIndex** function. NDIS and interface providers use this index to distinguish between multiple interfaces that have the same interface type. Therefore, this index is unique within a local computer.

The **IfType** member of the **NET_LUID** union is a 16-bit value that contains an Internet Assigned Numbers Authority (IANA)-defined interface type. For a list of valid interface types, see NDIS Interface Types.

The NET_LUID data type is equivalent to the *ifName* object in RFC 2863, because NDIS derives the *ifName* string from a NET_LUID value.

To create a NET_LUID value, an interface provider calls the **NdisIfAllocateNetLuidIndex** function to allocate a NET_LUID index and then calls the **NDIS_MAKE_NET_LUID** macro to build the NET_LUID value. For more information about creating NET_LUID values, see Using NET_LUID Indexes.

Using a NET_LUID Index

Article • 12/15/2021

NDIS provides functions to allocate and free the NET_LUID indexes that are required to create NET_LUID values. An NDIS interface provider must allocate a NET_LUID value to register an interface.

To allocate a NET_LUID index, an interface provider calls the NdisIfAllocateNetLuidIndex function. After allocating the index, the interface provider calls the NDIS_MAKE_NET_LUID macro to build the NET_LUID value. To free a NET_LUID index, an interface provider calls the NdisIfFreeNetLuidIndex function.

NdisIfAllocateNetLuidIndex attempts to allocate a 24-bit value that is associated with the interface type that the caller specified at the *IfType* parameter and that is unique to the local computer. If the index allocation succeeds, **NdisIfAllocateNetLuidIndex** returns NDIS_STATUS_SUCCESS and provides a NET_LUID index at the address that is provided in the *pNetLuidIndex* parameter. If NDIS is not able to find a free NET_LUID index, **NdisIfAllocateNetLuidIndex** returns NDIS_STATUS_RESOURCES. **NdisIfAllocateNetLuidIndex** can return other NDIS status values to indicate internal errors within NDIS. NDIS records the allocation of this index for when the computer subsequently restarts. NDIS will not use a particular index for future callers, even after the computer restarts, until the interface provider that allocated that index calls the **NdisIfFreeNetLuidIndex** function for that index.

NdisIfFreeNetLuidIndex frees a previously allocated NET_LUID index so that NDIS can possibly reallocate that index to another interface. The caller must pass in the same interface type at *IfType* that the caller used when it called NdisIfAllocateNetLuidIndex to allocate the NET_LUID index. If the free operation succeeds, **NdisIfFreeNetLuidIndex** returns NDIS_STATUS_SUCCESS. If the call to **NdisIfFreeNetLuidIndex** fails, the interface provider should remove any information that it saved in persistent storage that is related to the NET_LUID index. Removing the information will ensure that the provider does not keep trying to free an index that is already freed after every computer restart. After calling **NdisIfFreeNetLuidIndex**, the caller must not use the NET_LUID value again unless it calls **NdisIfAllocateNetLuidIndex** again for the same interface type and receives the same NET_LUID index that it freed.

To register a network interface, an interface provider must pass a valid NET_LUID value to the NdisIfRegisterInterface function. For more information about registering network interfaces, see Registering a Network Interface.

Registering a Network Interface

Article • 12/15/2021

Whenever a computer restarts, NDIS starts with an empty list of registered network interfaces. An interface provider calls the NdisIfRegisterInterface function whenever it starts or detects an interface and its NET_LUID value is known. The mechanism for starting or detecting an interface is application-specific.

NdisIfRegisterInterface returns NDIS_STATUS_SUCCESS only if NDIS successfully adds the specified interface to its list of known interfaces on the computer. In this case, **NdisIfRegisterInterface** returns an interface index at the *pIfIndex* parameter. However, a call to **NdisIfRegisterInterface** does not imply that the interface is active; this call guarantees only that the interface exists. **NdisIfRegisterInterface** returns NDIS_STATUS_RESOURCES if NDIS does not have sufficient resources available to register the interface. **NdisIfRegisterInterface** can also return other NDIS status values.

The *ProviderIfContext* parameter of **NdisIfRegisterInterface** contains a handle to the caller's context area for the interface--this handle is passed to the caller's OID query and set functions. The *pIfInfo* parameter contains a pointer to a NET_IF_INFORMATION structure that includes information about the interface.

The following topics provide more information about network interfaces that **NdisIfRegisterInterface** successfully registers:

Allocating an Interface Index

Network Interface Information

Allocating an Interface Index

Article • 12/15/2021

If an interface provider successfully registers an interface by calling the NdisIfRegisterInterface function, NDIS allocates an interface index for that interface and returns the index value at the location that the *pIfIndex* parameter specifies. The interface index is a 16-bit value that is unique on the local computer. NDIS does not guarantee that it will allocate the same interface index when an interface provider registers the same NET_LUID value after the computer restarts. The interface index value zero (NET_IFINDEX_UNSPECIFIED) is reserved, and NDIS does not assign it to any interface.

Network Interface Information

Article • 12/15/2021

An interface provider supplies information about each registered interface by using the following data structures.

- **NET_IF_INFORMATION**
- **NDIS_INTERFACE_INFORMATION**

To register an interface, a provider passes a pointer to an initialized NET_IF_INFORMATION structure to the **NdisIfRegisterInterface** function.

NDIS interface providers provide an **NDIS_INTERFACE_INFORMATION** structure in response to a query of the OID_GEN_INTERFACE_INFO OID.

NDIS can also query providers with other OIDs. For more information about NDIS provider OIDs, see NDIS Network Interface to OID Mapping. For more information about handling OID requests in interface providers, see Handling OID Query and Set Requests in an NDIS Interface Provider.

Deregistering a Network Interface

Article • 12/15/2021

An NDIS interface provider calls the NdisIfDeregisterInterface function to indicate that a specified interface should be removed from the list of known interfaces on the computer, for example, because the interface has been uninstalled. Other reasons for deregistering interfaces are application-specific. To promote good resource management, interface providers should always deregister interfaces that are no longer useful.

NdisIfDeregisterInterface releases the interface index that is associated with the specified interface. NDIS can reassign the index to an interface that is registered in the future. However the NET_LUID index that is associated with the corresponding NET_LUID value is not reclaimed--if necessary, the interface provider can release the NET_LUID index by calling the NdisIfFreeNetLuidIndex function.

Note The NDIS proxy provider deregisters interfaces for miniport adapters when they are uninstalled and filter modules when they are detached.

Mapping a NET_LUID Value to an Interface Index

Article • 12/15/2021

NDIS provides services to obtain the interface index for a given NET_LUID value, and vice versa. Note that the NET_LUID value is the persistent identification for an interface, and the interface index that corresponds to a particular NET_LUID value can change even if the computer does not restart (for example, when a filter module is attached and detached because the associated miniport adapter was disabled and reenabled).

NDIS provides the following mapping functions:

- NdisIfGetInterfaceIndexFromNetLuid
- NdisIfGetNetLuidFromInterfaceIndex

These functions return NDIS_STATUS_INTERFACE_NOT_FOUND if the given NET_LUID or interface index is not present in the list of registered interfaces.

NET_LUID Values for Miniport Adapters and Filter Modules

Article • 12/15/2021

NDIS registers interfaces on behalf of miniport drivers (for each miniport adapter) and filter drivers (for each filter module). A protocol driver can query NDIS for the interface index and NET_LUID value of a miniport adapter that the driver is bound to by using its binding handle. For example, the protocol-driver lower edge of a MUX intermediate driver might obtain the NET_LUID values to specify the layering order of its internal interfaces.

A protocol driver passes a binding handle at the *NdisBindingHandle* parameter to the NdisIfQueryBindingIfIndex function and receives interface indexes and NET_LUID values for the interfaces at the top and bottom of a filter stack. Alternatively, the protocol driver can retrieve these values in the NDIS_BIND_PARAMETERS structure.

A miniport driver can also query NDIS for the interface index of a miniport adapter by using the NDIS miniport adapter handle. A miniport driver receives an interface index and a NET_LUID value in the NDIS_MINIPORT_INIT_PARAMETERS structure.

A filter driver gets an interface index and a NET_LUID value for a filter module in the NDIS_FILTER_ATTACH_PARAMETERS structure.

Maintaining a Network Interface Stack

Article • 12/15/2021

NDIS provides services to maintain the interface stack table (*ifStackTable* in RFC 2863). NDIS maintains the stack table for NDIS miniport adapters, NDIS 5.*x* filter intermediate drivers, and NDIS filter modules. NDIS also provides services to enable NDIS drivers to add and delete entries in this table. For MUX intermediate drivers, NDIS does not have access to the relationship between the virtual miniport interface and the protocol lower interface. Therefore, NDIS 6.0 MUX intermediate drivers must specify these internal interface relationships.

To define a stack relationship between two interfaces, any NDIS driver can pass *HigherLayerIfIndex* and *LowerLayerIfIndex* parameters to the **NdisIfAddIfStackEntry** function. These parameters specify one network interface that should be higher in the network interface stack and one network interface that should be lower in the stack.

A driver that has stack order information about an interface that is related to another interface (for example, internal bindings in a MUX intermediate driver that are not visible to NDIS) calls **NdisIfAddIfStackEntry** to populate the interface stack table. This function returns NDIS_STATUS_SUCCESS if the stack entry was successfully made. Typically, the component that owns or is the interface provider for the higher layer interface (which *HigherLayerIfIndex* identifies) calls **NdisIfAddIfStackEntry**.

To remove a stack table entry, a driver passes *HigherLayerIfIndex* and *LowerLayerIfIndex* parameters to the **NdisIfDeleteIfStackEntry** function.

For an example of maintaining the interface stack, see the MUX 6.0 sample driver.

Handling OID Query and Set Requests in an NDIS Interface Provider

Article • 03/14/2023

The NDISIF interface defines several interface parameters (including statistical counters) that can be queried or set which correspond to information in RFC 2863. NDIS accesses these interface parameters through entry points that the interface provider defines when it calls the **NdisIfRegisterProvider** function. For more information about registering as an interface provider, see Registering as an Interface Provider.

Interface parameters are identified by object identifiers (OIDs). Some OIDs are specific to interface providers.

The following topics describe how to handle query and set requests for interface parameters:

Handling an Interface Object Query Request

Handling an Interface Object Set Request

Handling an Interface Object Query Request

Article • 12/15/2021

To obtain the current value that is associated with an interface object, NDIS calls an interface provider's **ProviderQueryObject** function. This function returns NDIS_STATUS_SUCCESS if it successfully processes the query request or an NDIS_STATUS_*Xxx* error code otherwise.

For a list of interface provider-specific OID requests, see NDIS Network Interface OIDs. For a list of OIDs that NDIS uses with providers, miniport adapters, and filter modules to support network interface objects, see NDIS Network Interface to OID Mapping.

The handle at the *ProviderIfContext* parameter of **ProviderQueryObject** identifies the context area that the interface provider passed to NDIS when it called the **NdisIfRegisterInterface** function to register the interface. The *ObjectId* parameter specifies the OID for the object that is being queried. The *pOutputBufferLength* and *pOutputBuffer* parameters provide a pointer to the resulting length of the output buffer and a pointer to the output buffer, respectively.

Handling an Interface Object Set Request

Article • 12/15/2021

To set the data that is associated with an interface object, NDIS calls an interface provider's **ProviderSetObject** function. This function returns NDIS_STATUS_SUCCESS if it successfully changed the data or an NDIS_STATUS_*Xxx* error code otherwise.

For a list of interface provider-specific OID requests, see NDIS Network Interface OIDs. For a list of OIDs that NDIS uses with providers, miniport adapters, and filter modules to support network interface objects, see NDIS Network Interface to OID Mapping.

The handle at the *ProviderIfContext* parameter of **ProviderSetObject** identifies the context area that the interface provider passed to NDIS when it called the **NdisIfRegisterInterface** function to register the interface. The *ObjectId* parameter specifies the OID for the object that is being set. The *InputBufferLength* and *pInputBuffer* parameters provide the length of the input buffer and a pointer to the input buffer, respectively.

Mapping of NDIS Network Interfaces to NDIS OIDs

Article • 03/14/2023

To respond to NDIS interface object requests, NDIS interface providers can cache information that they obtain from underlying drivers and can also issue OID requests to obtain information about underlying interfaces.

As a proxy interface provider, NDIS typically caches information that it receives about miniport adapters and filter modules. The NDIS proxy interface provider uses the cached information, if appropriate, to respond to interface requests. In some cases, the NDIS proxy interface provider issues OIDs to obtain information for interfaces. For example, the primary source of interface information for NDIS 5.*x* and earlier drivers is through OID requests. In NDIS 6.0 drivers, there are additional sources of interface information, such as the **NDIS_RESTART_ATTRIBUTES** and **NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES** structures. For more information about alternate sources of information in the OIDs, see the reference page for each OID.

The NDIS proxy interface provider also generates some interface information on behalf of miniport adapters and filter modules. For example, NDIS generates an interface alias (*ifAlias* in RFC 2863) in response to the *ifAlias* request. NDIS defines additional OIDs to obtain such information from NDIS interface providers. For example, OID_GEN_ALIAS allows an interface provider to specify an *ifAlias* object. Such OIDs are specific to interface providers and are never used to obtain information from other NDIS drivers.

In addition to the OIDs that are specific to interface providers, interface providers must support the other NDIS OIDs that NDIS can use to obtain interface information. NDIS can issue these OIDs to the provider and the provider can issue these OIDs, if necessary, to collect information from underlying interfaces.

Note NDIS defines additional statistics that are not included in RFC 2863. For a list that maps all of the NDIS-supported interface statistics to OIDs, see the members of the **NDIS_INTERFACE_INFORMATION** structure. The table in this topic defines the mapping for statistics that are defined in the RFC 2863 specification for readers that are trying to relate the specification to the NDIS implementation.

The following table shows the mapping from the objects that are defined in the management information base (MIB) to NDIS 6.0 OIDs and to OIDs that NDIS might use to obtain information from NDIS 5.*x* and earlier drivers. The table also includes some additional interface objects that are not defined as MIB objects. The interface objects also correspond to members in the **NDIS_INTERFACE_INFORMATION** structure that is associated with the OID_GEN_INTERFACE_INFO OID.

Note The NDIS 6.0 OIDs in the table that are marked with a asterisk (*) prefix are specific to interface providers. The other NDIS 6.0 OIDs can be issued to interface providers and other NDIS drivers.

Interfaces MIB value	NDIS 6.0 OIDs	NDIS 5.x and earlier OIDs
ifAdminStatus	* OID_GEN_ADMIN_STATUS

NDIS_MDL_LINKAGE macro

Article • 03/14/2023

The **NDIS_MDL_LINKAGE** macro retrieves a pointer to the next MDL that is associated with the specified MDL.

Syntax

```
ManagedCPlusPlus

PVOID NDIS_MDL_LINKAGE(
   PMDL _Mdl
);
```

Parameters

_Mdl
A pointer to an MDL.

Return value

NDIS_MDL_LINKAGE returns a pointer to an MDL or **NULL** if there is no next MDL.

Remarks

The **NDIS_MDL_LINKAGE** macro provides an MDL-based version of the NDIS_BUFFER_LINKAGE function.

Requirements

Target platform	Desktop
Version	Supported in NDIS 6.0 and later.
Header	Ndis.h (include Ndis.h)
IRQL	Any level

See also

NDIS_BUFFER_LINKAGE

NDIS_MDL_TO_SPAN_PAGES macro

Article • 03/14/2023

The **NDIS_MDL_TO_SPAN_PAGES** macro retrieves the number of physical pages of memory that are being used to back a given MDL.

Syntax

ManagedCPlusPlus

```
int NDIS_MDL_TO_SPAN_PAGES(
   PMDL _Mdl
);
```

Parameters

_Mdl
A pointer to an MDL.

Return value

NDIS_MDL_TO_SPAN_PAGES returns the number of pages that are backing the virtual range for the MDL.

Remarks

The **NDIS_MDL_TO_SPAN_PAGES** macro provides an MDL-based version of the NDIS_BUFFER_TO_SPAN_PAGES function.

Requirements

Target platform	Desktop
Version	Supported in NDIS 6.0 and later.
Header	Ndis.h (include Ndis.h)
IRQL	Any level

See also

NDIS_BUFFER_TO_SPAN_PAGES

NdisGetMdlPhysicalArraySize macro

Article • 12/15/2021

The **NdisGetMdlPhysicalArraySize** macro retrieves the number of disconnected physical memory blocks that are associated with an MDL.

Syntax

```
ManagedCPlusPlus

VOID NdisGetMdlPhysicalArraySize(
    _Mdl,
    _ArraySize
);
```

Parameters

_Mdl
A pointer to an MDL.

_ArraySize
A pointer to a caller-supplied variable in which this macro returns the number of disconnected physical memory blocks that are associated with the specified MDL.

Return value

None

Remarks

The **NdisGetMdlPhysicalArraySize** macro provides an MDL-based version of the NdisGetBufferPhysicalArraySize function.

Requirements

Target platform	Desktop
Version	Supported in NDIS 6.0 and later.

Header	Ndis.h (include Ndis.h)
IRQL	<= DISPATCH_LEVEL
DDI compliance rules	Irql_NetBuffer_Function

See also

NdisGetBufferPhysicalArraySize

NdisGetNextMdl macro

Article • 12/15/2021

The **NdisGetNextMdl** macro retrieves the next MDL in an MDL chain, given a pointer to the current MDL.

Syntax

ManagedCPlusPlus

```
VOID NdisGetNextMdl(
    _CurrentMdl,
    _NextMdl
);
```

Parameters

_CurrentMdl
A pointer to the specified current MDL.

_NextMdl
A pointer to a caller-supplied variable in which this macro returns a pointer to the next MDL in the MDL chain, if any, that follows the MDL at *_CurrentMdl* .

Return value

None

Remarks

The **NdisGetNextMdl** macro provides an MDL-based version of the NdisGetNextBuffer function.

Requirements

Target platform	Desktop
Version	Supported in NDIS 6.0 and later.

Header	Ndis.h (include Ndis.h)
IRQL	Any level

See also

NdisGetNextBuffer

NdisQueryMdl macro

Article • 12/15/2021

The **NdisQueryMdl** macro retrieves the buffer length, and optionally the base virtual address, from an MDL.

Syntax

```
ManagedCPlusPlus

VOID NdisQueryMdl(
    _Mdl,
    _VirtualAddress,
    _Length,
    _Priority
);
```

Parameters

_Mdl
A pointer to an MDL.

_VirtualAddress
A pointer to a caller-supplied variable in which this macro returns the base virtual address of the virtual address range that is described by the MDL. The base virtual address can be **NULL** for either of the following reasons:

- System resources are low or exhausted and the *_Priority* parameter is set to **LowPagePriority** or **NormalPagePriority**.

- System resources are exhausted and the *_Priority* parameter is set to **HighPagePriority**.

_Length
A pointer to a caller-supplied variable in which this macro returns the length, in bytes, of the virtual address range that is described by the MDL.

_Priority
A page priority value. For a list of the possible values for this parameter, see the *Priority* parameter of the MmGetSystemAddressForMdlSafe macro.

Return value

None

Remarks

The **NdisQueryMdl** macro provides an MDL-based version of the NdisQueryBuffer function.

Requirements

Target platform	Desktop
Version	Supported in NDIS 6.0 and later.
Header	Ndis.h (include Ndis.h)
IRQL	<= DISPATCH_LEVEL
DDI compliance rules	Irql_NetBuffer_Function

See also

MmGetSystemAddressForMdlSafe

NdisQueryBuffer

NdisQueryMdlOffset macro

Article • 12/15/2021

The **NdisQueryMdlOffset** macro retrieves the offset within a physical page at which a given MDL buffer begins and the length of the buffer.

Syntax

ManagedCPlusPlus

```
VOID NdisQueryMdlOffset(
    _Mdl,
    _Offset,
    _Length
);
```

Parameters

_Mdl
A pointer to an MDL.

_Offset
A pointer to a caller-supplied variable in which this macro returns the zero-based byte offset within the physical page that contains the MDL-specified buffer.

_Length
A pointer to a caller-supplied variable in which this macro returns the length, in bytes, of the virtual address range that is specified by the MDL.

Return value

None

Remarks

The **NdisQueryMdlOffset** macro provides an MDL-based version of the NdisQueryBufferOffset function.

Requirements

Target platform	Desktop
Version	Supported in NDIS 6.0 and later.
Header	Ndis.h (include Ndis.h)
IRQL	<= DISPATCH_LEVEL
DDI compliance rules	Irql_NetBuffer_Function

Overview of NDIS packet timestamping

Article • 03/14/2023

The NDIS packet timestamping interface supports the hardware timestamping capability of a network interface card (NIC) for the Precision Time Protocol (PTP) version 2.

Many NICs can generate timestamps in their hardware when a packet is received or transmitted using their own hardware clock. Starting with NDIS 6.82, NDIS packet timestamping allows you to add hardware timestamping support to your NIC driver.

You may want to enable timestamping support to improve the accuracy of clock synchronization applications. The miniport driver should disable all types of timestamping support by default.

Specifically, NDIS packet timestamping makes hardware timestamps available to the operating system so that applications implementing the PTP protocol with UDP as the transport can use them. PTP is a protocol that can utilize hardware timestamps to achieve more accurate time synchronization between systems.

The closer timestamp generation is to when a packet is sent or received by the network adapter hardware, the more accurate the synchronization application. NDIS packet timestamping can help improve the accuracy of time synchronization applications by enabling them to use timestamps generated in the NIC hardware.

NDIS packet timestamping enables PTP version 2 applications (as defined by IEEE) operating in the two-step mode to use the NIC’s hardware timestamping capabilities. In two-step mode, timestamps in PTP packets are retrieved from the hardware and conveyed as separate messages rather than being generated on the fly in the hardware.

NDIS packet timestamping provides the ability to:

- Discover the NIC hardware’s timestamping capabilities.
- Associate the NIC hardware clock’s timestamps to PTP version 2 traffic running over UDP (using the standard UDP ports defined for PTP, for example 319 and 320).
- Use the NIC hardware’s clock as a free running clock. The ability to query the network hardware’s clock and establish a relation between the network hardware clock and a system clock makes this possible.
- Generate software timestamps.

The target of the NDIS packet timestamping interface is Ethernet hardware. The interface works with both NICs that specifically support hardware timestamp generation for PTP version 2 traffic as well as NICs that can generate hardware timestamps for all traffic, as these NICs work with PTP traffic as well.

Reporting timestamping capabilities and current configuration

Article • 12/15/2021

Miniport drivers need to indicate the NIC's hardware timestamping capabilities and the miniport driver's software timestamping capabilities to NDIS and overlying drivers. They also need to report which timestamping capabilities are currently enabled or disabled. Miniport drivers use status indications to report the timestamping capabilities and their current configuration to the operating system.

During initialization, the miniport driver should report the timestamping capabilities and their current configuration within the *MiniportInitializeEx* function. The driver should:

1. Generate an NDIS_STATUS_TIMESTAMP_CAPABILITY status indication to report the timestamping capabilities.

2. Generate an NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG status indication to report the current timestamping configuration.

> ⓘ Note
>
> Miniport drivers read the ***PtpHardwareTimestamp** and ***SoftwareTimestamp** keywords values in the INF file to determine which timestamping capabilities are enabled or disabled. For more information, see Standardized INF keywords for NDIS packet timestamping.

Any time that the miniport driver detects a change in underlying hardware capabilities it must generate the **NDIS_STATUS_TIMESTAMP_CAPABILITY** status indication. It must also report the corresponding change in the current configuration using the **NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG** status indication.

The miniport driver must also generate the **NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG** status indication whenever it detects a change in the current timestamping configuration.

Attaching timestamps to packets

Article • 12/15/2021

After the miniport driver reports which timestamping capabilities are present and currently enabled, the driver can attach the relevant timestamps to packets using the NET_BUFFER_LIST (NBL) structure.

For more information on reporting the NIC's hardware timestamping capabilities and the miniport driver's software timestamping capabilities to the operating system, see Reporting timestamping capabilities and current configuration.

Hardware timestamps

The `PtpV2OverUdpIPv4EventMsgReceiveHw`, `PtpV2OverUdpIPv4AllMsgReceiveHw`, `PtpV2OverUdpIPv4EventMsgTransmitHw`, `PtpV2OverUdpIPv4AllMsgTransmitHw`, `PtpV2OverUdpIPv6EventMsgReceiveHw`, `PtpV2OverUdpIPv6AllMsgReceiveHw`, `PtpV2OverUdpIPv6EventMsgTransmitHw`, `PtpV2OverUdpIPv6AllMsgTransmitHw`, `AllReceiveHw`, `AllTransmitHw` and `TaggedTransmitHw` flags in the NDIS_TIMESTAMP_CAPABILITY_FLAGS structure indicate which hardware timestamps the miniport driver supports.

The timestamp that the NIC hardware generates on reception or transmission of a packet is represented by a 64-bit integer value. This should be the raw value of the NIC hardware's clock at the point the timestamp is captured. The timestamp is stored in the NBL structure's **NetBufferListInfo** array.

Miniport drivers can use the NET_BUFFER_LIST_TIMESTAMP structure to set the timestamp in the NBL's **NetBufferListInfo** field. The driver fills the **Timestamp** field of the **NET_BUFFER_LIST_TIMESTAMP** structure with the timestamp generated by the hardware and calls the NdisSetNblTimestampInfo utility function, passing in the structure.

Miniport drivers can use NdisGetNblTimestampInfo and NdisCopyNblTimestampInfo to retrieve and copy timestamps.

If a particular hardware timestamp setting is enabled but a timestamp that corresponds to that capability isn't generated, the miniport should set the timestamp it attaches to the NBL to **zero**.

ⓘ Note

When recognizing PTP version 2 packets to generate hardware timestamps, the implementation should not restrict timestamp generation to packets that use the multicast addresses (both IPv4 and IPv6) that are specified by the PTP specification. The implementation should try to recognize PTP packets in other ways, for example using the UDP header or the PTP payload. This is so timestamps are still generated in scenarios where a PTP implementation might not use the multicast addresses specified in the PTP specification, for example where unicast addresses are used.

Receive side timestamping

The hardware should obtain the timestamp as close as possible to the point when the hardware receives the frame from the medium. This guideline is specified by the IEEE 1588 standard.

When a packet is received, the miniport driver must:

1. Correct the timestamp for any delays that exist between when the hardware captured the timestamp and when the hardware actually received the frame.

2. Attach the timestamp generated in hardware to the NBL. The timestamp corresponds to the frame (NET_BUFFER structure) contained in the NBL.

3. Call NdisMIndicateReceiveNetBufferLists to indicate the NBL to NDIS.

Note that in the receive direction, miniport drivers for Ethernet hardware are required to indicate only one **NET_BUFFER** per NBL.

Transmit side timestamping

The hardware should obtain the timestamp as close as possible to the point when the hardware transmits the frame to the medium. This guideline is specified by the IEEE 1588 standard.

When a packet is transmitted, the miniport driver must:

1. Correct the timestamp for any delays that exist between when the hardware captured the timestamp and when the hardware actually transmitted the frame.

2. Attach the timestamp generated in hardware to the NBL. If the NBL contains multiple **NET_BUFFER**s, the hardware timestamp corresponding to the first **NET_BUFFER** in the NBL should be attached to the NBL.

3. Call NdisMSendNetBufferListsComplete to send complete the NBL to NDIS.

Miniports and NIC hardware that report that the `TaggedTransmitHw` capability flag is supported and currently enabled should check if the `NDIS_NBL_FLAGS_CAPTURE_TIMESTAMP_ON_TRANSMIT` flag is set in the **NblFlags** field of an NBL that is given to the miniport for transmission. If this flag is set, this indicates that a transmit time timestamp is needed for that NBL and a transmit time hardware timestamp should be generated for the NBL.

Software timestamps

The `AllReceiveSw`, `AllTransmitSw` and `TaggedTransmitSw` flags in the NDIS_TIMESTAMP_CAPABILITY_FLAGS structure indicate if the miniport supports generating software timestamps.

Software timestamps are also represented as 64-bit integer values and are stored in the same slot in the **NetBufferListInfo** array of the NET_BUFFER (NBL) structure as the hardware timestamps.

If software timestamping capabilities are present and enabled then the miniport driver sets the timestamp in the NBL using the performance counter value (QPC). The miniport driver must:

1. Call KeQueryPerformanceCounter to obtain the QPC.

2. Fill the **Timestamp** field of the NET_BUFFER_LIST_TIMESTAMP structure with the QPC.

3. Set the timestamp in the NBL by calling NdisSetNblTimestampInfo and passing in the **NET_BUFFER_LIST_TIMESTAMP**.

On receive the miniport driver should capture the QPC as early as possible but no earlier than when the packet arrived.

On transmit the miniport driver should capture the QPC as late as possible before the packet is given to the hardware for transmission.

The `TaggedTransmitSw` flag is analogous to the `TaggedTransmitHw` flag but corresponds to software timestamps. If the capability is supported and enabled then the miniport should check the `NDIS_NBL_FLAGS_CAPTURE_TIMESTAMP_ON_TRANSMIT` flag in the **NblFlags** field of the NBL. If this flag is set, the miniport should generate a transmit time software timestamp for the NBL.

NDIS_STATUS_TIMESTAMP_CAPABILITY

Article • 03/14/2023

Miniport drivers use the **NDIS_STATUS_TIMESTAMP_CAPABILITY** status indication to report the NIC's hardware timestamping capabilities and the miniport driver's software timestamping capabilities to NDIS and overlying drivers.

This status indication represents the timestamping capabilities of the hardware and miniport driver, not which capability is currently enabled or disabled. For more information on reporting the current timestamping configuration, see NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG.

Remarks

During initialization, the miniport driver should indicate its hardware and software timestamp capabilities from within its MiniportInitializeEx function. The driver should:

1. Initialize an NDIS_TIMESTAMP_CAPABILITIES structure with the NIC's hardware and software timestamp capabilities. The driver sets the members of the **NDIS_TIMESTAMP_CAPABILITIES** structure as follows:

   - The driver uses the **TimestampFlags** field to indicate the hardware and software timestamp capabilities.

   > ⓘ **Note**
   >
   > An implementation must support hardware timestamps and cross timestamps. Supporting software timestamps is optional.

   - The driver must set the **CrossTimestamp** field to **TRUE**.
   - The **HardwareClockFrequencyHz** field should contain the nominal operating frequency of the hardware clock used for timestamping by the NIC. This data may be used to display the nominal clock frequency to end users for informational purposes.
   - The **Type** field in the **Header** field should be set to **NDIS_OBJECT_TYPE_DEFAULT** and the **Revision** to **NDIS_TIMESTAMP_CAPABILITIES_REVISION_1**.

2. Generate an **NDIS_STATUS_TIMESTAMP_CAPABILITY** status indication by calling NdisMIndicateStatusEx to report the timestamping capabilities. The **StatusBuffer** field of the NDIS_STATUS_INDICATION structure should point to the initialized **NDIS_TIMESTAMP_CAPABILITIES** structure.

The miniport driver must also generate the NDIS_STATUS_TIMESTAMP_CAPABILITY status indication whenever it detects a change in underlying hardware capabilities.

Here's how a miniport driver might indicate its supported timestamping capabilities:

C++

```cpp
// From within its initialization routine, the miniport in this
// example indicates that it supports the following capabilities:
// - PtpV2OverUdpIPv4EventMsgReceiveHw
// - PtpV2OverUdpIPv6EventMsgReceiveHw
// - TaggedTransmitHw
// - CrossTimestamp

NDIS_STATUS MiniportInitializeEx(
    _In_ NDIS_HANDLE MiniportAdapterHandle,
    _In_ NDIS_HANDLE MiniportDriverContext,
    _In_ PNDIS_MINIPORT_INIT_PARAMETERS MiniportInitParameters
)
{
. . .
    NDIS_TIMESTAMP_CAPABILITIES timeStampCapabilities;
    NDIS_STATUS_INDICATION timeStampStatus;
. . .

    // Initialize an NDIS_TIMESTAMP_CAPABILITIES structure

    RtlZeroMemory(&timeStampCapabilities, sizeof(timeStampCapabilities));
    RtlZeroMemory(&timeStampStatus, sizeof(timeStampStatus));

    timeStampCapabilities.Header.Type = NDIS_OBJECT_TYPE_DEFAULT;
    timeStampCapabilities.Header.Size = sizeof(timeStampCapabilities);
    timeStampCapabilities.Header.Revision =
NDIS_TIMESTAMP_CAPABILITIES_REVISION_1;

    timeStampCapabilities.CrossTimestamp = TRUE;
    timeStampCapabilities.TimestampFlags.PtpV2OverUdpIPv4EventMsgReceiveHw =
TRUE;
    timeStampCapabilities.TimestampFlags.PtpV2OverUdpIPv6EventMsgReceiveHw =
TRUE;
    timeStampCapabilities.TimestampFlags.TaggedTransmitHw = TRUE;

    timeStampCapabilities.HardwareClockFrequencyHz = 150000;

    timeStampStatus.Header.Type = NDIS_OBJECT_TYPE_STATUS_INDICATION;
    timeStampStatus.Header.Revision = NDIS_STATUS_INDICATION_REVISION_1;
    timeStampStatus.Header.Size = NDIS_SIZEOF_STATUS_INDICATION_REVISION_1;
    timeStampStatus.SourceHandle = MiniportAdapterHandle;
    timeStampStatus.StatusBuffer = &timeStampCapabilities;
    timeStampStatus.StatusBufferSize = sizeof(timeStampCapabilities);
    timeStampStatus.StatusCode = NDIS_STATUS_TIMESTAMP_CAPABILITY;

    // Generate an NDIS_STATUS_TIMESTAMP_CAPABILITY status indication
    NdisMIndicateStatusEx(MiniportAdapterHandle, &timeStampStatus);
. . .
}
```

Requirements

Requirement	Value
Minimum supported client	Windows 11
Minimum supported server	Windows Server 2022
NDIS Version	NDIS 6.82 and later
Header	Ntddndis.h (include Ndis.h)

Reporting timestamping capabilities and current configuration

NDIS_TIMESTAMP_CAPABILITIES

NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG

MiniportInitializeEx

NdisMIndicateStatusEx

NDIS_STATUS_INDICATION

NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG

Article • 03/14/2023

Miniport drivers use the **NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG** status indication to report the current timestamping configuration of the NIC hardware and miniport driver to NDIS and overlying drivers.

This status indication represents which timestamping capabilities are currently enabled or disabled. For information about the status indication driver use to report the timestamping capabilities, see NDIS_STATUS_TIMESTAMP_CAPABILITY.

Remarks

During initialization, the miniport driver should indicate the current timestamping configuration from within its MiniportInitializeEx function. The driver should:

1. Initialize an NDIS_TIMESTAMP_CAPABILITIES structure with the current timestamping configuration. The driver sets the members of the **NDIS_TIMESTAMP_CAPABILITIES** structure as follows:

   - The driver uses the **TimestampFlags** field to indicate its current timestamping configuration. Each flag in the NDIS_TIMESTAMP_CAPABILITY_FLAGS structure should be set to **TRUE** if the corresponding timestamping capability is currently enabled or **FALSE** if it is not.

   > ⓘ Note
   >
   > To determine which timestamping capabilities are currently enabled or disabled, the miniport reads the current values of the timestamping related keywords ***PtpHardwareTimestamp** and ***SoftwareTimestamp**. For more on using these keywords and determining which timestamping capabilities to enable, see Standardized INF keywords for NDIS packet timestamping.

   > ⓘ Note
   >
   > If an implementation finds both hardware and software timestamps enabled through the keywords, then the miniport should only enable hardware timestamps and should disable software timestamps.

- The driver should set the **CrossTimestamp** field to **TRUE** if hardware cross timestamps are enabled in the current configuration or **FALSE** if they are not.
- The **HardwareClockFrequencyHz** field must contain the current operating frequency of the NIC's hardware clock.
- The **Type** field in the **Header** field should be set to **NDIS_OBJECT_TYPE_DEFAULT** and the **Revision** to **NDIS_TIMESTAMP_CAPABILITIES_REVISION_1**.

2. Generate an NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG status indication by calling NdisMIndicateStatusEx to report the current configuration. The **StatusBuffer** field of the NDIS_STATUS_INDICATION structure should point to the initialized **NDIS_TIMESTAMP_CAPABILITIES** structure.

The miniport driver must generate an NDIS_STATUS_TIMESTAMP_CAPABILITY indication at least once before indicating **NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG**. Otherwise NDIS will reject the **NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG** status indication and it will not be indicated to overlying drivers.

If the miniport driver indicates a change in the NIC's hardware timestamping *capability* using the NDIS_STATUS_TIMESTAMP_CAPABILITY status indication (for example, a change in the **HardwareClockFrequencyHz** field in the **NDIS_TIMESTAMP_CAPABILITIES** structure because of an underlying change in the NIC hardware), then it must also report the corresponding change in the current configuration using the **NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG** status indication.

The miniport driver must also generate the **NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG** status indication whenever it detects a change in current timestamping configuration.

Requirements

Requirement	Value

Standardized INF keywords for NDIS packet timestamping

Article • 03/14/2023

An INF file can define the following standardized INF keywords to enable or disable the timestamping capabilities that the miniport driver and NIC hardware supports.

Miniport drivers can use these keywords to determine the current configuration of the timestamping capabilities. For example, the driver can read these keyword values during initialization to determine which timestamping capabilities are enabled and the driver can therefore use.

***PtpHardwareTimestamp** INF keyword

***SoftwareTimestamp** INF keyword

For more information about standardized INF keywords, see Standardized INF Keywords for Network Devices.

*PtpHardwareTimestamp INF keyword

The ***PtpHardwareTimestamp** keyword is defined to enable or disable support for hardware timestamping for Precision Time Protocol (PTP) version 2 packets using UDP as the transport.

The default setting for the ***PtpHardwareTimestamp** keyword is disabled and the miniport driver should disable all types of hardware timestamping support in the NIC hardware by default.

Miniport drivers read the ***PtpHardwareTimestamp** keyword value to determine if hardware timestamping is currently enabled or disabled.

If ***PtpHardwareTimestamp** is enabled, the miniport driver should:

1. Enable the relevant hardware timestamping capabilities in the NIC hardware.

2. Generate the NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG status indication to report the timestamping capabilities it enabled to NDIS. The driver uses the NDIS_TIMESTAMP_CAPABILITIES structure to specify which capabilities it enabled. The flags within the **TimestampFlags** field in the **NDIS_TIMESTAMP_CAPABILITIES** structure that correspond to hardware timestamping are `PtpV2OverUdpIPv4EventMsgReceiveHw`, `PtpV2OverUdpIPv4AllMsgReceiveHw`,

`PtpV2OverUdpIPv4EventMsgTransmitHw`, `PtpV2OverUdpIPv4AllMsgTransmitHw`, `PtpV2OverUdpIPv6EventMsgReceiveHw`, `PtpV2OverUdpIPv6AllMsgReceiveHw`, `PtpV2OverUdpIPv6EventMsgTransmitHw`, `PtpV2OverUdpIPv6AllMsgTransmitHw`, `AllReceiveHw`, `AllTransmitHw` and `TaggedTransmitHw`. The **CrossTimestamp** field in the **NDIS_TIMESTAMP_CAPABILITIES** structure for the **NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG** status indicates if hardware cross timestamping is enabled.

When ***PtpHardwareTimestamp** is enabled the miniport should turn on some form of capability to generate hardware timestamps for both Rx and Tx for PTP version 2 over UDP. The miniport should also turn on the hardware cross timestamping capability if the hardware supports it.

The specific hardware timestamping capabilities that the miniport driver should enable in hardware depends on the capabilities of the NIC hardware. For example, if the NIC hardware only supports the `PtpV2OverUDPIPv4EventMsgReceiveHw`, `PtpV2OverUDPIPv6EventMsgReceiveHw` and `TaggedTransmitHw` capabilities, then the miniport can turn on these hardware timestamping capabilities if the ***PtpHardwareTimestamp** keyword is enabled.

If the NIC hardware supports multiple forms of hardware timestamping capabilities that can enable the PTP version 2 over UDP scenario, then the IHV should consider their hardware and issues such as performance impact to decide which capabilities the miniport should turn on. For example, the hardware may be capable of generating timestamps for `AllTransmitHw` and `TaggedTransmitHw`. If turning on `AllTransmitHw` is more expensive than turning on `TaggedTransmitHw`, then the IHV may choose to only turn on the `TaggedTransmitHw` capability for Tx.

In all cases, the miniport driver should accurately report which hardware timestamping capabilities it enabled or disabled using the **NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG** status indication.

> ⓘ Note
>
> PTP over raw Ethernet is not supported. The IHV needs to determine what the most efficient way of handling PTP over raw Ethernet packets when supporting PTP over UDP is enabled.

> ⓘ Note

No support is needed for PTP version 1. If the NIC hardware also supports PTP version 1, then the IHV needs to determine the most efficient way of handling PTP version 1 packets when supporting PTP version 2.

INF entries for *PtpHardwareTimestamp

The ***PtpHardwareTimestamp** INF keyword is an enumeration keyword. Enumeration standardized INF keywords have the following attributes:

SubkeyName: The name of the keyword that you must specify in the INF file.

ParamDesc: The display text that is associated with SubkeyName.

Value: The enumeration integer value that is associated with each SubkeyName in the list.

EnumDesc: The display text that is associated with each value that appears in the menu.

Default: The default value for the menu.

The following table describes the possible INF entries for the ***PtpHardwareTimestamp** INF keyword.

SubkeyName	ParamDesc	Value	EnumDesc
***PtpHardwareTimestamp**	PTP Hardware Timestamp	0 (Default)	Disabled
		1	Enabled

ⓘ Note

If the miniport driver finds an unsupported value for the ***PtpHardwareTimestamp** keyword, then it should disable the hardware timestamping capability completely.

*SoftwareTimestamp INF keyword

The ***SoftwareTimestamp** keyword corresponds to the types of software timestamping the miniport driver is capable of. The miniport driver uses the configured value for this keyword to determine which of the supported software timestamping capabilities are currently enabled.

The default setting for the ***SoftwareTimestamp** keyword is disabled and all types of software timestamping support in the miniport should be disabled by default.

The miniport generates the NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG status indication to inform NDIS of the various timestamping capabilities that are currently enabled.

The flags within the **TimestampFlags** field in the NDIS_TIMESTAMP_CAPABILITIES structure that correspond to software timestamping are `AllReceiveSw`, `AllTransmitSw` and `TaggedTransmitSw`.

If the ***SoftwareTimestamp** keyword contains a value that indicates that some configuration of software timestamping is enabled, then the miniport should enable the configured software timestamping capabilities and generate a **NDIS_STATUS_TIMESTAMP_CURRENT_CONFIG** status indication that accurately reports which software timestamping capabilities have been enabled.

If the miniport does not support any type of software timestamping then the ***SoftwareTimestamp** keyword should not be included in its INF file.

The ***SoftwareTimestamp** INF keyword is an enumeration keyword. Enumeration standardized INF keywords have the following attributes:

SubkeyName: The name of the keyword that you must specify in the INF file.

ParamDesc: The display text that is associated with SubkeyName.

Value: The enumeration integer value that is associated with each SubkeyName in the list.

EnumDesc: The display text that is associated with each value that appears in the menu.

Default: The default value for the menu.

The following table describes the possible INF entries for the ***SoftwareTimestamp** INF keyword.

SubkeyName	ParamDesc	Value	EnumDesc
***SoftwareTimestamp**	Software Timestamp	0 (Default)	Disabled
		1	**RxAll**: This enum value corresponds to the miniport driver capability to generate software timestamps for all packets during Rx.

SubkeyName	ParamDesc	Value	EnumDesc
		2	**TxAll**: This enum value corresponds to the miniport driver capability to generate software timestamps for all packets during Tx.
		3	**RxAll & TxAll**: This enum value corresponds to the miniport driver capability to generate software timestamps for all packets during Rx and Tx.
		4	**TaggedTx**: This enum value corresponds to the miniport driver capability to generate software timestamps for a specific Tx packet when indicated to do so by the operating system.
		5	**RxAll & TaggedTx**: This enum value corresponds to the miniport driver capability to generate software timestamps for all packets during Rx and for a specific Tx packet when indicated to do so by the operating system.

ⓘ **Note**

If the miniport driver finds an unsupported value for the ***SoftwareTimestamp** keyword, then it should disable the software timestamping capability completely.

Querying timestamping capabilities and configuration

Article • 12/15/2021

Once the miniport driver is initialized, overlying drivers and applications can issue the following OID query requests to obtain hardware and software timestamping information.

- OID_TIMESTAMP_CAPABILITY. An overlying driver issues an object identifier (OID) query request of OID_TIMESTAMP_CAPABILITY to obtain the hardware timestamping capabilities of the NIC and software timestamping capabilities of the miniport driver.

- OID_TIMESTAMP_CURRENT_CONFIG. An overlying driver issues an OID query request of OID_TIMESTAMP_CURRENT_CONFIG to obtain the current timestamping configuration of the NIC.

- OID_TIMESTAMP_GET_CROSSTIMESTAMP. An overlying driver issues an OID query request of OID_TIMESTAMP_GET_CROSSTIMESTAMP to obtain the cross timestamp from the NIC hardware. Precision Time Protocol (PTP) version 2 applications use the information provided in this OID to establish a relation between the NIC's hardware clock and a system clock.

NDIS handles the OID_TIMESTAMP_CAPABILITY and OID_TIMESTAMP_GET_CROSSTIMESTAMP OIDs based on the information that the miniport driver reported when it registered the timestamping capabilities and current configuration to the operating system.

The miniport driver completes the OID_TIMESTAMP_GET_CROSSTIMESTAMP OID. The miniport must support this OID if it sets the **CrossTimestamp** field to **TRUE** in the **NDIS_TIMESTAMP_CAPABILITIES** structure as part of the current configuration.

For more information on how the miniport driver reports the timestamping capabilities, see Reporting timestamping capabilities and current configuration.

Overview of NDIS Ports

Article • 03/14/2023

This section introduces NDIS ports, which are an NDIS 6.0 feature and which enable overlying networking layers to access subinterfaces. In NDIS, network interfaces are associated with miniport adapters, and subinterfaces of a miniport adapter are called *NDIS ports*.

The architecture of the driver stack is much simpler because every network interface is treated as a miniport adapter. For example, each miniport adapter has its own IP and MAC address. In most cases, the overlying drivers do not require information about the virtual or physical nature of the miniport adapter or information about the physical device at the bottom of the driver stack.

An NDIS miniport adapter can provide an interface for a physical device or a virtual device. NDIS intermediate drivers provide interfaces for virtual devices that are called *virtual miniports*. NDIS intermediate drivers can bind to underlying miniport adapters and expose virtual miniports that overlying protocol drivers bind to.

In many cases, there is no one-to-one relationship between the underlying physical devices and virtual miniports. For example, an intermediate driver that implements failover functionality can create one virtual miniport to support multiple physical devices, and a virtual LAN (VLAN) intermediate driver can create multiple virtual miniports that are associated with a single physical device. Also, a driver that combines both failover and VLAN functionality can create a set of virtual miniports (*N* number of VLANs) while the driver is bound to multiple physical devices (*M* number of physical devices). For more information about intermediate drivers and virtual miniports, see NDIS 6.0 Intermediate Drivers.

In some applications, the ability to address the subinterfaces that are below virtual miniports is either required or simplifies the design. For example, the Extensible Authentication Protocol (EAP) protocol must specify the physical device that an EAP packet is sent or received on. If multiple physical devices are associated with a single virtual device, the EAP protocol is bound to the virtual device. In that case, the NDIS interfaces prior to NDIS 6.0 hide the subinterfaces, and the EAP protocol cannot choose which underlying physical device should carry the EAP packets. The EAP protocol then does not have any access to the underlying physical miniport adapters. Exposing the underlying physical miniport adapters as NDIS ports allows the EAP protocol to target a particular physical device.

The following topics further describe NDIS ports:

Identifying an NDIS Port

Default NDIS Port

Types of NDIS Ports

NDIS Port States

Identifying an NDIS Port

Article • 03/14/2023

An NDIS port is identified by its port number. When a miniport driver calls the **NdisMAllocatePort** function to allocate a port, NDIS allocates and assigns the lowest available port number to the port. When a miniport driver calls the **NdisMFreePort** function to free a port, NDIS also frees the port number that is assigned to the freed port so that NDIS can reuse the port number.

If a driver maintains separate context areas for each port, the driver must provide an efficient algorithm for translating the port number to the corresponding context area.

Default NDIS Port

Article • 03/14/2023

Port zero is reserved as the default port for a miniport adapter. If the *PortNumber* parameter of any function or the **PortNumber** member of any structure is set to zero, either the miniport driver did not allocate any ports, or the current activity is not port-specific.

For a good example of the default NDIS port, consider a load balancing and failover (LBFO) MUX intermediate driver. The virtual miniport of such a driver can be port zero (the default port). The intermediate driver can assign ports to the underlying miniport adapters with the port numbers ranging from 1 through the number of ports (*N*). An overlying driver could send data to port zero to allow the LBFO driver to select one of the underlying ports, or the overlying driver could specify a port number from 1 through *N* to choose a specific port for the send operation.

Miniport drivers do not have to allocate any ports or support any port numbers other than the default port. Even if a miniport driver does not allocate ports, NDIS allocates the default port and activates it after the miniport driver calls the **NdisMSetMiniportAttributes** function to set the registration attributes in the **NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES** structure. Miniport drivers can start operations on the default port when **NdisMSetMiniportAttributes** successfully returns. In this case, NDIS frees the default port when the miniport driver returns from the *MiniportHaltEx* function.

Types of NDIS Ports

Article • 03/14/2023

NDIS ports can be one of the following types:

NdisPortTypeUndefined
The default port type. Use this type for general port applications that do not fit into one of the following types.

NdisPortTypeBridge
Reserved for system use.

NdisPortTypeRasConnection
A Remote Access Service (RAS) connection.

NdisPortType8021xSupplicant
A remote wireless station that is associated with an access point on this host computer.

NdisPortTypeNdisImPlatform
Reserved for system use.

Note This value is supported only in NDIS 6.30 and later.

The characteristics of an NDIS port vary from one port application to another. For example, for a bridge interface, the miniport driver upper edge of an intermediate driver creates an **NdisPortTypeBridge** port when the protocol edge of the intermediate driver binds to a physical miniport adapter that requires a bridge at layer three.

Overview of NDIS Ports

NDIS Port States

Article • 03/14/2023

NDIS ports have operating states that include initialization states and states that are specified in the NDIS_PORT_STATE structure. Port states fit into the following categories:

Initialization states
NDIS port initialization states are associated with startup initialization and Plug and Play (PnP) events. When NDIS or a miniport driver first allocates a port, the port is in the *allocated state*. After NDIS or the miniport driver activates a port, the port is in the *activated state*. Inactive ports cannot send or receive data, make status indications, receive OID requests, or initiate PnP events.

Link states
NDIS port link states are similar to link states that are associated with a miniport adapter and that are specified in an NDIS_LINK_STATE structure. The port link states indicate the media link connection state and link speeds. The link state of a port can be different from the link state of the associated miniport adapter.

Authentication states
NDIS port authentication states indicate if a port is controlled (requires authorization), the direction of data transmission (send, receive, or both), and the authorization state of a port (authorized, or not authorized). If a port is not controlled, the authenticated and not authenticated states are ignored.

A miniport driver can activate a port or deactivate a port with a PnP event. For more information about activating and deactivating ports, see Activating NDIS Ports and Deactivating NDIS Ports.

Overlying drivers use the OID_GEN_PORT_STATE OID to get the current state of the port that is specified in the **PortNumber** member of the NDIS_OID_REQUEST structure. NDIS handles this OID, and miniport drivers do not receive this OID query.

Miniport drivers that support NDIS ports must use the NDIS_STATUS_PORT_STATE status indication to indicate changes in the state of an NDIS port. Miniport drivers must set the port number in the **PortNumber** member of the NDIS_STATUS_INDICATION structure.

NDIS and overlying drivers use the OID_GEN_PORT_AUTHENTICATION_PARAMETERS OID to set the current authentication states of an NDIS port. Miniport drivers that support NDIS ports must support this OID.

Allocating an NDIS Port

Article • 03/14/2023

To allocate an NDIS port for a miniport adapter, a miniport driver calls the NdisMAllocatePort function. **NdisMAllocatePort** is synchronous and returns after NDIS has successfully allocated the resources that are required for the port.

Before the miniport driver calls **NdisMAllocatePort**, the driver must call the NdisMSetMiniportAttributes function to set the attributes in the NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES structure. Miniport drivers can call **NdisMAllocatePort** for a miniport adapter after the call to **NdisMSetMiniportAttributes** returns successfully and before NDIS calls the *MiniportHaltEx* function for that miniport adapter.

NDIS always allocates the default port (port zero) so miniport drivers should not allocate a default port. NDIS frees the default port after the miniport driver returns form *MiniportHaltEx*.

NDIS assigns a port number to a port when the miniport driver calls NdisMAllocatePort. The driver specifies port characteristics in the NDIS_PORT_CHARACTERISTICS structure before the driver calls **NdisMAllocatePort**. When **NdisMAllocatePort** successfully returns, the **PortNumber** member of NDIS_PORT_CHARACTERISTICS that the *PortCharacteristics* parameter specifies is set to the port number that NDIS assigned to the port.

Before returning from *MiniportHaltEx*, a miniport driver must call the NdisMFreePort function to free all of the ports that are associated with a miniport adapter. If a miniport adapter fails initialization, the driver must call **NdisMFreePort** to free all of the ports that the driver allocated before it returns from the *MiniportInitializeEx* function. For more information about freeing NDIS ports, see Freeing NDIS Ports.

The maximum number of ports that a miniport driver can allocate is 0xffffff. However, in practice, drivers will set a maximum number that is based on the port type and the requirements of the driver application. For example, for a bridge application, the number of ports is unlikely to exceed 16. The number of ports would be higher for access points that use 802.1x supplicant ports and significantly higher for WAN drivers that use virtual private network (VPN) ports.

After a miniport driver allocates a port, the port is in the allocated state, and the port is not active. A port cannot be used to send and receive data, initiate a status indication, issue an OID request, or initiate a Plug and Play (PnP) event, until the port is activated. NDIS activates the default port automatically after the miniport driver sets the registration attributes in an **NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES** structure. To request that NDIS not activate the default port, a miniport driver can set NDIS_MINIPORT_ATTRIBUTES_CONTROLS_DEFAULT_PORT in the **AttributeFlags** member of NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES.

NDIS passes the authentication state of the default port to the *MiniportInitializeEx* function at the **DefaultPortAuthStates** member of the **NDIS_MINIPORT_INIT_PARAMETERS** structure. If a miniport driver controls the default port, when the miniport driver activates the default port, it can activate the default port by using the default authentication settings. For more information about activating the default port, see Activating NDIS Ports.

Miniport drivers can use the NDIS_PORT_CHAR_USE_DEFAULT_AUTH_SETTINGS flag in the **Flags** member of the **NDIS_PORT_CHARACTERISTICS** structure for the ports that the drivers allocate and activate. For the allocation case, NDIS assigns the default authentication states to the new ports and ignores the authentication states that are passed to the **NdisMAllocatePort** function.

For more information about NDIS port states, see NDIS Port States. For more information about activating ports, see Activating NDIS Ports.

Freeing an NDIS Port

Article • 03/14/2023

Your miniport driver must free all NDIS ports that it allocates for miniport adapters in its *MiniportInitializeEx* function. It can free a port any time by calling **NdisMFreePort**, except for the two cases noted below.

Your miniport driver must free all allocated ports in these cases:

- If your driver's *MiniportInitializeEx* function fails, it must free all allocated ports.
- If a miniport adapter is halted, your driver's *MiniportHaltEx* function must free all allocated ports.

Your miniport driver cannot simply call **NdisMFreePort** in these cases:

- If the port is the default port, NDIS frees it automatically, so your miniport driver must not free it. If you try to free the default port, **NdisMFreePort** returns an NDIS_STATUS_INVALID_PORT error.
- If the port is active, your miniport driver will need to deactivate it before calling **NdisMFreePort**.

Allocating NDIS Ports

Deactivating NDIS Ports

Default NDIS Port

Activating an NDIS Port

Article • 03/14/2023

After a miniport driver successfully allocates an NDIS port, and before using the port number in NDIS functions, the driver must activate the port. To activate the port, the miniport driver sends a port activation Plug and Play (PnP) event to NDIS. To send the port activation PnP event, miniport drivers use the **NetEventPortActivation** PnP event code in the call to the NdisMNetPnPEvent function.

To activate ports, the miniport driver must set the members of the NET_PNP_EVENT_NOTIFICATION structure that the *NetPnPEvent* parameter of **NdisMNetPnPEvent** points to as follows:

PortNumber
The source port of the event notification. Set this member to zero because the port numbers are provided in the **Buffer** member of the structure that the **NetPnPEvent** member specifies.

NetPnPEvent
A NET_PNP_EVENT structure that describes the port activation event. Set the members of this structure as follows:

NetEvent
An event code that describes the event. Set this member to **NetEventPortActivation**.

Buffer
A pointer to a linked list of NDIS_PORT structures. The **Next** member of the NDIS_PORT structures points to the next NDIS_PORT structure in the list.

BufferLength
The number of bytes that are specified in **Buffer** . Set **BufferLength** to the size of the NDIS_PORT structures.

Other members
Set the remaining members of NET_PNP_EVENT to **NULL**.

The miniport driver lists the ports that have changed states from inactive to active in a linked list of NDIS_PORT structures. However, if the default port of a miniport adapter is the target of a **NetEventPortActivation** PnP event, the default port must be the only port in the list.

When the miniport driver notifies NDIS of the activation of a port (and possibly before this notification call returns), the miniport driver must be ready to handle send requests and OID requests that are associated with the port. Miniport drivers must not use the port number of a newly activated port in status or receive indications until after the call to **NdisMNetPnPEvent** returns.

NDIS does not notify overlying drivers about activated ports until after the default port is active. When NDIS calls the *ProtocolBindAdapterEx* function of a protocol driver, NDIS provides a list of all currently active ports in the **ActivePorts** member of the **NDIS_BIND_PARAMETERS** structure that the *BindParameters* parameter points to. When a miniport driver activates new ports, NDIS notifies all of the protocol drivers that are bound to the miniport driver with the **NetEventPortActivation** PnP event. For more information about handling these port activation events in a protocol driver, see Handling the Port Activation PnP Event.

Before a miniport driver allocates an NDIS port, the driver must call the **NdisMSetMiniportAttributes** function to set the registration attributes in the **NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES** structure. Miniport drivers can control the activation of the default port by setting the NDIS_MINIPORT_CONTROLS_DEFAULT_PORT attribute flag when they call **NdisMSetMiniportAttributes**. If a miniport driver assumes the responsibility for activating the default port, NDIS does not initiate the binding between the miniport adapter and the overlying drivers until the miniport driver activates the default port with the port activation PnP event.

All of the ports that are specified by the linked list of NDIS_PORT structures must be in the allocated state. A miniport driver should not attempt to activate a port that is already active; if the driver does attempt to activate an active port, NDIS treates the situation as a port activation failure.

If NDIS fails to activate any ports on the list, it fails the call to **NdisMNetPnPEvent**, and none of the ports on the list change state to the activated state. If NDIS fails to activate the ports because some of the ports do not exist, **NdisMNetPnPEvent** returns an NDIS_STATUS_INVALID_PORT return value. If NDIS fails to activate the ports because some of the ports are not in the allocated state, **NdisMNetPnPEvent** returns an NDIS_STATUS_INVALID_PORT_STATE return value.

After a port has been successfully activated, the port is in the activated state. Miniport drivers can indicate received data and status for a port in the activated state.

NDIS passes the authentication state of the default port to the *MiniportInitializeEx* function at the **DefaultPortAuthStates** member of the **NDIS_MINIPORT_INIT_PARAMETERS** structure. If a miniport driver controls the default port, when the miniport driver activates the default port, it can activate the default port by using the default authentication settings. To use the default authentication settings, set the NDIS_PORT_CHAR_USE_DEFAULT_AUTH_SETTINGS flag in the **Flags** member of **NDIS_PORT_CHARACTERISTICS** structure. Miniport drivers can use the NDIS_PORT_CHAR_USE_DEFAULT_AUTH_SETTINGS flag for the ports that they allocate and activate. For the activation case, NDIS assigns the default authentication states to the newly activated port and ignores the authentication states that are passed to **NdisMNetPnPEvent** for the **NetEventPortActivation** event.

For more information about controlling the default port and allocating ports, see Allocating NDIS Ports.

Managing an NDIS Port

Article • 03/14/2023

Interested NDIS drivers and user-mode applications can manage NDIS ports. NDIS provides services to help manage ports.

NDIS notifies the interested NDIS drivers and user mode applications of port state changes by issuing the associated status indications, and PnP events.

The port number that is passed to send and receive functions identifies the target port of a send operation or the source port of a receive indication. Similarly, the port number in the associated structures identifies the port for status indications, OID requests, and PnP events. For more information about port numbers, see NDIS Ports Introduction.

To help manage NDIS ports, the following structures include the port number:

NDIS_OID_REQUEST
Describes OID requests.

NDIS_STATUS_INDICATION
Describes NDIS status indications.

NET_PNP_EVENT_NOTIFICATION
Describes PnP event notifications.

This section includes:

NDIS Port Send and Receive Operations

NDIS Port OID Requests

Handling NDIS Ports Status Indications

Handling NDIS Ports PnP Event Notifications

NDIS Port Send and Receive Operations

Article • 03/14/2023

NDIS drivers can associate send and receive operations with NDIS ports.The port number in the *PortNumber* parameter of the NDIS send and receive functions identifies the target port of a send operation or the source port of a receive indication. If *PortNumber* is zero, the default port is used. When NDIS handles the default port and the miniport driver does not allocate any other ports, no NDIS drivers in the driver stack are required to do anything beyond always setting the *PortNumber* parameter to zero. For more information about allocating ports in a miniport driver, see Allocating NDIS Ports.

If the miniport driver allocates ports, overlying drivers can use the ports to send and receive data on the appropriate subinterfaces of the associated miniport adapter. However, the overlying driver must ensure that the ports are active before sending any data. Miniport drivers activate ports when the associated subinterfaces become available. For more information about activating a port in a miniport driver, see Activating NDIS Ports.

When NDIS calls the *ProtocolBindAdapterEx* function of a protocol driver, NDIS provides a list of all currently active ports in the **ActivePorts** member of the **NDIS_BIND_PARAMETERS** structure that the *BindParameters* parameter points to. NDIS also informs protocol drivers with a PnP event when ports are activated and deactivated. For more information about PnP port activation and deactivation notifications, see Handling NDIS Ports PnP Notifications. For more general information about send and receive operations, see Send and Receive Operations.

NDIS Port OID Requests

Article • 03/14/2023

NDIS drivers can associate OID requests with NDIS ports. In such an OID request, the **PortNumber** member of the **NDIS_OID_REQUEST** structure is set to the target port number. The port number is zero if the OID request is for the default port. The overlying driver must ensure that a port is active before making any OID requests that specify a specific port number.

When NDIS calls the *ProtocolBindAdapterEx* function of a protocol driver, NDIS provides a list of all currently active ports in the **ActivePorts** member of the **NDIS_BIND_PARAMETERS** structure that the *BindParameters* parameter points to. NDIS also informs protocol drivers with a PnP event when ports are activated and deactivated. For more information about PnP port activation and deactivation notifications, see Handling NDIS Ports PnP Notifications.

The following OIDs are specific to the NDIS ports interface:

OID_GEN_ENUMERATE_PORTS
Enumerates the active ports that are associated with a miniport adapter.

OID_GEN_PORT_STATE
Retrieves the current link and authentication port states.

OID_GEN_PORT_AUTHENTICATION_PARAMETERS
Sets the current authentication states of an NDIS port.

This section includes:

- Enumerating Ports
- Querying the Port State
- Setting Port Authentication Parameters

Enumerating Ports

Article • 12/15/2021

NDIS protocol drivers and filter drivers can use an OID_GEN_ENUMERATE_PORTS OID query request to determine the characteristics of the active NDIS ports that are associated with an underlying miniport adapter. NDIS handles this OID, and miniport drivers do not receive this OID query.

If the query succeeds, NDIS provides the results of the query in an **NDIS_PORT_ARRAY** structure. The **NumberOfPorts** member of NDIS_PORT_ARRAY contains the number of active ports that are associated with the miniport adapter. The **Ports** member of NDIS_PORT_ARRAY contains a list of pointers to **NDIS_PORT_CHARACTERISTICS** structures. Each NDIS_PORT_CHARACTERISTICS structure defines the characteristics of a single port.

Querying the Port State

Article • 12/15/2021

Overlying drivers can issue an OID_GEN_PORT_STATE OID query request to get the current state of the port that is specified in the **PortNumber** member of an **NDIS_OID_REQUEST** structure. NDIS handles this OID, and miniport drivers do not receive this OID query. NDIS receives port state information in the **NDIS_PORT_CHARACTERISTICS** structure.

The OID_GEN_PORT_STATE OID is supported in NDIS 6.0 and later versions.

Overlying drivers should avoid using OID_GEN_PORT_STATE when possible and should instead rely on the **NDIS_STATUS_PORT_STATE** status indication. For more information about port-related status indications, see Handling NDIS Ports Status Indications.

If the OID_GEN_PORT_STATE query succeeds, NDIS returns the port state information in an **NDIS_PORT_STATE** structure.

Setting Port Authentication Parameters

Article • 12/15/2021

NDIS and overlying drivers use an OID_GEN_PORT_AUTHENTICATION_PARAMETERS OID set request to set the current state of an NDIS port. Miniport drivers that support NDIS ports must support this OID.

If the set request is successful, the miniport driver uses the receive port direction, port control state, and authenticate state from an **NDIS_PORT_AUTHENTICATION_PARAMETERS** structure.

The miniport should generate an **NDIS_STATUS_PORT_STATE** status indication to notify overlying drivers of any state changes.

Handling NDIS Ports Status Indications

Article • 03/14/2023

If an NDIS port is the source of a status indication, a miniport driver should use the **PortNumber** member in the NDIS_STATUS_INDICATION structure to specify the source port. Miniport drivers never indicate status for inactive ports.

Miniport drivers should use the NDIS_STATUS_PORT_STATE status indication to indicate changes in the state of an NDIS port. For this status indication, miniport drivers must set the port number in the **PortNumber** member of the NDIS_STATUS_INDICATION structure. The **StatusBuffer** member of the NDIS_STATUS_INDICATION structure contains a pointer to an NDIS_PORT_STATE structure.

NDIS Ports PnP Event Notifications

Article • 03/14/2023

NDIS forwards PnP events to notify overlying drivers when ports are activated or deactivated. NDIS and miniport drivers do not generate a PnP event when a port is allocated. Miniport drivers notify NDIS that ports have been activated with the **NetEventPortActivation** PnP event and miniport drivers generate a **NetEventPortDeactivation** PnP event to notify NDIS that some ports have been deactivated.

When NDIS calls the *ProtocolBindAdapterEx* function of a protocol driver, NDIS provides a list of all currently active ports in the **ActivePorts** member of the **NDIS_BIND_PARAMETERS** structure at the *BindParameters* parameter.

The following topics describe how to handle port PnP events:

Handling the Port Activation PnP Event

Handling the Port Deactivation PnP Event

Handling the Port Activation PnP Event

Article • 12/15/2021

Overlying drivers must handle the **NetEventPortActivation** PnP event when a miniport driver activates an NDIS port. NDIS does not initiate the binding between a protocol driver and miniport adapter until the default port has been activated. Therefore, protocol drivers should treat the call to their *ProtocolBindAdapterEx* function as a notification that the default port is active.

Protocol drivers must not use a port number in any NDIS requests unless the driver received notification that the port is active, either through the bind parameters or through the **NetEventPortActivation** PnP event.

NDIS generates a port activation PnP event after the miniport driver activates some ports. (Miniport drivers specify the **NetEventPortActivation** PnP event code in the **NET_PNP_EVENT_NOTIFICATION** structure that the *NetPnPEvent* parameter points to in the call to **NdisMNetPnPEvent** to activate NDIS ports.)

Miniport drivers can indicate the activation of multiple ports in one PnP notification by using the **Next** member in an **NDIS_PORT** structure to link multiple NDIS_PORT structures. For more information about the linked list of NDIS_PORT structures, see Activating NDIS Ports.

NDIS generates a **NetEventPortDeactivation** PnP event to the bound protocol drivers when a miniport deactivates some ports. For more information about the **NetEventPortDeactivation** PnP event, see Handling the Port Deactivation PnP Event.

Handling the Port Deactivation PnP Event

Article • 12/15/2021

Overlying drivers must handle the **NetEventPortDeactivation** PnP event when a miniport driver deactivates an NDIS port. To notify overlying drivers about port deactivation events, NDIS propagates the port deactivation PnP event from the underlying miniport driver.

Before a protocol driver completes the handling of a port deactivation PnP event, it must ensure that all outstanding OID requests and send requests that are associated with the port have completed. After the protocol driver completes the PnP event, the driver must ensure that it does not issue any OID requests or send requests for that port.

Miniport drivers specify the **NetEventPortDeactivation** PnP event code in the **NET_PNP_EVENT_NOTIFICATION** structure that the *NetPnPEvent* parameter points to in the call to the **NdisMNetPnPEvent** function to report that some ports have been deactivated. The miniport driver specifies an array of NDIS_PORT_NUMBER values to list the deactivated ports. For more information about the array of port numbers, see Deactivating NDIS Ports.

Deactivating an NDIS Port

Article • 03/14/2023

To deactivate NDIS ports, a miniport driver sends a port deactivation Plug and Play (PnP) event to NDIS. After a miniport driver successfully activates a port, the driver must deactivate the port before it can free the port. Also, the driver might deactivate a port for application-specific reasons. A port can be reactivated after it is deactivated, but a port cannot be reactivated if it is freed.

To send a port deactivation PnP event, miniport drivers use the **NetEventPortDeactivation** PnP event code in the call to the NdisMNetPnPEvent function. To deactivate ports, the miniport driver must set the members of the NET_PNP_EVENT_NOTIFICATION structure that the *NetPnPEvent* parameter of **NdisMNetPnPEvent** points to as follows:

PortNumber
The source port of the event notification. Set this member to zero because the port numbers are provided in the **Buffer** member of the structure that the **NetPnPEvent** member specifies.

NetPnPEvent
A NET_PNP_EVENT structure that describes the port deactivation event. Set the members of this structure as follows:

NetEvent
An event code that describes the event. Set this member to **NetEventPortDeactivation**.

Buffer
A pointer to an array of NDIS_PORT_NUMBER-typed elements. The array contains the port numbers of all of the ports that the miniport driver is deactivating.

BufferLength
The number of bytes that are specified in **Buffer** . Set **BufferLength** to the size of the array that **Buffer** points to. To obtain the number of elements in the array, divide the value in **BufferLength** by the size of the NDIS_PORT_NUMBER data type.

Other members
Set the remaining members of NET_PNP_EVENT to **NULL**.

A miniport driver can provide an array with a list of ports to deactivate. However, if the default port of a miniport adapter is the target of a **NetEventPortDeactivation** PnP event, the default port must be the only port that is specified in the array.

Miniport drivers can deactivate active ports at any time. However, before a miniport driver deactivates a port, it must ensure that there are no outstanding status indications or receive indications that are associated with that port. After the miniport driver sends the port deactivation PnP event, it must not initiate any status or receive indications that are associated with the deactivated ports.

A miniport driver can also reactivate a port. For more information about activating NDIS ports, see Activating NDIS Ports.

When a miniport driver deactivates ports, NDIS notifies all of the protocol drivers that are bound to the miniport driver with the **NetEventPortDeactivation** PnP event. This PnP event lists those ports that have changed to the allocated state and does not include any ports that are already deactivated. For more information about handling port deactivation events in a protocol driver, see Handling the Port Deactivation PnP Event.

Before a miniport driver allocates an NDIS port, the driver must call the **NdisMSetMiniportAttributes** function to set the registration attributes in the **NDIS_MINIPORT_ADAPTER_REGISTRATION_ATTRIBUTES** structure. Miniport drivers can control the activation of the default port by setting the NDIS_MINIPORT_CONTROLS_DEFAULT_PORT attribute flag when they call **NdisMSetMiniportAttributes**. If a miniport driver assumes the responsibility for activating the default port and the miniport driver activated the default port, it must deactivate the default port before returning from the *MiniportHaltEx* function.

All of the ports that are specified by the array of NDIS_PORT_NUMBER elements must be in the activated state. A miniport driver should not attempt to deactivate a port that has already deactivated.

If NDIS fails to deactivate any ports in the port array, none of the ports in the port array will change state. If the deactivation fails because some of the specified ports do not exist, the **NdisMNetPnPEvent** function returns the NDIS_STATUS_INVALID_PORT return value. If the deactivation fails because some of the ports are not in the activated state, **NdisMNetPnPEvent** returns the NDIS_STATUS_INVALID_PORT_STATE return value.

Until the call to **NdisMNetPnPEvent** returns, a port is not deactivated, and miniport drivers must be able to handle OID requests and send requests that are associated with that port.

When a miniport driver deactivates the default port, NDIS closes all of the bindings between the overlying protocol drivers and the miniport adapter. If a miniport driver tries to deactivate the default port and default port is already deactivated, **NdisMNetPnPEvent** fails and returns the NDIS_STATUS_INVALID_PORT_STATE return value. If a miniport driver tries to deactivates the default port and the default port is not the only port that is specified in the array of NDIS_PORT_NUMBER elements, **NdisMNetPnPEvent** fails and returns the NDIS_STATUS_INVALID_PORT return value. If a miniport driver sets the **Buffer** member to **NULL** or **BufferLength** member to zero, NDIS fails the **NdisMNetPnPEvent** call and returns the NDIS_STATUS_INVALID_PARAMETER return value.

After a port is successfully deactivated, the port is in the allocated state. Miniport drivers cannot indicate received data or status for the port in the allocated state.

Creating NDIS Interfaces for NDIS Ports

Article • 03/14/2023

By default, NDIS does not create an NDIS network interface for an NDIS port. If necessary, NDIS drivers can call the **NdisIfRegisterProvider** function to register as an NDIS interface provider and call the **NdisIfRegisterInterface** function to register an interface for a port.

For more information about NDIS network interfaces, see NDIS 6.0 Network Interfaces.

Power Management (NDIS 6.30)

Article • 03/14/2023

This section describes the power management interface that was introduced with NDIS 6.30 in Windows 8.

This section includes the following topics:

NDIS Packet Coalescing

NDIS Selective Suspend

NDIS Wake Reason Status Indications

Note The NDIS 6.30 power management interface is an extension to the NDIS 6.20 power management interface. For more information about the NDIS 6.20 power management interface, see Power Management (NDIS 6.20).

Introduction to NDIS Packet Coalescing

Article • 03/14/2023

Starting with NDIS 6.30, network adapters can support NDIS packet coalescing. This feature reduces the processing overhead and power consumption on a host system due to the reception of random broadcast or multicast packets.

This section includes the following topics:

Overview of Packet Coalescing

Article • 12/15/2021

Certain IP version 4 (IPv4) and IP version 6 (IPv6) network protocols involve the transmission of packets to broadcast or multicast addresses. These packets are received by multiple hosts in the IPv4/IPv6 subnet. In most cases, the host that receives these packets does not do anything with these packets. Therefore, the reception of these unwanted multicast or broadcast packets causes unnecessary processing and power consumption to occur within the receiving host.

For example, host A sends a multicast Link-local Multicast Name Resolution (LLMNR) request on an IPv6 subnet to resolve host B's name. Except for host A, this LLMNR request is received by all hosts on the subnet. Except for host B, the TCP/IP protocol stack that runs on the other hosts inspects the packet and determines that the packet is not intended for it. Therefore, the protocol stack rejects the packet and calls **NdisReturnNetBufferLists** to return the packet to the miniport driver.

Starting with NDIS 6.30, network adapters can support NDIS packet coalescing. By reducing the number of receive interrupts through the coalescing of random broadcast or multicast packets, the processing overhead and power consumption is significantly reduced on the system.

Packet coalescing involves the following steps:

1. Overlying drivers, such as the TCP/IP protocol stack, define NDIS receive filters that are used to screen broadcast and multicast packets. The overlying drivers download these filters to the underlying miniport driver that supports packet coalescing. Once downloaded, the miniport driver configures the network adapter with the packet coalescing receive filters.

   For more information about these filters, see Packet Coalescing Receive Filters.

2. Received packets that match receive filters are cached, or *coalesced*, on the network adapter. The adapter does not generate a receive interrupt for coalesced packets. Instead, the adapter interrupts the host when another hardware event occurs.

   When this interrupt is generated, the adapter must indicate a receive event with the interrupt. This allows the network adapter to process coalesced packets that were received by the network adapter.

   For example, the network adapter that supports packet coalescing can generate a receive interrupt when one of the following events occur:

- The expiration of a hardware timer whose expiration time is set to a maximum coalescing delay value of the matching receive filter.
- The available space within the hardware coalescing buffer reaches an adapter-specified low-water mark.
- A packet is received that does not match a coalescing filter.
- Another interrupt event, such as a send completion event, has occurred.

For more information about this process, see Handling Packet Coalescing Receive Filters.

The following points apply to the support of packet coalescing by NDIS:

- NDIS supports packet coalescing for packets received on the default NDIS port (port 0) assigned to the physical network adapter. NDIS does not support packet coalescing on NDIS ports that are assigned to virtual network adapters. For more information, see NDIS Ports.

- NDIS supports packet coalescing for packets received on the default receive queue of the network adapter. This receive queue has an identifier of NDIS_DEFAULT_RECEIVE_QUEUE_ID.

Packet Coalescing Receive Filters

Article • 12/15/2021

Starting with NDIS 6.30, NDIS receive filters have been extended to support packet coalescing. Each receive filter for packet coalescing defines the following:

- A set of fields within the various protocol headers of a packet, such as the destination address of a media access control (MAC) header or destination port of a User Datagram Protocol (UDP) header.

- The maximum time that a packet that matches a coalescing receive filter is coalesced by the network adapter. The adapter uses this value to set an expiration value on a hardware timer on the adapter. As soon as the timer expires, the adapter must interrupt the host so the miniport driver can process the coalesced packets.

  Note As soon as the first packet that matches a receive filter is coalesced and the timer is started, the network adapter must coalesce additional packets that match receive filters without resetting and restarting the timer.

Overlying drivers, such as protocol and filter drivers, download the packet coalescing receive filters to the miniport driver by issuing object identifier (OID) set requests of OID_RECEIVE_FILTER_SET_FILTER. For more information, see Setting Packet Coalescing Receive Filters.

Overlying drivers can also query the packet coalescing receive filters downloaded to the miniport driver. Overlying drivers do this by issuing OID method requests of OID_RECEIVE_FILTER_ENUM_FILTERS to the miniport driver. For more information, see Querying Packet Coalescing Receive Filters.

Reporting Packet Coalescing Capabilities

Article • 12/15/2021

Miniport drivers register the following capabilities with NDIS during network adapter initialization:

- The packet coalescing capabilities that the network adapter supports.
- The packet coalescing capabilities that are currently enabled on the network adapter.
- The packet coalescing receive filtering capabilities that are currently enabled on the network adapter.

Note A miniport driver's support for packet coalescing can be enabled or disabled through the ***PacketCoalescing** INF keyword setting. This setting is displayed in the **Advanced** property page for the network adapter. For more information about the packet coalescing INF file setting, see Standardized INF Keywords for Packet Coalescing.

The miniport driver reports the packet coalescing and filtering capabilities of the underlying network adapter through an **NDIS_RECEIVE_FILTER_CAPABILITIES** structure. If the ***PacketCoalescing** keyword setting in the registry has a value of one, packet coalescing is enabled and the miniport driver initializes the **NDIS_RECEIVE_FILTER_CAPABILITIES** structure in the following way:

1. The miniport driver initializes the **Header** member. The driver sets the **Type** member of **Header** to NDIS_OBJECT_TYPE_DEFAULT.

   If the driver supports packet coalescing, it sets the **Revision** member of **Header** to the NDIS_RECEIVE_FILTER_CAPABILITIES_REVISION_2 and the **Size** member to NDIS_SIZEOF_RECEIVE_FILTER_CAPABILITIES_REVISION_2.

2. The miniport driver sets the NDIS_RECEIVE_FILTER_PACKET_COALESCING_SUPPORTED_ON_DEFAULT_QUEUE flag in the **SupportedQueueProperties** member.

   If this flag is set, the network adapter must support the filtering of received multicast packets in hardware. This filtering is based on the multicast addresses that NDIS offloaded to the network adapter by sending it OID_802_3_MULTICAST_LIST OID set requests.

> **Note** Protocol drivers can also change the contents of the multicast address list by sending OID_802_3_ADD_MULTICAST_ADDRESS and OID_802_3_DELETE_MULTICAST_ADDRESS requests. NDIS combines these requests into OID_802_3_MULTICAST_LIST OID set requests.

Note The adapter is required to reject any incoming multicast packet whose destination media access control (MAC) address does not match any of the multicast addresses specified by these OID set requests.

3. The miniport driver sets the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag in the **EnabledFilterTypes** member.

   Note If the driver sets this flag, it must also set the NDIS_RECEIVE_FILTER_PACKET_COALESCING_SUPPORTED_ON_DEFAULT_QUEUE flag in the **SupportedQueueProperties** member. Otherwise, NDIS will fail the call to **NdisMSetMiniportAttributes** by returning NDIS_STATUS_BAD_CHARACTERISTICS.

4. If the miniport driver sets the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the driver must support all receive filter test criteria. The driver advertises this support by setting the following flags in the **SupportedFilterTests** member:

   - NDIS_RECEIVE_FILTER_TEST_HEADER_FIELD_EQUAL_SUPPORTED

   - NDIS_RECEIVE_FILTER_TEST_HEADER_FIELD_MASK_EQUAL_SUPPORTED

   - NDIS_RECEIVE_FILTER_TEST_HEADER_FIELD_NOT_EQUAL_SUPPORTED

   Note If the miniport driver does not set the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the driver must set the **SupportedFilterTests** member to zero.

5. If the miniport driver sets the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the miniport driver must support the filtering of data within various fields of the media access control (MAC), IP version 4 (IPv4), and IP version 6 (IPv6) headers. The driver advertises this support by setting the following flags in the **SupportedHeaders** member:

   - NDIS_RECEIVE_FILTER_MAC_HEADER_SUPPORTED

   - NDIS_RECEIVE_FILTER_ARP_HEADER_SUPPORTED

- NDIS_RECEIVE_FILTER_IPV4_HEADER_SUPPORTED
- NDIS_RECEIVE_FILTER_IPV6_HEADER_SUPPORTED
- NDIS_RECEIVE_FILTER_UDP_HEADER_SUPPORTED

Note If the miniport driver does not set the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the driver must set the **SupportedHeaders** member to zero.

6. If the miniport driver sets the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the miniport driver must support the filtering of data within the media access control (MAC) header of the received packet. The driver advertises this support by setting the following flags in the **SupportedMacHeaderFields** member:

   - NDIS_RECEIVE_FILTER_MAC_HEADER_DEST_ADDR_SUPPORTED
   - NDIS_RECEIVE_FILTER_MAC_HEADER_PROTOCOL_SUPPORTED
   - NDIS_RECEIVE_FILTER_MAC_HEADER_PACKET_TYPE_SUPPORTED

   Note If the miniport driver does not set the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the driver must set the **SupportedMacHeaderFields** member to zero.

7. If the miniport driver sets the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the miniport driver must support the filtering of data within the header of a received Address Resolution Protocol (ARP) packet. The driver advertises this support by setting the following flags in the **SupportedARPHeaderFields** member:

   - NDIS_RECEIVE_FILTER_ARP_HEADER_OPERATION_SUPPORTED
   - NDIS_RECEIVE_FILTER_ARP_HEADER_SPA_SUPPORTED
   - NDIS_RECEIVE_FILTER_ARP_HEADER_TPA_SUPPORTED

   Note If the miniport driver does not set the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the driver must set the **SupportedARPHeaderFields** member to zero.

8. If the miniport driver sets the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the miniport driver must support the filtering of data within the Open Systems Interconnection (OSI) layer 3 (L3) header of a received IP version 4 (IPv4) packet. The driver

advertises this support by setting the following flags in the **SupportedIPv4HeaderFields** member:

- NDIS_RECEIVE_FILTER_IPV4_HEADER_PROTOCOL_SUPPORTED

Note If the miniport driver does not set the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the driver must set the **SupportedIPv4HeaderFields** member to zero.

9. If the miniport driver sets the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the miniport driver must support the filtering of data within the L3 header of a received IP version 6 (IPv6) packet. The driver advertises this support by setting the following flags in the **SupportedIPv6HeaderFields** member:

   - NDIS_RECEIVE_FILTER_IPV6_HEADER_PROTOCOL_SUPPORTED

   Note If the miniport driver does not set the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the driver must set the **SupportedIPv6HeaderFields** member to zero.

10. If the miniport driver sets the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the miniport driver must support the filtering of data within the OSI layer 4 (L4) header of a received User Datagram Protocol (UDP) packet. The driver advertises this support by setting the following flags in the **SupportedIUdpHeaderFields** member:

    - NDIS_RECEIVE_FILTER_UDP_HEADER_DEST_PORT_SUPPORTED

    Note If the received UDP packet contains IPv4 options or IPv6 extension headers, the network adapter can handle the packet as if it failed the UDP filter test. In this way, the adapter can automatically drop the received packet.

Note If the miniport driver does not set the NDIS_RECEIVE_FILTER_PACKET_COALESCING_FILTERS_ENABLED flag, the driver must set the **SupportedIUdpHeaderFields** member to zero.

11. The miniport driver must report the maximum number of tests on packet header fields that can be specified for a single packet coalescing filter. The driver specifies this value in the **MaxFieldTestsPerPacketCoalescingFilter** member.

    Note Network adapters that support packet coalescing must support five or more packet header fields that can be specified for a single packet coalescing filter. If the adapter does not support packet coalescing, the miniport driver must set this value to zero.

12. The miniport driver must report the maximum number of packet coalescing filters that are supported by the network adapter. The driver specifies this value in the **MaxPacketCoalescingFilters** member.

    Note Network adapters that support packet coalescing must support ten or more packet coalescing filters. If the adapter does not support packet coalescing, the miniport driver must set this value to zero.

When NDIS calls the miniport driver's *MiniportInitializeEx* function, the driver reports the packet coalescing and filtering capabilities of the underlying network adapter by following these steps:

- The miniport driver initializes an **NDIS_MINIPORT_ADAPTER_HARDWARE_ASSIST_ATTRIBUTES** structure.

  If the ***PacketCoalescing** keyword setting in the registry has a value of one, the miniport driver sets the **HardwareReceiveFilterCapabilities** member to a pointer to the previously initialized **NDIS_RECEIVE_FILTER_CAPABILITIES** structure.

  If the ***PacketCoalescing** keyword setting in the registry has a value of zero, the miniport driver does not advertise support for packet coalescing. It must set the **HardwareReceiveFilterCapabilities** member to NULL.

- The driver calls **NdisMSetMiniportAttributes** and sets the *MiniportAttributes* parameter to a pointer to the **NDIS_MINIPORT_ADAPTER_HARDWARE_ASSIST_ATTRIBUTES** structure.

The method that is used by miniport drivers to report the packet coalescing and filtering capabilities of the underlying network adapter is based on the NDIS 6.20 method for reporting power management capabilities. For more information about this method, see Reporting Power Management Capabilities.

For more information about the adapter initialization process, see Initializing a Miniport Adapter.

Querying Packet Coalescing Capabilities

Article • 12/15/2021

Once the miniport driver is initialized, overlying drivers and applications can issue the following OID query requests to obtain the packet coalescing capabilities of the network adapter:

- OID_RECEIVE_FILTER_HARDWARE_CAPABILITIES
- OID_RECEIVE_FILTER_CURRENT_CAPABILITIES
- OID_RECEIVE_FILTER_GLOBAL_PARAMETERS

NDIS handles these OID query requests for miniport drivers and returns the packet coalescing capabilities that the miniport driver registered when NDIS called the driver's *MiniportInitializeEx* function. Therefore, these OID query requests are not handled by miniport drivers.

For more information about how the miniport driver registers its packet coalescing capabilities, see Determining Receive Filtering Capabilities.

Guidelines for Managing Packet Coalescing Receive Filters

Article • 12/15/2021

If the miniport driver supports NDIS packet coalescing, it must follow these guidelines for managing packet coalescing receive filters:

- The miniport driver and underlying network adapter must be able to handle the setting and clearing of receive filters dynamically. Individual receive filters may be set or cleared at any time.

- The miniport driver must maintain a coalesced packet counter. This 64-bit counter contains a value for the number of received packets that have matched a packet coalescing filter. NDIS queries this counter through an OID query request of OID_PACKET_COALESCING_FILTER_MATCH_COUNT.

  Note The miniport driver clears this counter when it transitions to a full-power state by handling an OID set request of OID_PNP_SET_POWER. The miniport driver also clears the counter when its *MiniportResetEx* function is called.

- The miniport driver must not discard the packet coalescing receive filters when it transitions to a low-power state. However, while the network adapter is in a low-power state, it must only filter received packets based on wake-up patterns that have been offloaded to the adapter through OID set requests of OID_PNP_ENABLE_WAKE_UP.

  The miniport driver must configure the network adapter with the packet coalescing receive filters when the adapter transitions to a full-power state.

- The miniport driver must not discard the packet coalescing receive filters when NDIS calls the driver's *MiniportResetEx* function. After the driver resets the network adapter, it must configure the adapter with the packet coalescing filters. Also, the driver *must clear* the coalesced packet counter.

  Note The miniport driver must perform this operation regardless of whether the driver sets the *AddressingReset* parameter to TRUE.

- If the miniport driver is operating in the Native 802.11 extensible station (ExtSTA) mode, it must not discard the packet coalescing receive filters when it handles an OID method request of OID_DOT11_RESET_REQUEST. After the miniport driver performs the 802.11 reset operation, it must configure the network adapter with the packet coalescing receive filters. Also, the driver *must not clear* the coalesced packet counter.

For more information about the Native 802.11 extensible station mode, see Extensible Station Operation Mode.

Note NDIS does not support packet coalescing for native 802.11 miniport drivers that operate in extensible access point (ExtAP) mode. For more information about the ExtAP operation mode, see Extensible Access Point Operation Mode.

Specifying a Packet Coalescing Receive Filter

Article • 12/15/2021

An overlying driver can set one or more receive filters on a miniport driver that support NDIS packet coalescing. The overlying driver can specify up to the maximum number of receive filters that the miniport driver specified in the **MaxPacketCoalescingFilters** member of the NDIS_RECEIVE_FILTER_CAPABILITIES structure.

Note The overlying protocol driver obtains the NDIS_RECEIVE_FILTER_CAPABILITIES structure within the NDIS_BIND_PARAMETERS structure. The overlying filter driver obtains the **NDIS_RECEIVE_FILTER_CAPABILITIES** structure within the NDIS_FILTER_ATTACH_PARAMETERS structure.

The overlying driver downloads receive filters to the miniport driver by issuing OID method requests of OID_RECEIVE_FILTER_SET_FILTER. The **InformationBuffer** member of the NDIS_OID_REQUEST structure for this OID request contains a pointer to a caller-allocated buffer. This buffer is formatted to contain the following:

- An NDIS_RECEIVE_FILTER_PARAMETERS structure that specifies the parameters for an NDIS receive filter.

  For more information about how to initialize this structure, see Specifying a Receive Filter.

- An array of NDIS_RECEIVE_FILTER_FIELD_PARAMETERS structures that specifies the filter test criterion for a field in a network packet header.

  For more information about how to initialize these structures, see Specifying Header Field Tests.

Specifying a Receive Filter

An overlying driver specifies a packet coalescing receive filter by initializing an NDIS_RECEIVE_FILTER_PARAMETERS structure with the configuration parameters for the filter. When it initializes the **NDIS_RECEIVE_FILTER_PARAMETERS** structure, the overlying driver must follow these rules:

- The **FilterType** member must be set to the NDIS_RECEIVE_FILTER_TYPE enumeration value of **NdisReceiveFilterTypePacketCoalescing**.

- The **QueueId** member must be set to NDIS_DEFAULT_RECEIVE_QUEUE_ID.

  Note Starting with NDIS 6.30, packet coalescing receive filter are only supported on the default receive queue of the network adapter. This receive queue has an identifier of NDIS_DEFAULT_RECEIVE_QUEUE_ID.

- If the overlying driver is creating a new receive filter, it must set the **FilterId** member to NDIS_DEFAULT_RECEIVE_FILTER_ID.

  Note NDIS will generate a unique filter identifier (ID) for the receive filter before it forwards the OID method request of OID_RECEIVE_FILTER_SET_FILTER to the miniport driver.

- If the overlying driver is modifying an existing receive filter, it must set the **FilterId** member to the nonzero filter ID of the receive filter. The overlying driver obtains the filter ID for the receive filter when it issues an OID method request of OID_RECEIVE_FILTER_ENUM_FILTERS. For more information about how to modify a receive filter, see Modifying Packet Coalescing Receive Filters.

- The **FieldParametersArrayOffset**, **FieldParametersArrayNumElements**, and **FieldParametersArrayElementSize** members of the **NDIS_RECEIVE_FILTER_PARAMETERS** structure must be set to define a field parameter's array. Each element in the array is an **NDIS_RECEIVE_FILTER_FIELD_PARAMETERS** structure that specifies the parameters for a header field test of a receive filter.

- The **RequestedFilterIdBitCount** member must be set to zero.

- The **MaxCoalescingDelay** must be set to the maximum time, in units of milliseconds, that the first packet that matches the receive filter is saved and coalesced on the network adapter. As soon as the first packet that matches the filter is received, the network adapter coalesces the packet and starts a hardware timer whose expiration time is set to the value of the **MaxCoalescingDelay** member.

The overlying driver must order the header field tests in the field parameters array to be in the same order that the associated MAC and protocol headers would exist in a packet.

For example, before the overlying driver specifies the filter parameters for an IP version 4 (IPv4) protocol field, it must first specify the filter parameters for a MAC header protocol field (NdisMacHeaderFieldProtocol). In this manner, the driver specifies a header field test that verifies the field is set to the correct EtherType value (0x0800) for

IPv4 packets. If the test fails, the adapter does not have to perform the test of the IPV4 protocol field.

Specifying Header Field Tests

Each receive filter can specify one or more test criteria (*header field tests*). The network adapter performs these tests to determine whether a received packet should be coalesced in a hardware coalescing buffer on the adapter. Also, the overlying driver can specify separate filter tests for various media access control (MAC), IP version 4 (IPv4), and IP version 6 (IPv6) header fields.

To optimize filtering on the network adapter, header field tests are based on standardized header field names instead of byte offset/length specifications within the packet data. By using header/field names, the network adapter's hardware or firmware can optimize how multiple header field tests are performed on a received packet.

Each receive filter can contain one or more header field tests specified by an **NDIS_RECEIVE_FILTER_FIELD_PARAMETERS** structure. Each **NDIS_RECEIVE_FILTER_FIELD_PARAMETERS** structure is an element of the field parameters array that is referenced by the **FieldParametersArrayOffset**, **FieldParametersArrayNumElements**, and **FieldParametersArrayElementSize** members of the **NDIS_RECEIVE_FILTER_PARAMETERS** structure.

The miniport driver must follow these guidelines when it handles an OID method request of OID_RECEIVE_FILTER_SET_FILTER:

- If the **NDIS_RECEIVE_FILTER_FIELD_MAC_HEADER_VLAN_UNTAGGED_OR_ZERO** flag is set in the **Flags** member of the **NDIS_RECEIVE_FILTER_FIELD_PARAMETERS** structure, the network adapter must only indicate received packets with a matching MAC address and untagged packets or packets with a VLAN identifier of zero. That is, the network adapter must not indicate packets with a matching MAC address and a nonzero VLAN identifier.

- If the **NDIS_RECEIVE_FILTER_FIELD_MAC_HEADER_VLAN_UNTAGGED_OR_ZERO** flag is not set and there is no VLAN identifier filter configured by an OID set request of OID_RECEIVE_FILTER_SET_FILTER, the miniport driver must do one of the following:

  - If the miniport driver supports NDIS 6.20, it must return a failed status for the OID request of OID_RECEIVE_FILTER_SET_FILTER.

  - If the miniport driver supports NDIS 6.30 or later versions of NDIS, it must configure the network adapter to inspect and filter the specified MAC address fields. If a VLAN tag is present in the received packet, the network adapter must remove it from the packet data. The miniport driver must put the VLAN tag in an NDIS_NET_BUFFER_LIST_8021Q_INFO that is associated with the packet's NET_BUFFER_LIST structure.

- If the overlying driver sets a MAC address filter and a VLAN identifier filter in the NDIS_RECEIVE_FILTER_PARAMETERS structure, it does not set the **NDIS_RECEIVE_FILTER_FIELD_MAC_HEADER_VLAN_UNTAGGED_OR_ZERO** flag in either of the filter fields. In this case, the miniport driver should indicate packets that match both the specified MAC address and the VLAN identifier. That is, the miniport driver should not indicate packets with a matching MAC address that have a zero VLAN identifier or are untagged packets.

Setting a Packet Coalescing Receive Filter

Article • 12/15/2021

To download and set a receive filter on a miniport driver that supports packet coalescing, an overlying driver issues an OID method request of OID_RECEIVE_FILTER_SET_FILTER. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure for the OID request contains a pointer to a caller-allocated buffer. This buffer is formatted to contain the following:

- An **NDIS_RECEIVE_FILTER_PARAMETERS** structure that specifies the parameters for an NDIS receive filter.

- An array of **NDIS_RECEIVE_FILTER_FIELD_PARAMETERS** structures that specifies the filter test criterion for a field in a network packet header.

For more information about how an overlying driver specifies the parameters for a packet coalescing receive filter, see Specifying a Packet Coalescing Receive Filter.

When NDIS receives an OID request to set a receive filter on the underlying network adapter, it verifies the receive filter parameters. If the overlying driver is specifying a new receive filter, NDIS will also generate a unique filter identifier (ID) for the receive filter.

After NDIS allocates the necessary resources and the filter ID, it forwards the OID request to the miniport driver. If the miniport driver can successfully allocate the necessary software and hardware resources for the receive filter, the miniport driver completes the OID request with a status of NDIS_STATUS_SUCCESS.

After a successful return from the OID method request of OID_RECEIVE_FILTER_SET_FILTER, the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to an **NDIS_RECEIVE_FILTER_PARAMETERS** structure. This structure is updated by NDIS with the new filter ID.

Using the Filter ID

Article • 12/15/2021

Overlying drivers download receive filters to the miniport driver by issuing OID method requests of OID_RECEIVE_FILTER_SET_FILTER. Each receive filter that is downloaded to the miniport driver has a unique filter identifier (ID) that is generated by NDIS. The overlying driver must use this filter ID in later OID requests in order to do the following:

- Query the receive filter parameters. For more information about how to query the parameters of a receive filter, see Querying Packet Coalescing Receive Filters.
- Modify the receive filter parameters. For more information about how to modify the parameters of a receive filter, see Modifying Packet Coalescing Receive Filters.
- Free, or *clear*, a receive filter. For more information about how to clear receive filters, see Clearing Packet Coalescing Receive Filters.

The miniport driver must retain the filter IDs for the allocated receive filters. When it receives an OID request to modify, query, or free a receive filter, the miniport driver must verify that the specified filter ID in the OID request matches an allocated receive filter from a previous OID method request of OID_RECEIVE_FILTER_SET_FILTER. If the filter ID does not match any of the allocated receive filters, the miniport driver must complete the OID request with a failed status.

Querying Packet Coalescing Receive Filters

Article • 12/15/2021

Overlying drivers and applications can query packet coalescing receive filters that have been downloaded to a miniport driver by doing the following:

- Request an enumerated list of the receive filters on the miniport driver by issuing an OID method request of OID_RECEIVE_FILTER_ENUM_FILTERS. For more information, see Enumerating the Receive Filters on a Miniport Driver.

- Request the test criterion parameters for a receive filter on the miniport driver by issuing an OID method request of OID_RECEIVE_FILTER_PARAMETERS. For more information, see Querying the Receive Filters on a Miniport Driver

NDIS handles the OID_RECEIVE_FILTER_ENUM_FILTERS and OID_RECEIVE_FILTER_PARAMETERS method OID requests for miniport drivers. NDIS obtained the information from an internal cache of the data that it received from the OID_RECEIVE_FILTER_SET_FILTER OID request.

Enumerating the Receive Filters on a Miniport Driver

To obtain a list of all the packet coalescing receive filters that have been downloaded to a miniport driver, overlying drivers and applications issue an OID method request of OID_RECEIVE_FILTER_ENUM_FILTERS. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to an **NDIS_RECEIVE_FILTER_INFO_ARRAY** structure.

Note When the overlying driver or application initializes the **NDIS_RECEIVE_FILTER_INFO_ARRAY** structure, it must set the **QueueId** member to NDIS_DEFAULT_RECEIVE_QUEUE_ID.

After a successful return from the OID method request, the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to a buffer. This buffer is formatted to contain the following:

- An **NDIS_RECEIVE_FILTER_INFO_ARRAY** structure that specifies a list of receive filters that are currently configured on a miniport driver.

- An array of **NDIS_RECEIVE_FILTER_INFO** structures about a receive filter that is currently configured on a miniport driver.

Querying the Parameters of a Receive Filters on a Miniport Driver

To obtain the parameters of a specific packet coalescing receive filter that was downloaded to the miniport driver, overlying drivers or applications issue an OID method request of OID_RECEIVE_FILTER_PARAMETERS. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to an **NDIS_RECEIVE_FILTER_PARAMETERS** structure. The overlying driver or application initializes the **NDIS_RECEIVE_FILTER_PARAMETERS** structure by setting the **FilterId** member to the nonzero ID value of the filter whose parameters are to be returned.

Note The overlying driver obtained the filter ID from an earlier OID method request of OID_RECEIVE_FILTER_SET_FILTER or OID_RECEIVE_FILTER_ENUM_FILTERS. The application can only obtain the filter ID from an earlier OID method request of OID_RECEIVE_FILTER_ENUM_FILTERS.

After a successful return from the OID method request, the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to a buffer. This buffer is formatted to contain the following:

- An **NDIS_RECEIVE_FILTER_PARAMETERS** structure that specifies the parameters for an NDIS receive filter.

- An array of **NDIS_RECEIVE_FILTER_FIELD_PARAMETERS** structures that specifies the filter test criterion for one field in a network packet header.

Modifying Packet Coalescing Receive Filters

Article • 12/15/2021

To modify a receive filter on a miniport driver that supports packet coalescing, an overlying protocol or filter driver performs the following steps:

1. To obtain a list of all the packet coalescing receive filters that have been downloaded to a miniport driver, the overlying driver issues an OID method request of OID_RECEIVE_FILTER_ENUM_FILTERS. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to an **NDIS_RECEIVE_FILTER_INFO_ARRAY** structure.

   Note When the overlying driver or application initializes the **NDIS_RECEIVE_FILTER_INFO_ARRAY** structure, it must set the **QueueId** member to NDIS_DEFAULT_RECEIVE_QUEUE_ID.

   After a successful return from the OID method request of OID_RECEIVE_FILTER_ENUM_FILTERS, the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to an updated **NDIS_RECEIVE_FILTER_INFO_ARRAY** structure that is followed by one or more **NDIS_RECEIVE_FILTER_INFO** structures. Each **NDIS_RECEIVE_FILTER_INFO** structure specifies the identifier (ID) for a filter that is set on the network adapter.

2. To obtain the parameters of a specific packet coalescing receive filter that was downloaded to the miniport driver, the overlying driver issues OID method request of OID_RECEIVE_FILTER_PARAMETERS. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to an **NDIS_RECEIVE_FILTER_PARAMETERS** structure. The overlying driver or application initializes the **NDIS_RECEIVE_FILTER_PARAMETERS** structure by setting the **FilterId** member to the nonzero ID value of the filter whose parameters are to be returned.

   After a successful return from the OID method request, the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to a buffer. This buffer is formatted to contain the following:

   - An **NDIS_RECEIVE_FILTER_PARAMETERS** structure that specifies the parameters for the NDIS receive filter.

   - An array of **NDIS_RECEIVE_FILTER_FIELD_PARAMETERS** structures that specifies the filter test criterion for one field in a network packet header.

3. The overlying driver modifies the receive filter to add, delete, or change the filter's set of test criterion. The driver does this by adding, deleting, or modifying individual **NDIS_RECEIVE_FILTER_FIELD_PARAMETERS** structures from the field parameter array specified by the **NDIS_RECEIVE_FILTER_PARAMETERS** structure.

   When the overlying driver has completed the modifications to the test criterion, it must update the members of the **NDIS_RECEIVE_FILTER_PARAMETERS** structure to reflect the changes that were made to the receive filter. For example, the overlying driver must update the **FieldParametersArrayNumElements** member to contain the new number of elements in the array.

   For more information, see Specifying a Packet Coalescing Receive Filter.

4. The overlying driver issues an OID method request of OID_RECEIVE_FILTER_SET_FILTER to download the modified receive filter to the miniport driver.

   For more information, see Setting a Packet Coalescing Receive Filter.

Clearing Packet Coalescing Receive Filters

Article • 12/15/2021

To free, or *clear*, a receive filter on a miniport driver that supports packet coalescing, an overlying driver issues an OID set request of OID_RECEIVE_FILTER_CLEAR_FILTER. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to an **NDIS_RECEIVE_FILTER_CLEAR_PARAMETERS** structure.

The overlying driver, such as a protocol or filter driver, initializes the **NDIS_RECEIVE_FILTER_CLEAR_PARAMETERS** structure in the following way:

- The **QueueId** member must be set to NDIS_DEFAULT_RECEIVE_QUEUE_ID.

  Note Starting with NDIS 6.30, packet coalescing receive filters are only supported on the default receive queue of the network adapter. This receive queue has an identifier of NDIS_DEFAULT_RECEIVE_QUEUE_ID.

- The **FilterId** member must be set to the nonzero identifier (ID) value of the filter to be cleared on the miniport driver. The overlying driver obtained the filter ID from an earlier OID method request of OID_RECEIVE_FILTER_SET_FILTER or OID_RECEIVE_FILTER_ENUM_FILTERS.

  Note Only the overlying driver that set the packet coalescing receive filter can clear it.

Note Before it completes the unbind or detach operation, the overlying protocol or filter driver must clear all the packet coalescing receive filters that it set on the underlying miniport driver.

Handling Packet Coalescing Receive Filters

Article • 12/15/2021

Multiple receive filters are downloaded to a miniport driver through OID method requests of OID_RECEIVE_FILTER_SET_FILTER. Each filter can specify one or more tests (*header field tests*) that the network adapter uses to determine whether a received packet should be coalesced in a hardware coalescing buffer on the adapter.

Before the miniport driver configures the network adapter with the receive filters, the driver should optimize the receive filters based on the hardware capabilities of the adapter. For example, all receive filters require a header field test for the MAC header. Therefore, the driver could optimize filter rules based on the results of this test. This allows the adapter to determine which Open Systems Interconnection (OSI) layer 3 (L3) and layer 4 (L4) header field tests to perform next.

As soon as the network adapter has been configured with receive filters, it must do the following:

- All the header field test parameters for a particular filter must match on the received packet in order to coalesce the packet in the coalescing buffer.

  The network adapter combines the results from all header field tests of a receive filter with a logical AND operation. That is, if any header field test that is included in the array of **NDIS_RECEIVE_FILTER_FIELD_PARAMETERS** structures for a receive filter fails, the received packet does not meet the specified filter criterion and must not be coalesced.

- The network adapter only inspects packet data based on the specified header field test parameters. The adapter must ignore all header fields in the packet for which header field tests are not specified.

- If a received packet matches all the header field tests for any of the receive filters, the network adapter must coalesce the packet within the hardware coalescing buffer. As soon as the first packet is coalesced, the network adapter must start a hardware timer and must set the expiration time to the value of the **MaxCoalescingDelay** member of the **NDIS_RECEIVE_FILTER_PARAMETERS** structure for the matching receive filter.

- As more packets are received that match a packet coalescing receive filter, the network adapter puts them into the coalescing buffer.

If the hardware timer is already running, the adapter must not stop or restart the timer for the matching receive filter. However, the adapter can configure the hardware timer with the smallest expiration value from matching receive filters. For example, when the driver receives a packet that matches receive filter *X*, the adapter starts the timer with the specified expiration value for that receive filter. If the adapter then receives a packet that matches receive filter *Y*, the adapter can reconfigure the hardware timer with the specified expiration value for that receive filter.

Note The network adapter must not reconfigure the hardware timer if the time that is remaining on the timer is less than a receive filter's expiration time.

- As soon as received packets are coalesced, the network adapter generates an interrupt if any of the following events occur:

  - If the available space within the hardware coalescing buffer reaches a hardware-specific low-water mark, the network adapter must generate a receive interrupt so that the miniport driver can process the coalesced receive packets.

  - If the hardware timer used for the hardware coalescing buffer expires, the network adapter must generate a receive interrupt so that the miniport driver can process the coalesced receive packets.

  - If a receive filter is cleared and packets have been coalesced that match that filter, the network adapter must generate a receive interrupt so that the miniport driver can process the coalesced receive packets.

  - If a received packet does not match any of the receive filters, the network adapter must generate a receive interrupt so that the miniport driver can process the received packet. If any packets have been coalesced, the miniport driver must also process those packets.

  - If the network adapter generates an interrupt for any other interrupt status other than a receive interrupt, the network adapter must also signal a receive interrupt status so that the miniport driver can process the coalesced received packets.

  As soon as the interrupt is generated, the network adapter must stop the hardware timer if it hasn't expired and must clear the hardware coalescing buffer.

The miniport driver must maintain a coalesced packet counter, which contains a value for the number of received packets that have matched a packet coalescing filter. NDIS queries this counter through an OID query request of OID_PACKET_COALESCING_FILTER_MATCH_COUNT.

The network adapter only performs packet coalescing while the hardware is operating in a full-power state. While the hardware is in a low-power state, the adapter must only filter received packets based on wake-up patterns that have been offloaded to the adapter through OID set requests of OID_PNP_ENABLE_WAKE_UP.

When the network adapter transitions to a full-power state, the miniport driver must follow these steps:

- The miniport driver must configure the network adapter to discard any coalesced packets within the hardware coalescing buffer. The network adapter may have coalesced these packets when it was transitioned to a low-power state.

- The miniport driver must configure the network adapter with the set of packet coalescing receive filters that were downloaded to the driver before the low-power transition.

- The miniport driver must clear the coalesced packet counter.

Standardized INF Keywords for Packet Coalescing

Article • 12/15/2021

A standardized INF keyword is defined to enable or disable support for packet coalescing on a miniport driver.

The INF file for the miniport driver of an adapter that supports packet coalescing must specify the ***PacketCoalescing** standardized INF keyword. Once the driver is installed, administrators can update the ***PacketCoalescing** keyword value in the **Advanced** property page for the adapter. For more information about advanced properties, see Specifying Configuration Parameters for the Advanced Properties Page.

Note The miniport driver is automatically restarted after a change is made in the **Advanced** property page for the adapter.

The ***PacketCoalescing** INF keyword is an enumeration keyword. The following table describes the possible INF entries for the ***PacketCoalescing** INF keyword. The columns in this table describe the following attributes for an enumeration keyword:

SubkeyName
The name of the keyword that you must specify in the INF file. This name also appears in the registry under the **NDI\params\** key for the network adapter.

ParamDesc
The display text that is associated with SubkeyName.

Note The independent hardware vendor (IHV) can define any descriptive text for the SubkeyName.

Value
The enumeration integer value that is associated with each SubkeyName in the list.

EnumDesc
The display text that is associated with each value that appears in the menu.

SubkeyName	ParamDesc	Value	EnumDesc
*PacketCoalescing	Packet coalescing	0	Disabled
		1 (Default)	Enabled

The miniport driver must check the ***PacketCoalescing** keyword value in the registry before it advertises its support for packet coalescing. If the ***PacketCoalescing** keyword has a value of zero, the miniport must not advertise support for any packet coalescing capabilities. For more information, see Reporting Packet Coalescing Capabilities.

For more information about standardized INF keywords, see Standardized INF Keywords for Network Devices.

Introduction to NDIS Selective Suspend

Article • 03/14/2023

Starting with NDIS 6.30, the NDIS selective suspend interface allows NDIS to suspend an idle network adapter by transitioning the adapter to a low-power state. This enables the system to reduce the power overhead on the CPU and network adapter.

This section includes the following topics:

Overview of NDIS Selective Suspend

Reporting NDIS Selective Suspend Capabilities

Registering NDIS Selective Suspend Handler Functions

NDIS Selective Suspend Idle Notifications

Standardized INF Keywords for NDIS Selective Suspend

NDIS Selective Suspend Implementation Guidelines

Note Although the NDIS selective suspend interface is especially useful for USB network adapters, the interface is bus-independent. As a result, miniport drivers can use the interface for network adapters on other bus types in order to reduce CPU and power overhead.

Overview of NDIS Selective Suspend

Article • 03/14/2023

Starting with NDIS 6.30, the NDIS selective suspend interface enables NDIS to suspend an idle network adapter by transitioning the adapter to a low-power state. This enables the system to reduce the CPU and power overhead of the adapter.

NDIS selective suspend is especially useful for network adapters that are based on the USB v1.1 and v2.0 interface. These adapters are continuously polled for received packets regardless of whether they are active or idle. By suspending idle USB adapters, the CPU overhead can be reduced by as much as 10 percent.

NDIS selective suspend is based on the USB selective suspend technology. However, NDIS selective suspend is designed to be bus-independent. In this way, bus-independent I/O request packets (IRPs) for selective suspend are issued by NDIS. This makes the miniport driver responsible for issuing any IRPs that are required for selective suspend on a specific bus. For example, miniport drivers for USB network adapters issue the bus-specific USB idle request IRP (**IOCTL_INTERNAL_USB_SUBMIT_IDLE_NOTIFICATION**) to the USB bus driver during a selective suspend operation.

NDIS and the miniport driver participate in NDIS selective suspend in the following way:

1. If a miniport driver has registered its support for NDIS selective suspend, NDIS monitors the I/O activity of the network adapter. I/O activity includes receive packet indications, send packet completions, and OID requests that are handled by the miniport driver.

2. NDIS considers the network adapter to be idle if it has been inactive for longer than a specified idle time-out period. When this happens, NDIS starts a selective suspend operation by issuing an idle notification to the miniport driver in order to transition the network adapter to a low-power state.

   > ⓘ **Note**
   >
   > The length of the idle time-out period is specified by the value of the ***SSIdleTimeout** standardized INF keyword. For more information about this keyword, see **Standardized INF Keywords for NDIS Selective Suspend**.

   For more information about how NDIS determines that a network adapter is idle, see How NDIS Detects Idle Network Adapters.

3. NDIS issues the idle notification to the miniport driver by calling the driver's *MiniportIdleNotification* handler function. When this function is called, the miniport driver determines whether the network adapter can transition to a low-power state. The miniport driver performs this determination in a bus-specific manner.

   For example, a USB miniport driver determines whether the network adapter can transition to a low-power state by issuing a USB idle request IRP (**IOCTL_INTERNAL_USB_SUBMIT_IDLE_NOTIFICATION**) to the underlying USB bus driver. This informs the bus driver that the network adapter is idle and confirms whether the adapter can be transitioned to a low-power state.

   > ⓘ Note
   >
   > The miniport driver must specify a callback and completion routine for the USB idle request IRP.

   For more information about how a miniport driver handles an idle notification, see Handling the NDIS Selective Suspend Idle Notification.

4. After the miniport driver confirms that the network adapter can transition to a low-power state, it calls **NdisMIdleNotificationConfirm**. In this call, the miniport driver specifies the lowest power state that the network adapter can transition to.

5. When **NdisMIdleNotificationConfirm** is called, NDIS issues OID requests to the miniport driver to prepare the adapter for the transition to a low-power state. NDIS also issues IRPs to the underlying bus driver to set the adapter to a low-power state.

6. After the network adapter has been suspended, it remains in a low power state until the outstanding idle notification is canceled.

   NDIS cancels the outstanding idle notification by calling the miniport driver's *MiniportCancelIdleNotification* handler function. NDIS calls this handler function if one or more of the following conditions are true:

   - NDIS detects send packet requests or OID requests that are issued to the miniport driver from overlying protocol or filter drivers.

   - The network adapter signals a wake-up event. This might occur when the adapter receives a packet or detects a change in its media connection status.

   After the network adapter has been suspended, the miniport driver can also complete the idle notification in order to resume the adapter to a full-power state.

The reasons for doing this are specific to the design and requirements of the driver and adapter.

For more information about how NDIS cancels the idle notification, see Canceling the NDIS Selective Suspend Idle Notification.

For more information about how the miniport driver completes the idle notification, see Completing the NDIS Selective Suspend Idle Notification.

7. When the *MiniportCancelIdleNotification* handler function is called, the miniport driver determines whether the network adapter can resume to a full-power state. The driver also cancels any bus-specific IRPs that it may have previously issued for the idle notification.

   The determination that the network adapter can transition to a full-power state is bus-specific. For example, when *MiniportCancelIdleNotification* is called, the USB miniport must cancel the previously issued USB idle request IRP. As soon as the USB driver has canceled the IRP, it calls the IRP's completion routine to confirm that the IRP is canceled and the network adapter can resume to a full-power state. In the context of the completion routine, the miniport driver calls **NdisMIdleNotificationComplete**.

   When the miniport determines that the network adapter can resume to a full-power state, it calls **NdisMIdleNotificationComplete**. This call notifies NDIS that the idle notification has been completed. NDIS then proceeds with completing the selective suspend operation by transitioning the network adapter to a full-power state.

8. When **NdisMIdleNotificationComplete** is called, NDIS issues OID requests to the miniport driver to prepare the adapter for the transition to a full-power state. NDIS also issues IRPs to the underlying bus driver to set the adapter to a full-power state.

9. When the network adapter resumes to a full-power state, the selective suspend operation is completed. NDIS resumes monitoring the I/O activity of the network adapter. If the adapter becomes inactive after another idle time-out period, NDIS issues an idle notification to the miniport driver in order to suspend the network adapter.

Reporting NDIS Selective Suspend Capabilities

Article • 03/14/2023

Starting with NDIS 6.30, miniport drivers must report whether the driver has enabled the support for NDIS selective suspend. The support for NDIS selective suspend is enabled or disabled through the setting of the ***SelectiveSuspend** standardized INF keyword. For more information about this INF keyword, see Standardized INF Keywords for NDIS Selective Suspend.

When NDIS calls the driver's *MiniportInitializeEx* function, the miniport driver reports its support for NDIS selective suspend support by following these steps:

1. The driver initializes an **NDIS_PM_CAPABILITIES** structure with the power management capabilities of the underlying hardware.

   If the driver enables the support for NDIS selective suspend, it must set the members of the **NDIS_PM_CAPABILITIES** structure as follows:

   - The miniport driver must specify NDIS_PM_CAPABILITIES_REVISION_2 and NDIS_SIZEOF_NDIS_PM_CAPABILITIES_REVISION_2 for the revision and length of the **NDIS_PM_CAPABILITIES** structure within the structure's **Header** member.
   - If the ***SelectiveSuspend** keyword has a value of one, the miniport driver support for NDIS selective suspend is enabled. The miniport driver reports this by setting the NDIS_PM_SELECTIVE_SUSPEND_SUPPORTED flag within the **Flags** member of this structure.

2. Once it has initialized the **NDIS_PM_CAPABILITIES** structure, the miniport driver sets the **PowerManagementCapabilitiesEx** member of the **NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES** structure to point to the initialized **NDIS_PM_CAPABILITIES** structure. The miniport driver passes a pointer to an **NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES** structure in the *MiniportAttributes* parameter when the driver calls the **NdisMSetMiniportAttributes** function.

The method that is used by miniport drivers to report the support status of NDIS selective suspend is based on the NDIS 6.20 method for reporting power management capabilities. For more information about this method, see Reporting Power Management Capabilities.

For more information about the adapter initialization process, see Initializing a Miniport Adapter.

Registering NDIS Selective Suspend Handler Functions

Article • 03/14/2023

If a miniport driver supports NDIS selective suspend, NDIS notifies the driver that the underlying network adapter has become idle. The miniport driver must provide the following functions to handle these idle notifications:

MiniportIdleNotification
NDIS calls the *MiniportIdleNotification* handler function to notify the miniport driver that the network adapter has become idle. The miniport driver handles the idle notification by determining whether the network adapter can transition to a low-power state. The miniport driver performs this determination in a bus-specific manner.

For example, a USB miniport driver determines whether the network adapter can transition to a low-power state by issuing an I/O request packet (IRP) for a USB idle request (**IOCTL_INTERNAL_USB_SUBMIT_IDLE_NOTIFICATION**) to the underlying USB bus driver. Through the processing of this IRP, the miniport driver is notified that the adapter is idle and can be transitioned to a low-power state.

MiniportCancelIdleNotification
NDIS calls the *MiniportCancelIdleNotification* handler function to cancel the outstanding idle notification. When this function is called, the miniport driver cancels any bus-specific IRPs that it may have previously issued for the idle notification.

For example, when *MiniportCancelIdleNotification* is called, the USB miniport must cancel the previously-issued USB idle request IRP. When the IRP is canceled, the miniport driver is notified that the adapter can now be transitioned to a full-power state.

When the miniport driver's **DriverEntry** function is called, the driver registers its NDIS selective suspend handler functions by following these steps:

1. The miniport driver must set the **SetOptionsHandler** member of the **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** structure to the entry point for the driver's *MiniportSetOptions* function. The driver calls **NdisMRegisterMiniportDriver** to register its **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** structure with NDIS.

2. NDIS calls the *MiniportSetOptions* function in the context of the call to **NdisMRegisterMiniportDriver**.

   When *MiniportSetOptions* is called, the miniport driver initializes an **NDIS_MINIPORT_SS_CHARACTERISTICS** structure with pointers to the handler functions. The miniport driver then calls **NdisSetOptionalHandlers** and sets the *OptionalHandlers* parameter to a pointer to the **NDIS_MINIPORT_SS_CHARACTERISTICS** structure.

For more information on how to handle idle notifications for NDIS selective suspend, see NDIS Selective Suspend Idle Notifications.

Overview of NDIS Selective Suspend Idle Notifications

Article • 03/14/2023

When the miniport driver has enabled and registered support for NDIS selective suspend, NDIS monitors the I/O activity of the underlying network adapter. If NDIS determines that the driver and adapter are idle, NDIS performs a selective suspend operation. This operation suspends the network adapter by transitioning the adapter to a low-power state.

NDIS starts the selective suspend operation by issuing an idle notification to the miniport driver. When the network adapter is suspended in a low-power state, the adapter can resume to a full-power state only when the idle notification is canceled. After the notification is canceled and the adapter is in a full-power state, the selective suspend operation is complete.

The following topics provide more information on the NDIS selective suspend operation and idle notifications:

How NDIS Detects Idle Network Adapters

Handling the NDIS Selective Suspend Idle Notification

Canceling the NDIS Selective Suspend Idle Notification

Completing the NDIS Selective Suspend Idle Notification

How NDIS Detects Idle Network Adapters

Article • 03/14/2023

After the miniport driver has enabled NDIS selective suspend and registered its handler functions, NDIS monitors the I/O activity of the network adapter in the following way:

- NDIS monitors the calls to the I/O handler functions that the miniport driver registers through the **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** and **NDIS_MINIPORT_PNP_CHARACTERISTICS** structures. For example, NDIS monitors calls to the miniport driver's *MiniportSendNetBufferLists* or *MiniportReturnNetBufferLists* to determine whether the driver is involved in any packet I/O activity.

- NDIS also monitors the calls of **NdisOidRequest** and **NdisDirectOidRequest** made by overlying protocol drivers.

  Note NDIS monitors only those object identifier (OID) requests to the underlying miniport driver that are not handled directly by NDIS.

NDIS determines that the network adapter is idle if it does not detect any activity on the adapter for an idle time-out period. The duration of this time-out period is specified by the value of the ***SSIdleTimeout** standardized INF keyword. For more information about this keyword, see Standardized INF Keywords for NDIS Selective Suspend.

After the network adapter has become idle, NDIS starts the selective suspend operation. Through this operation, the network adapter is suspended by transitioning it to a low-power state.

NDIS begins this selective suspend operation by issuing an idle notification to the miniport driver. NDIS does this by calling the driver's *MiniportIdleNotification* handler function. For more information about how the miniport driver handles this notification, see Handling the NDIS Selective Suspend Idle Notification.

If NDIS detects that I/O requests to the network adapter are issued from overlaying drivers or if the adapter signals a wake-up event, NDIS cancels the idle notification. NDIS does this by calling the miniport driver's *MiniportCancelIdleNotification* handler function.

For more information about how NDIS cancels the idle notification, see Canceling the NDIS Selective Suspend Idle Notification.

For more information about how the miniport driver completes the idle notification, see Completing the NDIS Selective Suspend Idle Notification.

Handling the NDIS Selective Suspend Idle Notification

Article • 03/14/2023

NDIS starts a selective suspend operation if one of the following events occurs:

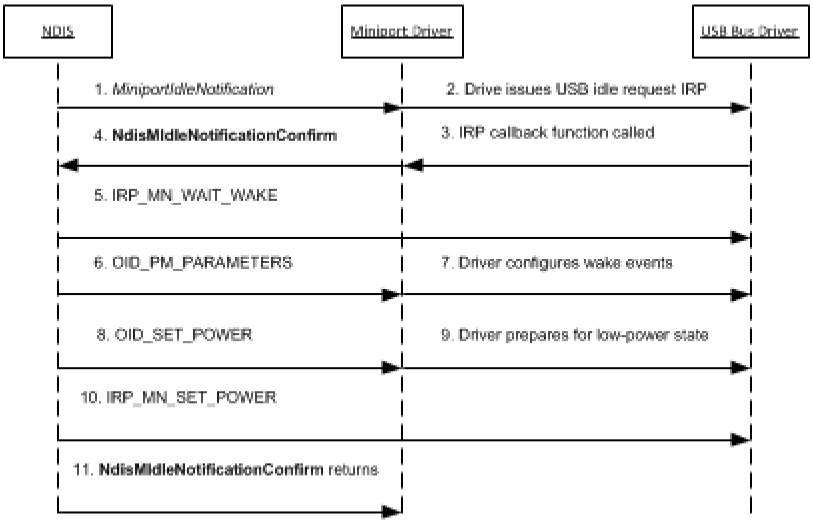
- The network adapter has been inactive for longer than an idle time-out period. The duration of this time-out period is specified by the value of the ***SSIdleTimeout** standardized INF keyword. For more information about this keyword, see Standardized INF Keywords for NDIS Selective Suspend.

  For more information about how NDIS determines that a network adapter is idle, see How NDIS Detects Idle Network Adapters.

- The system that is compliant with the Always On Always Connected (AOAC) technology is being transitioned to a Connected Standby state.

Through the selective suspend operation, the network adapter is transitioned to a low-power state. NDIS begins this operation by calling the *MiniportIdleNotification* handler function to issue an idle notification to the miniport driver.

The miniport driver may need to perform bus-dependent actions when it handles the idle notification. The following figure shows the steps that are involved with handling an idle notification by a miniport driver for a USB network adapter.



NDIS
Miniport Driver
USB Bus Driver
1. *MiniportIdleNotification*
2. Drive issues USB idle request IRP
3. IRP callback function called
4. **NdisMIdleNotificationConfirm**
5. IRP_MN_WAIT_WAKE
6. OID_PM_PARAMETERS
7. Driver configures wake events
8. OID_SET_POWER
9. Driver prepares for low-power state
10. IRP_MN_SET_POWER
11. **NdisMIdleNotificationConfirm** returns

This topic includes the following information about how to handle an NDIS selective suspend idle notification:

Guidelines for Handling the Call to *MiniportIdleNotification*

Guidelines for the Call to **NdisMIdleNotificationConfirm**

Canceling and Completing an NDIS Selective Suspend Idle Notification

Guidelines for Handling the Call to *MiniportIdleNotification*

NDIS and the miniport driver follow these steps when NDIS calls *MiniportIdleNotification*:

1. NDIS calls the *MiniportIdleNotification* handler function to notify the driver that the underlying network adapter seems to be idle. NDIS sets the *ForceIdle* parameter of the *MiniportIdleNotification* handler function to one of the following values:

   - NDIS sets the *ForceIdle* parameter to **FALSE** when the network adapter has been inactive for longer than the idle time-out period.

   - NDIS sets the *ForceIdle* parameter to **TRUE** when a system that is compliant with the Always On Always Connected (AOAC) technology is transitioning to a Connected Standby state.

2. When *MiniportIdleNotification* is called, the miniport driver can veto the idle notification and the selective suspend operation by returning NDIS_STATUS_BUSY. For example, the driver could veto the idle notification if the driver detects activity on the network adapter.

   If the miniport driver vetoes the idle notification, NDIS restarts the monitor of activity on the network adapter. If the adapter becomes inactive again within the idle time-out period, NDIS calls *MiniportIdleNotification*.

   Note The miniport driver must not veto the idle notification if the *ForceIdle* parameter is set to **TRUE**. In this case, the driver must continue with the selective suspend operation.

3. If the miniport driver does not veto the idle notification, it must perform any bus-specific operations to prepare the network adapter for a selective suspend operation. For example, the miniport driver for a USB network adapter performs the following steps to determine whether the network adapter can transition to a low-power state:

   a. The miniport driver calls **IoCallDriver** to issue an I/O request packet (IRP) for a USB idle request (**IOCTL_INTERNAL_USB_SUBMIT_IDLE_NOTIFICATION**) to the underlying USB bus driver. In this IRP, the miniport driver must specify a callback and completion routine.

The USB bus driver does not immediately complete the IRP. The IRP is left in a pending state through the low-power transition. The bus driver completes the IRP later when any of the following events occur:

    - The miniport driver cancels the IRP.
    - A system power state change is required.
    - The device is removed from the USB hub.

   b. After the USB bus driver determines that it can put the network adapter in a low-power state, it calls the miniport driver's IRP callback routine. This call confirms that the network adapter can transition to a low-power state.

      For guidelines on how to write a callback routine for the USB idle request IRP, see Implementing a USB Idle Request IRP Callback Routine.

4. After the miniport driver completes the preparation of the network adapter for a selective suspend operation, it calls **NdisMIdleNotificationConfirm**. In this call, the miniport driver specifies the lowest power state that the network adapter can transition to.

   Depending on the bus requirements for selective suspend operations, the miniport driver calls **NdisMIdleNotificationConfirm** either synchronously in the context of the call to *MiniportIdleNotification* or asynchronously after *MiniportIdleNotification* returns. For example, the miniport driver for a USB network adapter calls **NdisMIdleNotificationConfirm** within the context of the callback routine for the USB idle request. The USB bus driver calls the callback routine either synchronously in the context of the call to **IoCallDriver** or asynchronously after *MiniportIdleNotification* returns.

5. If the network adapter can be transitioned to a low-power state, the miniport driver returns NDIS_STATUS_PENDING from the call to *MiniportIdleNotification*.

   Note The miniport driver returns NDIS_STATUS_PENDING because the idle notification is not completed until the driver calls **NdisMIdleNotificationComplete**. The miniport driver must not return NDIS_STATUS_SUCCESS from *MiniportIdleNotification*.

The miniport driver should perform the following operations until the network adapter is suspended and transitioned to a low-power state:

- The miniport driver should process received packets and indicate them to NDIS by calling **NdisMIndicateReceiveNetBufferLists**.

- The miniport driver should process completed send packets and indicate them to NDIS by calling **NdisMSendNetBufferListsComplete**.

  Note NDIS will not call the driver's *MiniportSendNetBufferLists* function to send packets if *MiniportIdleNotification* returns NDIS_STATUS_PENDING.

Guidelines for the Call to NdisMIdleNotificationConfirm

NDIS and the miniport driver follow these steps when the miniport driver calls **NdisMIdleNotificationConfirm**:

1. NDIS issues **IRP_MN_WAIT_WAKE** to the underlying bus driver. This IRP enables the bus driver to wake the network adapter in response to an external wake-up signal.

2. NDIS issues an object identifier (OID) set request of OID_PM_PARAMETERS to the miniport driver. This OID request is associated with an **NDIS_PM_PARAMETERS** structure that specifies the settings under which the network adapter generates a wake-up event.

   The miniport driver must follow these guidelines when it processes the members of the **NDIS_PM_PARAMETERS** structure:

   - If the *ForceIdle* parameter of the *MiniportIdleNotification* handler function was set to FALSE, NDIS only sets the NDIS_PM_SELECTIVE_SUSPEND_ENABLED flag in the **WakeUpFlags** member of the **NDIS_PM_PARAMETERS** structure. In this case, the network adapter can signal a wake-up event when one of the following events occur:

     - The network adapter receives a packet that matches a receive packet filter. The adapter is configured to use these filters through OID set requests of OID_GEN_CURRENT_PACKET_FILTER.

     - The network adapter detects other external events that require processing by the networking driver stack, such as when the link state changes to either media disconnect or media connected.

   - If the *ForceIdle* parameter of the *MiniportIdleNotification* handler function was set to **TRUE**, NDIS does not set the NDIS_PM_SELECTIVE_SUSPEND_ENABLED flag in the **WakeUpFlags** member of the **NDIS_PM_PARAMETERS** structure. In this case, NDIS sets other members in the **NDIS_PM_PARAMETERS** structure for wake-up events not related to NDIS selective suspend.

Note NDIS sets the *ForceIdle* parameter to **TRUE** only when a system that is compliant with the Always On Always Connected (AOAC) technology is transitioning to a Connected Standby state.

The driver completes the OID request with NDIS_STATUS_SUCCESS.

Note If NDIS sets the NDIS_PM_SELECTIVE_SUSPEND_ENABLED flag in the **WakeUpFlags** member of **NDIS_PM_PARAMETERS** structure, it issues the OID set request of OID_PM_PARAMETERS directly to the miniport driver. This allows NDIS to bypass the processing by filter drivers in the networking driver stack.

3. After the OID set request of OID_PM_PARAMETERS is completed successfully, NDIS issues an OID set request OID_PNP_SET_POWER to the miniport driver.

   When it handles this OID set request, the driver prepares the network adapter to transition to the low-power state that is specified in the OID request. The driver must complete all pending operations in the following way:

   - The miniport driver waits for all previously indicated receive packets to be returned through calls to *MiniportReturnNetBufferLists*.

   - The miniport driver waits for send requests processed by the hardware to finish. After the requests are completed, the miniport driver must call **NdisMSendNetBufferListsComplete**.

   - The miniport driver completes all pending send requests by calling **NdisMSendNetBufferListsComplete**.

   - The miniport driver must cancel all pending NDIS timers and work items. After these are canceled, the driver must wait for the completion of these timers and work items.

   - The miniport driver must put the network adapter in a quiescent state. For example, the driver must cancel all hardware timers.

   The miniport driver configures the underlying network adapter to enable the specified wake-up events that were previously specified in the OID set request of OID_PM_PARAMETERS. After the network adapter is prepared for the low-power transition, the miniport driver completes the OID set request of OID_PNP_SET_POWER with NDIS_STATUS_SUCCESS.

4. NDIS issues an **IRP_MN_SET_POWER** to the underlying bus driver. This IRP requests that the network adapter be transitioned to a low-power state.

> **Note** During a selective suspend operation, the network adapter will be transitioned to the device power state that was specified in the call to **NdisMIdleNotificationConfirm**. The miniport driver specifies this device power state in the *IdlePowerState* parameter of this function.

After the IRP is completed, NDIS returns from the call to **NdisMIdleNotificationConfirm**.

Canceling and Completing an NDIS Selective Suspend Idle Notification

After the idle notification is issued, it can be canceled and completed in the following ways:

- NDIS can cancel the outstanding idle notification if the following conditions are true:

  - An overlying protocol or filter driver issues either a send packet request or an OID request to the miniport driver.

  - The underlying adapter signals a wake-up event, such as receiving a packet that matches a wake-on-LAN (WOL) pattern or detecting a change in its media connection status.

  NDIS cancels the idle notification by calling *MiniportCancelIdleNotification*. When this handler function is called, the miniport driver cancels any bus-specific IRPs that it may have previously issued for the idle notification. Finally, the miniport driver calls **NdisMIdleNotificationComplete** to complete the idle notification.

  For more information about how NDIS cancels the idle notification, see Canceling the NDIS Selective Suspend Idle Notification.

- After the network adapter is in a low-power state, the miniport driver can complete the idle notification itself to resume the adapter to a full-power state. The reasons for doing this are specific to the design and requirements of the driver and adapter. The miniport driver completes the idle notification by calling **NdisMIdleNotificationComplete**.

  For more information about how the miniport driver completes the idle notification, see Completing the NDIS Selective Suspend Idle Notification.

Canceling the NDIS Selective Suspend Idle Notification

Article • 03/14/2023

If the network adapter becomes inactive for an idle time-out period, NDIS starts the selective suspend operation. Through this operation, the network adapter is transitioned to a low-power state. NDIS begins this operation by issuing an idle notification to the miniport driver. For more information about this operation, see Handling the NDIS Selective Suspend Idle Notification.

NDIS calls the *MiniportIdleNotification* handler function to notify the driver that the underlying network adapter seems to be idle. After the idle notification is issued, NDIS cancels a pending idle notification if one or more of the following conditions are true:

- An overlying protocol or filter driver issues either a send packet request or an object identifier (OID) request to the miniport driver.

  For more information about how NDIS cancels the idle notification for this scenario, see Canceling the Idle Notification because of Overlying Driver Activity.

- The underlying adapter signals a wake-up event, such as receiving a packet or detecting a change in its media connection status.

  For more information about how NDIS cancels the idle notification for this scenario, see Canceling the Idle Notification because of Wake-up Events.

NDIS cancels the idle notification by calling the *MiniportCancelIdleNotification* handler function of the underlying miniport driver. When this function is called, the miniport driver must complete the idle notification to resume the adapter to a full-power state. For guidelines on this process, see Completing the NDIS Selective Suspend Idle Notification.

For more information about how to implement the *MiniportCancelIdleNotification* handler function, see Implementing a *MiniportCancelIdleNotification* Handler Function.

Canceling the Idle Notification Because of Overlying Driver Activity

NDIS monitors send requests and OID requests that are issued to a miniport driver whose network adapter has been suspended and is in a low-power state. When this happens, NDIS cancels the outstanding idle notification so that the network adapter can resume to a full-power state.

NDIS and the miniport driver follow these steps when an idle notification is canceled:

1. NDIS calls the *MiniportCancelIdleNotification* handler function to cancel an outstanding idle notification. When this handler function is called, the miniport driver must cancel any bus-specific I/O request packets (IRPs) that it may have previously issued for the idle notification.

   For example, when *MiniportCancelIdleNotification* is called, the miniport for a USB network adapter performs the following steps:

   a. The miniport driver cancels the pending USB idle request (**IOCTL_INTERNAL_USB_SUBMIT_IDLE_NOTIFICATION**) IRP. The miniport driver previously issued this IRP to the underlying USB bus driver when NDIS called the driver's *MiniportIdleNotification* function. The miniport driver cancels this IRP by calling **IoCancelIrp**.

   b. When the bus driver cancels the USB idle request IRP, it calls the miniport driver's completion routine for the IRP. This call notifies the driver that the IRP is completed and the network adapter can transition to a full-power state. From the context of the completion routine, the driver calls **NdisMIdleNotificationComplete** to notify NDIS that the network adapter can be transitioned to a full-power state.

   Note Depending on the dependencies for canceling bus-specific idle requests, the miniport driver calls **NdisMIdleNotificationComplete** either synchronously in the context of the call to *MiniportCancelIdleNotification* or asynchronously after *MiniportCancelIdleNotification* returns.

   For more information about how to implement a USB idle request IRP completion routine, see Implementing a USB Idle Request IRP Completion Routine.

2. After the miniport driver cancels any bus-specific IRPs for the idle notification, it calls **NdisMIdleNotificationComplete**. This call notifies NDIS that the idle notification has been completed. NDIS then completes the selective suspend operation by transitioning the network adapter to a full-power state.

   When **NdisMIdleNotificationComplete** is called, NDIS performs the following steps:

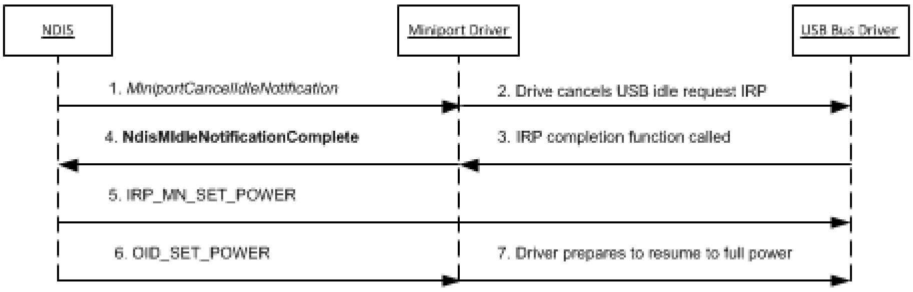
   a. NDIS issues **IRP_MN_SET_POWER** to the underlying bus driver. This IRP requests the bus driver to set the power state of the network adapter to

PowerDeviceD0.

b. NDIS issues an OID set request of OID_PNP_SET_POWER to the miniport driver. In this OID request, NDIS specifies that the network adapter is now transitioning to a full-power state of NdisDeviceStateD0.

   When it handles this OID set request, the driver prepares the adapter for full-power operation. This includes restoring the receive and send engines to the same state they were in before the transition to the low-power state. The driver then completes the OID request with NDIS_STATUS_SUCCESS.

The following figure shows the steps that are involved when NDIS cancels an idle notification that was issued to a miniport driver for a USB network adapter.



NDIS
Miniport Driver
USB Bus Driver
1. MiniportCancelIdleNotification
2. Drive cancels USB idle request IRP
3. IRP completion function called
4. NdisMIdleNotificationComplete
5. IRP_MN_SET_POWER
6. OID_SET_POWER
7. Driver prepares to resume to full power

Canceling the Idle Notification Because of Wake-up Events

Before the network adapter is transitioned to a low-power state, NDIS issues an OID set request of OID_PM_PARAMETERS to the network adapter. This OID request specifies the types of wake-up events that the adapter can signal to resume to a full-power state. For NDIS selective suspend, the adapter is configured to signal any of the following wake-up events:

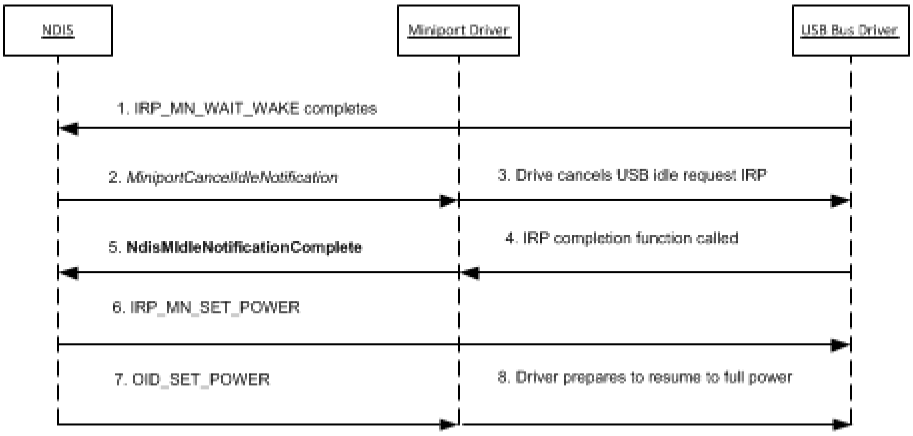
- The reception of a packet that matches a filter that was previously configured through an OID set request of OID_PM_ADD_WOL_PATTERN or OID_GEN_CURRENT_PACKET_FILTER.
- A change in the media connection status on the adapter.

NDIS and the miniport driver follow these steps when NDIS cancels an idle notification because of a wake-up signal generated by the network adapter:

1. The bus driver completes the **IRP_MN_WAIT_WAKE** that was issued by NDIS before transitioning the adapter to a low-power state. By completing the IRP, the bus driver notifies NDIS that the network adapter has generated a wake-up signal.

2. NDIS calls the *MiniportCancelIdleNotification* handler function to start the operation of canceling the idle notification. The steps that are involved in this operation are the same as described in Canceling the Idle Notification because of Overlying Driver Activity.

For example, the following figure shows the steps that are involved when NDIS cancels an idle notification because of a wake-up event signaled by a USB network adapter.



NDIS
Miniport Driver
USB Bus Driver
1. IRP_MN_WAIT_WAKE completes
2. *MiniportCancelIdleNotification*
3. Drive cancels USB idle request IRP
4. IRP completion function called
5. **NdisMIdleNotificationComplete**
6. IRP_MN_SET_POWER
7. OID_SET_POWER
8. Driver prepares to resume to full power

Completing the NDIS Selective Suspend Idle Notification

Article • 03/14/2023

NDIS calls the *MiniportIdleNotification* handler function to notify the driver that the underlying network adapter seems to be idle. For more information about this operation, see Handling the NDIS Selective Suspend Idle Notification.

After the idle notification is issued, the miniport driver completes the NDIS selective suspend idle notification under the following conditions:

- NDIS cancels the idle notification by calling the *MiniportCancelIdleNotification* handler function of the underlying miniport driver.
- The miniport driver completes the idle notification itself. The reasons for doing this are specific to the design and requirements of the driver and adapter. For example, the driver could complete the idle notification if it detects receive activity on the network adapter.

Note The miniport driver cannot explicitly cancel the idle notification. When NDIS cancels the idle notification, the miniport driver must complete the notification as described in this topic. For more information, see Canceling the NDIS Selective Suspend Idle Notification.

In either case, the miniport driver must complete the idle notification to resume the adapter to a full-power state. To complete the idle notification, the miniport driver must cancel any bus-specific I/O request packets (IRPs) that it may have previously issued for the idle notification. Finally, the driver calls **NdisMIdleNotificationComplete** to notify NDIS that the network adapter can be transitioned to a full-power state.

For example, the miniport driver for a USB network adapter completes an idle notification by following these steps:

1. The miniport driver cancels the pending USB idle request (**IOCTL_INTERNAL_USB_SUBMIT_IDLE_NOTIFICATION**) IRP. The miniport driver previously issued this IRP to the underlying USB bus driver when NDIS called the driver's *MiniportIdleNotification* function. The miniport driver cancels this IRP by calling **IoCancelIrp**.
2. When the bus driver cancels the USB idle request IRP, it calls the miniport driver's completion routine for the IRP. This call notifies the driver that the IRP is completed and the network adapter can transition to a full-power state. From the

context of the completion routine, the driver calls **NdisMIdleNotificationComplete** to notify NDIS that the network adapter can be transitioned to a full-power state.

For more information about how to implement a USB idle request IRP completion routine, see Implementing a USB Idle Request IRP Completion Routine.

Note Depending on the dependencies for canceling bus-specific idle requests, the miniport driver calls **NdisMIdleNotificationComplete** either synchronously in the context of the call to *MiniportCancelIdleNotification* or asynchronously after *MiniportCancelIdleNotification* returns.

After the miniport driver cancels any bus-specific IRPs for the idle notification, it calls **NdisMIdleNotificationComplete**. This call notifies NDIS that the idle notification has been completed. NDIS then completes the selective suspend operation by transitioning the network adapter to a full-power state.

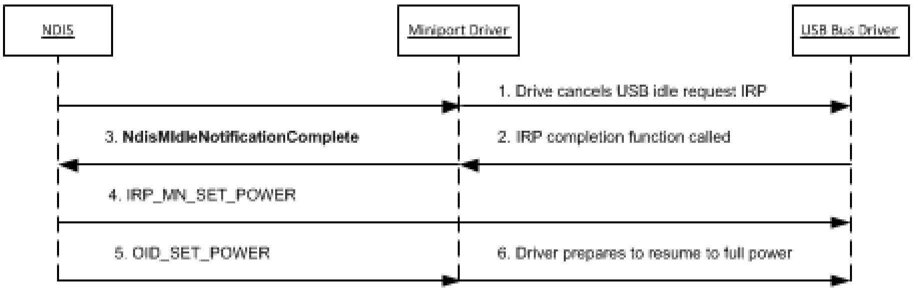
When **NdisMIdleNotificationComplete** is called, NDIS performs the following steps:

1. NDIS issues **IRP_MN_SET_POWER** to the underlying bus driver. This IRP requests the bus driver to set the power state of the network adapter to PowerDeviceD0.

2. NDIS issues an object identifier (OID) set request of OID_PNP_SET_POWER to the miniport driver. In this OID request, NDIS specifies that the network adapter is now transitioning to a full-power state of NdisDeviceStateD0.

   When it handles this OID set request, the driver prepares the adapter for full-power operation. This includes restoring the receive and send engines to the same state they were in before the transition to the low-power state. The driver then completes the OID request with NDIS_STATUS_SUCCESS.

The following figure shows the steps that are involved when the miniport driver completes an idle notification for a USB network adapter.



NDIS
Miniport Driver
USB Bus Driver
1. Drive cancels USB idle request IRP
3. NdisMIdleNotificationComplete
2. IRP completion function called
4. IRP_MN_SET_POWER
5. OID_SET_POWER
6. Driver prepares to resume to full power

Note When the miniport driver completes an idle notification, it must not call **NdisMIdleNotificationConfirm** for an idle notification that was previously completed through a call to **NdisMIdleNotificationComplete**.

Standardized INF Keywords for NDIS Selective Suspend

Article • 03/14/2023

> ⓘ **Note**
>
> Selective Suspend related keywords are for traditional NDIS miniport driver use only. They are deprecated in **Network Adapter WDF Class Extension (NetAdapterCx)** and must not be used by its client drivers.

The following standardized INF keywords are defined to enable, disable, and configure parameters for NDIS selective suspend on a miniport driver:

***SelectiveSuspend** INF Keyword

***SSIdleTimeout** INF Keyword

***SSIdleTimeoutScreenOff** INF Keyword

For more information about standardized INF keywords, see Standardized INF Keywords for Network Devices.

*SelectiveSuspend INF Keyword

The INF file for the miniport driver that supports NDIS selective suspend must specify the ***SelectiveSuspend** standardized INF keyword. After the driver is installed, administrators can update the ***SelectiveSuspend** keyword value in the **Advanced** property page for the network adapter. For more information about advanced properties, see Specifying Configuration Parameters for the Advanced Properties Page.

Note The miniport driver is automatically restarted after a change is made in the **Advanced** property page for the adapter.

The ***SelectiveSuspend** INF keyword is an enumeration keyword. The following table describes the possible INF entries for the ***SelectiveSuspend** INF keyword. The columns in this table describe the following attributes for an enumeration keyword:

SubkeyName
The name of the keyword that you must specify in the INF file. This name also appears in the registry under the **NDI\params\** key for the network adapter.

ParamDesc
The display text that is associated with SubkeyName.

Note The independent hardware vendor (IHV) can define any descriptive text for the SubkeyName.

Value
The enumeration integer value that is associated with each SubkeyName in the list.

EnumDesc
The display text that is associated with each value that appears in the **Advanced** property page.

SubkeyName	ParamDesc	Value	EnumDesc
***SelectiveSuspend**	Selective suspend	0	Disabled
		1 (Default)	Enabled

The miniport driver must check the ***SelectiveSuspend** keyword value in the registry before it advertises its support for NDIS selective suspend. If the ***SelectiveSuspend** keyword has a value of zero, the miniport must not advertise support for any selective suspend capabilities. For more information, see Reporting NDIS Selective Suspend Capabilities.

*SSIdleTimeout INF Keyword

The INF file for the miniport driver that supports NDIS selective suspend should specify the optional ***SSIdleTimeout** standardized INF keyword. This keyword specifies the idle time-out period in units of seconds. If NDIS does not detect any activity on the network adapter for a period that exceeds the ***SSIdleTimeout** value, NDIS starts a selective suspend operation by calling the miniport driver's *MiniportIdleNotification* handler function.

After the driver is installed, administrators can update the ***SSIdleTimeout** keyword value in the **Advanced** property page for the network adapter. For more information about advanced properties, see Specifying Configuration Parameters for the Advanced Properties Page.

Note The miniport driver is automatically restarted after a change is made in the advanced property page for the adapter.

The ***SSIdleTimeout** INF keyword is a numeric (**Int**) keyword. The following table describes the possible INF entries for the ***SSIdleTimeout** INF keyword. The columns in the table describe the following attributes for an **Int** keyword:

SubkeyName
The name of the keyword that you must specify in the INF file. This name also appears in the registry under the **NDI\params\** key for the network adapter.

ParamDesc
The display text that is associated with SubkeyName.

Note The independent hardware vendor (IHV) can define any descriptive text for the SubkeyName.

Default value
The default value for the integer.

Minimum value
The minimum value that is allowed for an integer.

Maximum value
The maximum value that is allowed for an integer.

SubkeyName	ParamDesc	Default value	Minimum value	Maximum value
***SSIdleTimeout**	Selective suspend idle time-out in units of seconds	5	1	60

Note NDIS reads the value of the ***SSIdleTimeout** standardized INF keyword for every instance of the network adapter whose driver supports NDIS selective suspend. Miniport drivers should not read this keyword.

NDIS measures the idle time-out by using timers that are precise to within 30 percent of the ***SSIdleTimeout** value. For example, if the ***SSIdleTimeout** value is 10, the adapter is suspended between 10 to 13 seconds after NDIS first detects the adapter is idle.

*SSIdleTimeoutScreenOff INF Keyword

The INF file for the miniport driver that supports NDIS selective suspend should specify the optional ***SSIdleTimeoutScreenOff** standardized INF keyword. This keyword specifies the idle time-out period in units of seconds and is only applicable when the screen is off. If NDIS does not detect any activity on the network adapter for a period that exceeds the ***SSIdleTimeoutScreenOff** value after the screen is off, NDIS starts a selective suspend operation by calling the miniport driver's *MiniportIdleNotification* handler function.

After the driver is installed, administrators can update the ***SSIdleTimeoutScreenOff** keyword value in the **Advanced** property page for the network adapter. For more information about advanced properties, see Specifying Configuration Parameters for the Advanced Properties Page.

Note The miniport driver is automatically restarted after a change is made in the advanced property page for the adapter.

The ***SSIdleTimeoutScreenOff** INF keyword is a numeric (**Int**) keyword. The following table describes the possible INF entries for the ***SSIdleTimeoutScreenOff** INF keyword. The columns in the table describe the following attributes for an **Int** keyword:

SubkeyName
The name of the keyword that you must specify in the INF file. This name also appears in the registry under the **NDI\params\** key for the network adapter.

ParamDesc
The display text that is associated with SubkeyName.

Note The independent hardware vendor (IHV) can define any descriptive text for the SubkeyName.

Default value
The default value for the integer.

Minimum value
The minimum value that is allowed for an integer.

Maximum value
The maximum value that is allowed for an integer.

SubkeyName	ParamDesc	Default value	Minimum value	Maximum value
*SSIdleTimeoutScreenOff	Selective suspend idle time-out in units of seconds	3	1	60

Note NDIS reads the value of the ***SSIdleTimeoutScreenOff** standardized INF keyword for every instance of the network adapter whose driver supports NDIS selective suspend.

Miniport drivers should not read this keyword.

Note The maximum value is only for testing purposes. The HLK certification test will explicitly check and fail if the value is more than 5.

NDIS measures the idle time-out by using timers that are precise to within 30 percent of the ***SSIdleTimeoutScreenOff** value. For example, if the ***SSIdleTimeoutScreenOff** value is 5, the adapter is suspended between 5 to 6.5 seconds after NDIS first detects the adapter is idle.

Managing IRP Resources for NDIS Selective Suspend

Article • 03/14/2023

If a miniport driver supports and enables NDIS selective suspend, NDIS calls *MiniportIdleNotification* to issue an idle notification to the driver if the network adapter becomes inactive. When the miniport driver handles this notification, it may need to issue I/O request packets (IRPs) to the underlying bus driver. These IRPs notify the bus driver about the adapter's idle state and request confirmation that the adapter can transition to a low-power state.

IRPs that are issued by the miniport driver are bus-specific. For example, when NDIS calls *MiniportIdleNotification*, the USB miniport issues an USB idle request (**IOCTL_INTERNAL_USB_SUBMIT_IDLE_NOTIFICATION**) IRP to the underlying USB bus driver.

NDIS may issue the idle notification to the miniport driver many times after the driver has been initialized. Therefore, we recommend that the driver allocate the resources for the USB idle request IRP in the context of the call to the driver's *MiniportInitializeEx* function.

The following example shows how the miniport driver allocates the IRP resources.

C++

```
//
// MiniportInitializeEx()
//
// In the miniport's initialization routine, the miniport should allocate
// an IRP.  It can also set up the USB_IDLE_CALLBACK_INFO structure that
// will be used with each successive USB idle request.
//
NDIS_STATUS MiniportInitializeEx(
    _In_ NDIS_HANDLE MiniportAdapterHandle,
    _In_ NDIS_HANDLE MiniportDriverContext,
    _In_ PNDIS_MINIPORT_INIT_PARAMETERS MiniportInitParameters
    )
    {
    PIRP UsbSsIrp;
    USB_IDLE_CALLBACK_INFO UsbSsCallback;
    ...

    UsbSsIrp = IoAllocateIrp(Adapter->Fdo->StackSize, FALSE);
    if (!UsbSsIrp)
       {
       // Handle failure
       return NDIS_STATUS_RESOURCES;
       }

    UsbSsCallback.IdleCallback = MiniportUsbIdleRequestCallback;
    UsbSsCallback.IdleContext = Adapter;

    // Save these in the adapter structure for later use
    Adapter->UsbSsIrp = UsbSsIrp;
    Adapter->UsbSsCallback = UsbSsCallback;
    ...
    }
```

If the miniport driver allocates the IRP resources during the call to *MiniportInitializeEx*, the driver must free those resources during the call to *MiniportHaltEx*.

The following example shows how the miniport driver frees the IRP resources.

```C++
//
// MiniportHaltEx
//
// During halt (or when the miniport performs its cleanup from
// MiniportInitializeEx) the miniport should free the IRP allocated
// earlier.
//
VOID MiniportHaltEx(
     _In_  NDIS_HANDLE MiniportAdapterContext,
     _In_  NDIS_HALT_ACTION HaltAction
    )
    {
    ...
    if (Adapter->UsbSsIrp)
        {
        IoFreeIrp(Adapter->UsbSsIrp);
        Adapter->UsbSsIrp = NULL;
        }
    ...
    }
```

Implementing a MiniportIdleNotification Handler Function

Article • 12/15/2021

NDIS calls the miniport driver's *MiniportIdleNotification* handler function in order to selectively suspend the network adapter. The adapter is suspended when NDIS transitions the adapter to a low-power state.

The miniport driver can veto the idle notification if the network adapter is still being used. The driver does this by returning NDIS_STATUS_BUSY from the *MiniportIdleNotification* handler function.

Note The miniport driver cannot veto the idle notification if the *ForceIdle* parameter of the *MiniportIdleNotification* handler function is set to **TRUE**.

If the miniport driver does not veto the idle notification, it may have to issue bus-specific I/O request packets (IRPs) to the underlying bus driver. These IRPs notify the bus driver about the adapter's idle state and request confirmation that the adapter can transition to a low-power state.

For example, when *MiniportIdleNotification* is called, the USB miniport driver prepares an I/O request packet (IRP) for a USB idle request (**IOCTL_INTERNAL_USB_SUBMIT_IDLE_NOTIFICATION**). When the miniport driver prepares the IRP, it must specify a callback function. The driver must also call either **IoSetCompletionRoutine** or **IoSetCompletionRoutineEx** to specify a completion routine for the IRP. The miniport driver then calls **IoCallDriver** to issue the IRP to the USB bus driver.

Note The USB bus driver does not immediately complete the IRP. The IRP is left in a pending state through the low-power transition. The bus driver completes the IRP only when it is canceled by the miniport driver or a hardware event occurs, such as the surprise removal of the network adapter from the USB hub.

The following is an example of a *MiniportIdleNotification* handler function for a USB miniport driver. This example shows the steps that are involved with issuing a USB idle request IRP to the underlying USB driver. This example also shows how the IRP resources, which were previously allocated in *MiniportInitializeEx*, can be reused for the IRP.

C++

```
//
// MiniportIdleNotification()
//
// This routine is invoked by NDIS when it has detected that the miniport
// is idle.  The miniport must prepare to issue its selective suspend IRP
// to the USB stack.  The driver can return NDIS_STATUS_BUSY if it is
// unwilling to become idle at this moment; NDIS will then retry later.
// Otherwise, the miniport should return NDIS_STATUS_PENDING.
//
NDIS_STATUS MiniportIdleNotification(
    _In_ NDIS_HANDLE MiniportAdapterContext,
    _In_ BOOLEAN ForceIdle
    )
{
    PIO_STACK_LOCATION IoSp;

    IoReuseIrp(Adapter->UsbSsIrp, STATUS_NOT_SUPPORTED);

    IoSp = IoGetNextIrpStackLocation(Adapter->UsbSsIrp);
    IoSp->MajorFunction = IRP_MJ_INTERNAL_DEVICE_CONTROL;
    IoSp->Parameters.DeviceIoControl.IoControlCode
            = IOCTL_INTERNAL_USB_SUBMIT_IDLE_NOTIFICATION;
    IoSp->Parameters.DeviceIoControl.InputBufferLength
            = sizeof(Adapter->UsbSsCallback);
    IoSp->Parameters.DeviceIoControl.Type3InputBuffer
            = Adapter->UsbSsCallback;

    IoSetCompletionRoutine(
            Adapter->UsbSsIrp,
            MiniportUsbIdleRequestCompletion,
            Adapter,
            TRUE,
            TRUE,
            TRUE);

    NtStatus = IoCallDriver(Adapter->Fdo, Adapter->UsbSsIrp);
    if (!NT_SUCCESS(NtStatus))
    {
       return NDIS_STATUS_FAILURE;
    }

    return NDIS_STATUS_PENDING;
}
```

For guidelines on implementing a callback routine for a USB idle request IRP, see Implementing a USB Idle Request IRP Callback Routine.

Implementing a USB Idle Request IRP Callback Routine

Article • 12/15/2021

When *MiniportIdleNotification* is called, the USB miniport driver calls **IoCallDriver** to issue an I/O request packet (IRP) for a USB idle request (**IOCTL_INTERNAL_USB_SUBMIT_IDLE_NOTIFICATION**) to the underlying USB bus driver. The miniport driver issues this IRP to inform the USB bus driver that the network adapter is idle and must be suspended.

The USB miniport driver must provide an IRP callback routine for the USB idle request IRP. The USB bus driver calls this routine when it determines that the network adapter can be suspended and transitioned to a low-power state.

Note After the USB bus driver handles the USB idle request IRP, it calls the callback routine either synchronously in the context of the call to **IoCallDriver** or asynchronously after *MiniportIdleNotification* returns.

The callback routine only has to call **NdisMIdleNotificationConfirm** in order to notify NDIS that it can continue with the low-power state transition of the network adapter. When the driver calls **NdisMIdleNotificationConfirm**, it must also specify the lowest device power state that the network adapter can transition to.

Within the context of the call to **NdisMIdleNotificationConfirm**, NDIS performs the steps that are required to transition the network adapter to a low-power state. For more information, see Handling the NDIS Selective Suspend Idle Notification.

The following is an example of a callback routine for a USB idle request IRP.

C++

```
//
// MiniportUsbIdleRequestCallback()
//
// This is the USB selective suspend idle notification.  All that is
// needed is to inform NDIS that the USB stack is ready to go to a
// low-power state.  Be aware that USB devices will always be requested
// to transition to a power state of NdisDeviceStateD2.
//
VOID MiniportUsbIdleRequestCallback(PVOID AdapterContext)
{
    NdisMIdleNotificationConfirm(
        AdapterContext->MiniportAdapterHandle,
        NdisDeviceStateD2
        );
    return;
}
```

For more information about the USB idle request callback routine, see USB Idle Request IRP Callback Routine.

Implementing a MiniportCancelIdleNotification Handler Function

Article • 12/15/2021

NDIS calls the miniport driver's *MiniportCancelIdleNotification* handler function in order to cancel the idle notification process and transition the network adapter to a full-power state. When this function is called, the miniport driver must follow these steps:

1. The miniport driver must cancel any bus-specific IRPs that it may have previously issued for the idle notification.

2. The miniport driver calls **NdisMIdleNotificationComplete**. This call notifies NDIS that the idle notification has been completed. NDIS then comples the selective suspend operation by transitioning the network adapter to a full-power state.

For example, when *MiniportCancelIdleNotification* is called, the USB miniport driver calls **IoCancelIrp** to cancel the I/O request packet (IRP) for a USB idle request (**IOCTL_INTERNAL_USB_SUBMIT_IDLE_NOTIFICATION**). The USB miniport driver previously issued this IRP in its *MiniportIdleNotification* handler function. As soon as the USB bus driver has canceled the IRP, it calls the IRP's completion routine. When the USB bus driver calls the completion routine, it confirms that the IRP is canceled and the device can resume to a full-power state. In the context of the completion routine, the miniport driver calls **NdisMIdleNotificationComplete**.

Note The USB bus driver can call the completion routine either synchronously in the context of the call to **IoCancelIrp** or asynchronously after *MiniportCancelIdleNotification* returns.

The following is an example of a *MiniportCancelIdleNotification* handler function for a USB miniport driver. This example shows the steps that are involved with canceling a USB idle request IRP.

```C++
//
// MiniportCancelIdleNotification()
//
// This routine is called if NDIS has to cancel an idle notification.
// All that is needed is to cancel the selective suspend IRP.
//
VOID MiniportCancelIdleNotification(
    _In_ NDIS_HANDLE MiniportAdapterContext
    )
{
    IoCancelIrp(Adapter->UsbSsIrp);
}
```

For guidelines on implementing a completion routine for a USB idle request IRP, see Implementing a USB Idle Request IRP Completion Routine.

Implementing a USB Idle Request IRP Completion Routine

Article • 12/15/2021

When *MiniportIdleNotification* is called, the USB miniport driver calls **IoCallDriver** to issue an I/O request packet (IRP) for a USB idle request (**IOCTL_INTERNAL_USB_SUBMIT_IDLE_NOTIFICATION**) to the underlying USB bus driver. The miniport driver issues this IRP to inform the USB bus driver that the network adapter is idle and must be suspended.

The USB miniport driver must also call **IoSetCompletionRoutineEx** in order to register a completion routine for the USB idle request IRP. The USB bus driver calls the completion routine when it completes the IRP after it is canceled by the USB miniport driver. The USB miniport driver cancels the IRP when NDIS cancels the idle notification by calling *MiniportCancelIdleNotification*.

The completion routine only has to call **NdisMIdleNotificationComplete** in order to notify NDIS that it can continue with the full-power state transition of the network adapter.

Note The completion routine must return STATUS_MORE_PROCESSING_REQUIRED if the USB miniport driver will reuse the IRP resources during another idle notification from NDIS.

The following is an example of a completion routine for the USB idle request IRP.

C++

```cpp
//
// MiniportUsbIdleRequestCompletion()
//
// This is the IO_COMPLETION_ROUTINE for the selective suspend IOCTL.
// All that is needed is to inform NDIS that the IdleNotification
// operation is complete.
//
VOID MiniportUsbIdleRequestCompletion(PVOID AdapterContext)
{
    NdisMIdleNotificationComplete(Adapter->MiniportAdapterHandle);

    // We will be reusing the IRP later, so do not let the IO manager delete
it.
    return STATUS_MORE_PROCESSING_REQUIRED;
}
```

For more information about the USB idle request callback routine, see USB Idle Request IRP Completion Routine.

Overview of NDIS Wake Reason Status Indications

Article • 03/14/2023

Starting with NDIS 6.30, miniport drivers issue an NDIS wake reason status indication (**NDIS_STATUS_PM_WAKE_REASON**) to notify NDIS and overlying drivers about the reason for a system wake-up event. If the network adapter generates a wake-up event, the miniport driver immediately issues an NDIS status indication of **NDIS_STATUS_PM_WAKE_REASON** when the network adapter resumes to a full-power state.

Note Support for NDIS wake reason status indications is optional for Mobile Broadband (MB) miniport drivers.

The miniport driver is configured with power management (PM) parameters through an object identifier (OID) set request of OID_PM_PARAMETERS. This OID request specifies the PM parameters through an **NDIS_PM_PARAMETERS** structure.

The **NDIS_PM_PARAMETERS** structure specifies the parameters for the following types of wake-up events.

Received Packet Wake-up Events
The network adapter generates a wake-up event if it receives a packet that matched a wake-on-LAN (WOL) pattern. WOL patterns include the following:

- Media-independent WOL patterns, such as magic packets or TCP/IP data patterns within the packet payload. For example, the **NDIS_PM_PARAMETERS** structure could specify a WOL pattern for a TCP SYN frame.

- Media-specific WOL patterns, such as an EAPOL request identifier packet or mobile broadband (MB) Short Message Service (SMS) message.

- Wildcard patterns that match a receive filter specified through an OID set request of OID_GEN_CURRENT_PACKET_FILTER.

Note For this type of wake reason status indication, the network adapter must be able to save the received packet. The driver must return the received packet within the status indication.

WOL patterns are specified through the **EnabledWoLPacketPatterns** member of the **NDIS_PM_PARAMETERS** structure.

Media-Specific Wake-up Events
The network adapter generates a wake-up event because of a media-specific reason, such as a disassociation from an 802.11 access point (AP) or the receipt of a mobile broadband (MB) Short Message Service (SMS) message.

Wake-up events of this type are specified through the **MediaSpecificWakeUpEvents** member of the **NDIS_PM_PARAMETERS** structure.

Media-Independent Wake-up Events
The network adapter generates a wake-up event because of a media-independent reason, such as media connection or disconnection.

Wake-up events of this type are specified through the **WakeUpFlags** member of the **NDIS_PM_PARAMETERS** structure.

The miniport driver must follow these guidelines for NDIS wake reason status indications:

- If the miniport driver supports the ability to issue wake packet indications, it must report this ability when NDIS calls the driver's *MiniportInitializeEx* function. For more information, see Reporting Wake Reason Status Indication Capabilities.

  Note The miniport driver does not have to report its ability to issue NDIS wake reason status indications for events that are not related to the receipt of a WOL packet.

- When the miniport driver issues a wake packet indication for a WOL packet, it must include the packet that caused the wake-up event. For more information, see Issuing NDIS Wake Reason Status Indications.

- If the network adapter generated a wake-up signal, the miniport driver must issue an **NDIS_STATUS_PM_WAKE_REASON** status indication. The driver does this while it is handling the OID set request of OID_PNP_SET_POWER for the transition to a full-power state.

- The miniport driver must issue an **NDIS_STATUS_PM_WAKE_REASON** status indication before it issues a status indication that is related to the wake-up event. For example, if the wake-up event was due to a change in the media connectivity state, the miniport driver must issue an **NDIS_STATUS_LINK_STATE** status indication after it has issued the **NDIS_STATUS_PM_WAKE_REASON** status indication.

- The miniport driver must ssue an **NDIS_STATUS_PM_WAKE_REASON** status indication only for power management events that were previously enabled through an OID set request of OID_PM_PARAMETERS.

- The miniport driver must issue an **NDIS_STATUS_PM_WAKE_REASON** status indication only for wake-up events that were generated by the underlying network adapter.

Reporting Wake Reason Status Indication Capabilities

Article • 12/15/2021

Starting with NDIS 6.30, the miniport driver must report whether it can issue an NDIS wake reason status indication (**NDIS_STATUS_PM_WAKE_REASON**) to report wake-up events caused by one of the following:

- The network adapter received a packet that matched a wake-on-LAN (WOL) pattern. This includes the receipt of a packet that matches a receive filter specified through an object identifier (OID) set request of OID_GEN_CURRENT_PACKET_FILTER.

  Note For this type of wake reason status indication, the network adapter must be able to save the received packet. The driver must return the received packet within the status indication.

- The network adapter detected a media-specific event, such as a disassociation from an 802.11 access point (AP) or the receipt of a mobile broadband (MB) Short Message Service (SMS) message.

- The network adapter detected another enabled event that is not specific to a WOL pattern or media type (*media-independent event*). For example, the miniport driver issues the **NDIS_STATUS_PM_WAKE_REASON** status indication if it enabled the network adapter to detect media connection or disconnection.

Note Support for NDIS wake reason status indications is optional for Mobile Broadband (MB) miniport drivers.

When NDIS calls the driver's *MiniportInitializeEx* function, the miniport driver reports its wake reason status indication capabilities by following these steps:

1. The miniport driver initializes an **NDIS_PM_CAPABILITIES** structure with the power management capabilities of the underlying hardware.

   To enable the support for wake reason status indications, the miniport driver must set the members of the **NDIS_PM_CAPABILITIES** structure as follows:

   - The miniport driver must specify NDIS_PM_CAPABILITIES_REVISION_2 and NDIS_SIZEOF_NDIS_PM_CAPABILITIES_REVISION_2 for the revision and length of the **NDIS_PM_CAPABILITIES** structure within the structure's **Header** member.

- If the network adapter can store the received packet that caused a system wake-up event, the miniport driver sets the NDIS_PM_WAKE_PACKET_INDICATION_SUPPORTED flag within the **Flags** member of this structure.

  If this flag is set, the network adapter must be able to save the received packet that caused the adapter to generate a wake-up event. In addition, the miniport driver must be able to do the following with this packet after the network adapter transitions to a full-power state:

  - The miniport driver must be able to indicate the packet by calling **NdisMIndicateReceiveNetBufferLists**.

  - The miniport driver must be able to issue an **NDIS_STATUS_PM_WAKE_REASON** status indication and must pass the packet with indication.

- The miniport driver sets the **MaxWoLPacketSaveBuffer** member to the maximum size, in units of bytes, of the buffer that contains the WOL packet that caused a system wake-up event.

  The value of the **MaxWoLPacketSaveBuffer** member must be less than or equal to the size, in bytes, of the maximum transmission unit (MTU) and media access control (MAC) header for the network media. The driver reports the MTU size through OID query requests of OID_GEN_MAXIMUM_FRAME_SIZE.

- The miniport driver sets the **SupportedWakeUpEvents** to the media-independent wake-up events that the network adapter supports, such as generating a wake-up event when the adapter becomes connected to the networking interface.

- The miniport driver sets the **MediaSpecificWakeUpEvents** to the media-specific wake-up events that the network adapter supports. These events include generating a wake-up event when the 802.11 adapter becomes disassociated with the AP.

2. The miniport driver initializes an NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES structure and sets the**PowerManagementCapabilitiesEx** member to the address of the initialized **NDIS_PM_CAPABILITIES** structure.

3. The miniport driver calls the **NdisMSetMiniportAttributes** function to register its power management capabilities. When the miniport driver calls this function, it

sets the *MiniportAttributes* parameter to the address of the **NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES** structure.

The method that is used by miniport drivers to report the wake reason status indication capabilities is based on the NDIS 6.20 method for reporting power management capabilities. For more information about this method, see Reporting Power Management Capabilities.

For more information about the adapter initialization process, see Initializing a Miniport Adapter.

For more information about how to report power management capabilities, see Reporting Power Management Capabilities.

Issuing NDIS Wake Reason Status Indications

Article • 03/14/2023

If a miniport driver supports NDIS wake reason status indications (**NDIS_STATUS_PM_WAKE_REASON**), it must generate this status indication immediately after the network adapter generates a wake-up event and the adapter resumes to a full-power state.

Note Support for NDIS wake reason status indications is optional for Mobile Broadband (MB) miniport drivers.

The miniport driver is configured with power management (PM) parameters through an object identifier (OID) set request of OID_PM_PARAMETERS. This OID request specifies the PM parameters through an **NDIS_PM_PARAMETERS** structure.

The **NDIS_PM_PARAMETERS** structure specifies the parameters for the following types of wake-up events.

Received Packet Wake-up Events
The network adapter generates a wake-up event if it receives a packet that matched a wake-on-LAN (WOL) pattern. WOL patterns include the following:

- Media-independent WOL patterns, such as magic packets or TCP/IP data patterns within the packet payload. For example, the **NDIS_PM_PARAMETERS** structure could specify a WOL pattern for a TCP SYN frame.

- Media-specific WOL patterns, such as an EAPOL request identifier packet or mobile broadband (MB) Short Message Service (SMS) message.

- Wildcard patterns that match a receive filter specified through an OID set request of OID_GEN_CURRENT_PACKET_FILTER.

Note For this type of wake reason status indication, the network adapter must be able to save the received packet. The driver must return the received packet within the status indication.

WOL patterns are specified through the **EnabledWoLPacketPatterns** member of the **NDIS_PM_PARAMETERS** structure.

Media-Specific Wake-up Events
The network adapter generates a wake-up event because of a media-specific reason,

such as a disassociation from an 802.11 access point (AP) or the receipt of a mobile broadband (MB) Short Message Service (SMS) message.

Wake-up events of this type are specified through the **MediaSpecificWakeUpEvents** member of the NDIS_PM_PARAMETERS structure.

Media-Independent Wake-up Events
The network adapter generates a wake-up event because of a media-independent reason, such as media connection or disconnection.

Wake-up events of this type are specified through the **WakeUpFlags** member of the NDIS_PM_PARAMETERS structure.

If the network adapter generated a wake-up signal, the miniport driver must issue an NDIS_STATUS_PM_WAKE_REASON status indication. The driver does this while it is handling the OID set request of OID_PNP_SET_POWER for the transition of the adapter to a full-power state.

Note The miniport driver must issue an NDIS_STATUS_PM_WAKE_REASON status indication before it issues a status indication that is related to the wake-up event. For example, if the wake-up event was due to a change in the media connectivity state, the miniport driver must issue an NDIS_STATUS_LINK_STATE status indication after it has issued the **NDIS_STATUS_PM_WAKE_REASON** status indication.

When the miniport driver issues the NDIS_STATUS_PM_WAKE_REASON status indication, it must follow these steps:

1. The miniport driver must allocate a buffer that is large enough to contain the following:

    - An NDIS_PM_WAKE_REASON structure.

    - An NDIS_PM_WAKE_PACKET structure along with the received packet (*wake packet*) that caused the network adapter to generate the wake-up event.

      Note The miniport driver does not need to allocate this buffer space if it indicates media-specific or media-independent wake-up events.

2. The miniport driver initializes an NDIS_PM_WAKE_REASON structure at the start of the buffer. The driver sets the **WakeReason** member to an NDIS_PM_WAKE_REASON_TYPE enumeration value that defines the type of the wake-up event.

   For example, if the miniport driver is indicating a received packet wake-up event, it must set the **WakeReason** member to **NdisWakeReasonPacket**. Otherwise, the driver sets the **WakeReason** member to the enumeration value that best describes the media-specific or media-independent wake-up event.

3. If the miniportdriver is issuing an NDIS_STATUS_PM_WAKE_REASON status indication for a received packet wake-up event, it must follow these steps:

   a. The miniport driver sets the **InfoBufferOffset** member to the offset of an NDIS_PM_WAKE_PACKET structure that follows the NDIS_PM_WAKE_REASON structure in the buffer.

   Note The miniport driver must align the start of the NDIS_PM_WAKE_PACKET structure on a 64-bit boundary.

   b. The miniport driver sets the **InfoBufferSize** member to the size of the NDIS_PM_WAKE_PACKET structure plus the size of the packet that caused the wake-up event.

   c. The miniport driver initializes an NDIS_PM_WAKE_PACKET structure following the NDIS_PM_WAKE_REASON structure in the buffer.

   The miniport driver sets the members of the NDIS_PM_WAKE_PACKET structure as follows:

   - The **PatternId** member is set to the identifier of the WOL pattern that matches the wake packet. This identifier is specified by the **PatternId** member of the NDIS_PM_WOL_PATTERN structure that is passed to the driver during an OID set request of OID_PM_ADD_WOL_PATTERN.

   - The **PatternFriendlyName** member is set to the user-readable description of the wake pattern that is specified by the **PatternId** member. This value is specified by the **FriendlyName** member of the NDIS_PM_WOL_PATTERN structure.

     Note The miniport driver does not need to initialize this member. NDIS sets the **PatternFriendlyName** member to the correct value before it passes the NDIS_PM_WAKE_PACKET structure to overlying drivers.

   - The **OriginalPacketSize** member is set to the length of the packet as received by the network adapter.

   - The **SavedPacketSize** member must be set to the length of the packet that is being reported through the NDIS_STATUS_PM_WAKE_REASON status indication.

Note The value of this member must not be greater than the value that the miniport driver set in the **MaxWoLPacketSaveBuffer** member of the **NDIS_PM_CAPABILITIES** structure. The driver returns this structure when it reports its wake packet indication capabilities. For more information, see Reporting Wake Reason Status Indication Capabilities.

- The **SavedPacketOffset** member must be set to the offset, in units of bytes, to the wake packet that follows the **NDIS_PM_WAKE_PACKET** structure.

  Note The miniport driver must align the start of the wake packet on a 64-bit boundary in the buffer.

d. The miniport copies the wake packet into the buffer at the offset specified by the **SavedPacketOffset** member.

4. If the miniport driver is issuing an **NDIS_STATUS_PM_WAKE_REASON** status indication for a media-specific or media-independent wake-up event, it sets the **InfoBufferOffset** and **InfoBufferSize** members of the **NDIS_PM_WAKE_REASON** structure to zero.

5. The miniport driver initializes an **NDIS_STATUS_INDICATION** structure. The driver sets the **StatusCode** member to NDIS_STATUS_PM_WAKE_REASON. The driver also sets the **StatusBuffer** member to point to the buffer, and sets the **StatusBufferLength** to the length, in bytes, of the buffer.

6. The miniport driver calls **NdisMIndicateStatusEx** and passes a pointer to the **NDIS_STATUS_INDICATION** structure in the *StatusIndication* parameter.

Note After the miniport driver issues the **NDIS_STATUS_PM_WAKE_REASON** status indication for a received packet wake-up event, it must indicate this received packet by calling **NdisMIndicateReceiveNetBufferLists**.

NDIS Power Management Overview

Article • 03/14/2023

This section provides an overview of the features that are provided with the power management interface that is introduced in Windows 7 for NDIS 6.20 drivers.

Miniport drivers and protocol drivers that support NDIS 6.20 and later versions of NDIS must support the NDIS 6.20 power management interface. However, NDIS provides translation to the previous interface for older network adapters and NDIS 6.1 or earlier miniport drivers that do not support the NDIS 6.20 power management features. For more information about NDIS 6.20 backward compatibility issues, see NDIS 6.20 Backward Compatibility.

The NDIS 6.20 power management interface supports:

- Wake-on-LAN (WOL) patterns that are based on the packet type in addition to the NDIS 6.1 and earlier methods. Therefore, NDIS 6.20 WOL patterns can be more specific to avoid unnecessary wake-up events. For example, a network adapter can identify TCP synchronize (SYN) packets. For more information about WOL methods, see WOL Methods in NDIS 6.20.

- Protocol offloads to network adapters for some of the most common protocols. Because the protocols are offloaded to the network adapter, it can respond on behalf of the computer to avoid unwanted wake-up events. For example, a network adapter can handle IPv4 Address Resolution Protocol (ARP) and IPv6 Neighbor Solicitation (NS) protocol packets without waking the computer. For more information about power management protocol offloads, see Protocol Offloads for NDIS Power Management.

For information about the WOL event sequences that NDIS uses to set a low-power state and restore full power, see Low Power for Wake on LAN.

The NDIS 6.20 power management also supports:

- NDIS 6.20 can return the network adapter to a full-power state when the media connects. The operating system puts the network adapter in a low-power state when the media is disconnected. For more information about setting a low-power state when media disconnects, see Low Power on Media Disconnect.

This section includes the following topics:

WOL Methods in NDIS 6.20

WOL Patterns for NDIS Power Management

Protocol Offloads for NDIS Power Management

WOL Methods in NDIS 6.20

Article • 03/14/2023

The power management capabilities that are supported in NDIS 6.20 and later versions of NDIS consist of the following wake-on-LAN (WOL) methods:

- Wake on magic packet
- Wake on pattern match
- Wake device on media connect

For more information about the power management capabilities in previous versions of Windows, see Power Management (NDIS 6.0 and Later).

The *wake on magic packet* method wakes the computer when the network adapter receives a *magic packet*. A *magic packet* contains 16 contiguous copies of the receiving network adapter's Ethernet address.

The *wake on magic packet* method is separate from the *wake on pattern match* method. WOL patterns include other packet types or a bitmap. For more information about WOL patterns, see WOL Patterns for NDIS Power Management.

Although some network adapters report support for the *wake device on media connect* method, previous versions of Windows did not. Windows 7 fully supports the *wake device on media connect* method if an NDIS 6.20 miniport driver reports support. NDIS sets the network adapter to a low power state if the media is disconnected.

For more information about the *wake device on media connect* method, see Low Power on Media Disconnect.

WOL Patterns for NDIS Power Management

Article • 03/14/2023

Starting with NDIS 6.20, Wake-on-LAN (WOL) patterns are supported for the *wake on pattern match* method. This WOL method minimizes spurious wake-up events and ensures that the computer is brought back to running state when expected. The interface for WOL patterns identifies specific patterns that are based on the packet type (for example, TCP SYN packets on IPv4). Specific patterns provide reliable pattern matches.

There are two types of WOL patterns:

WOL packet
A packet in which the wake-up pattern defines a specific packet type (such as TCP SYN on IPv4).

WOL bitmap
A WOL pattern that is specified with an offset and bitmap.

Note NDIS 6.20 and later versions of NDIS also support the *wake on magic packet* method. This method is separate from the *wake on pattern match* method.

Starting with NDIS 6.20, multiple protocol drivers can set WOL patterns on a network adapter. To ensure that the correct set of WOL patterns is set when the number of requested WOL patterns is higher than the number that the network adapter can support, protocol drivers assign a priority to each WOL pattern. When NDIS cannot add a new high-priority WOL pattern because the network adapter is out of resources, NDIS can delete the lower priority patterns.

For more information about managing WOL patterns, see Adding and Deleting Wake on LAN Patterns.

For more information about WOL methods supported in NDIS 6.20 and later versions, see WOL Methods in NDIS 6.20.

Protocol Offloads for NDIS Power Management

Article • 03/14/2023

NDIS 6.20 and later versions of NDIS support protocol offloads for NDIS power management. For example, NDIS can offload the handling of Address Resolution Protocol (ARP) requests to a network adapter. Some applications use periodic ARP request packets to discover and ensure the presence of a host on the network. These applications send the ARP requests even when there is no current need to send data to the host. Such ARP requests wake up the host and waste power when there is nothing for the host to do.

Note In Windows 7, the power management offload functionality is enabled only when all protocol and filter drivers that are bound to the miniport adapter support NDIS 6.20 and later versions. In Windows 8, the power management offload functionality is enabled if the miniport adapter supports it, regardless of the protocol and filter driver versions.

Note If an incoming packet matches both an offloaded protocol and a pattern (for example, because of a configuration error), the network adapter responds to the packet and wakes up the computer.

To minimize spurious wake ups, NDIS protocol drivers attempt to offload the response to commonly used network requests to the hardware. Some network protocols require the host to periodically advertise certain information. When a network adapter responds to ARP requests, or takes over protocol specific periodic advertisements without waking up the system for processing these requests, many spurious wake-up events can be avoided.

There are three types of low power protocol offloads:

- IPv4 ARP
- IPv6 Neighbor Solicitation (NS)
- IEEE 802.11 robust secure network (RSN) 4-way and 2-way handshake

NDIS allows multiple protocol drivers to offload different protocols to a network adapter. To ensure that the correct set of protocols is offloaded when the number of requested protocol offloads is higher than the number that the network adapter can support, protocol drivers assign a priority to each protocol offload. When NDIS cannot add a new high-priority protocol offload because the network adapter is out of resources, NDIS might delete the lower priority offloads.

For more information about managing protocol offloads, see Adding and Deleting Low Power Protocol Offloads.

Standardized INF Keywords for Power Management

Article • 12/15/2021

The power management standardized keywords are defined in the device driver INF file. The operating system reads these standardized keywords and adjusts the current power management capabilities of the device.

Both Network Adapter WDF Class Extension (NetAdapterCx) client drivers and traditional NDIS miniport device drivers use these power management keywords. However, some keywords are used exclusively by NetAdapterCx drivers while others are used exclusively by NDIS drivers as the following sections describe:

- Power management keywords for NetAdapterCx and NDIS
- Power management keywords exclusive to NetAdapterCx
- Power management keywords exclusive to NDIS

The traditional NDIS miniport device driver should always indicate the device's hardware power management capabilities to NDIS in the **NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES** structure.

For more information about standardized INF keywords, see Standardized INF Keywords for Network Devices.

Power management keywords for NetAdapterCx and NDIS

The following standardized INF keywords are defined to enable or disable support for power management features of network adapters. They are used by both NetAdapterCx client drivers and traditional NDIS miniport device drivers.

***WakeOnPattern**
A value that describes whether the device should be enabled to wake the computer when a network packet matches a specified pattern.

***WakeOnMagicPacket**
A value that describes whether the device should be enabled to wake the computer when the device receives a *magic packet*. (A *magic packet* is a packet that contains 16 contiguous copies of the receiving network adapter's Ethernet address)

***PMARPOffload**
A value that describes whether the device should be enabled to offload the Address Resolution Protocol (ARP) when the system enters a sleep state.

***PMNSOffload**
A value that describes whether the device should be enabled to offload neighbor solicitation (NS) when the system enters a sleep state.

***PMWiFiRekeyOffload**
A value that describes whether the device should be enabled to offload group temporal key (GTK) rekeying for wake-on-wireless-LAN (WOL) when the computer enters a sleep state.

***EEE**
A value that describes whether the device should enable IEEE 802.3az Energy-Efficient Ethernet.

The columns in the table at the end of this topic describe the following attributes for enumeration keywords:

SubkeyName
The name of the keyword that you must specify in the INF file and that appears in the registry.

ParamDesc
The display text that is associated with SubkeyName.

Value
The enumeration integer value that is associated with each option in the list. This value is stored in **NDI\params\**_SubkeyName\Value_.

EnumDesc
The display text that is associated with each value that appears in the menu.

The following table describes the possible INF entries for the power management keywords used by NDIS and NetAdapterCx drivers.

SubkeyName	ParamDesc	Value	EnumDesc
***WakeOnPattern**	Wake on pattern match	0	Disabled
		1 (Default)	Enabled
***WakeOnMagicPacket**	Wake on magic packet	0	Disabled
		1 (Default)	Enabled

SubkeyName	ParamDesc	Value	EnumDesc
***PMARPOffload**	ARP offload	0	Disabled
		1 (Default)	Enabled
***PMNSOffload**	NS offload	0	Disabled
		1 (Default)	Enabled
***PMWiFiRekeyOffload**	WiFi rekeying offload	0	Disabled
		1 (Default)	Enabled
***EEE**	Energy-Efficient Ethernet	0	Disabled
		1 (Default)	Enabled

Power management keywords exclusive to NetAdapterCx

The following power management keywords are for NetAdapterCx client driver use only.

In addition to the standard WDF process for giving user control over the device idle and wake behavior as described in User Control of Device Idle and Wake Behavior, NetAdapterCx also defines a network device specific standardized INF keyword for allowing more control.

***IdleRestriction**
If a network device has both idle power down and wake on packet filter capabilities, this setting allows the user to decide when the device idle power down can happen.

***IdleRestriction** is an enumeration standardized INF keyword and has the following attributes:

The following table describes the possible INF entries for the ***IdleRestriction** keyword.

SubkeyName	ParamDesc	Value	EnumDesc
***IdleRestriction**	idle power down restriction	0 (Default)	No Restriction
		1	Only idle when user is not present

Power management keywords exclusive to NDIS

The following power management keywords are for traditional NDIS miniport driver use only. They must not be used by NetAdapterCx client drivers.

***ModernStandbyWoLMagicPacket**
A value that describes whether the device should be enabled to wake the computer when the device receives a *magic paket* and the system is in the *S0ix* power state. This does not apply when the system is in the *S4* power state.

> ⓘ Note
>
> ***ModernStandbyWoLMagicPacket** is supported in NDIS 6.60 and later, or Windows 10, version 1607 and later.

***DeviceSleepOnDisconnect**
A value that describes whether the device should be enabled to put the device into a low-power state (sleep state) when media is disconnected and return to a full-power state (wake state) when media is connected again.

The following table describes the possible INF entries for the power management keywords used by NDIS miniport drivers.

SubkeyName	ParamDesc	Value	EnumDesc
***ModernStandbyWoLMagicPacket**	Wake on magic packet when system is in the *S0ix* power state	0 (Default)	Disabled
		1	Enabled
***DeviceSleepOnDisconnect**	Device sleep on disconnect	0	Disabled
		1 (Default)	Enabled

Reporting Power Management Capabilities

Article • 12/15/2021

Miniport drivers that support NDIS 6.20 and later versions of NDIS report their hardware power management capabilities during initialization. NDIS reports the current capabilities to overlying NDIS protocol drivers during the bind operation. However, NDIS can hide some capabilities from the protocol driver. For example, NDIS might report different capabilities when a user disables some or all of the power management capabilities.

Note that the current power management capabilities that NDIS reports to a protocol driver are not necessarily the same as the hardware capabilities that the miniport driver reported to NDIS.

If an NDIS 6.1 or earlier miniport driver is bound to an NDIS 6.20 protocol driver, NDIS translates the power management capabilities to a format that is supported by the NDIS 6.20 protocol driver. NDIS also translates power management capabilities that an NDIS 6.20 miniport driver reports into a format that is supported by the NDIS 6.1 and earlier overlying drivers.

The hardware capabilities that a miniport driver reports can be enabled or disabled in INF file settings. For more information about power management INF file settings, see Standardized INF Keywords for Power Management.

During miniport initialization, a miniport driver initializes an **NDIS_PM_CAPABILITIES** structure with the power management capabilities of the underlying hardware. The miniport driver sets the **PowerManagementCapabilitiesEx** member of the **NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES** structure to point to the **NDIS_PM_CAPABILITIES** structure.

The **NDIS_PM_CAPABILITIES** structure includes the following information:

Flags
For NDIS 6.20, this member is reserved for NDIS.

Starting with NDIS 6.30, the following flags are defined:

NDIS_PM_WAKE_PACKET_INDICATION_SUPPORTED
If this flag is set, the network adapter can save the received packet that caused the adapter to generate a wake-up event.

For more information about this power management capability, see NDIS Wake Reason Status Indications.

NDIS_PM_SELECTIVE_SUSPEND_SUPPORTED
If this flag is set, the miniport driver supports NDIS selective suspend for network adapters.

For more information about this power management capability, see NDIS Selective Suspend.

SupportedWoLPacketPatterns
Contains flags that specify the wake-on-LAN (WOL) packet patterns that a network adapter supports. For example, the network adapter can generate a wake-up event when it receives a bitmap, a WOL magic packet, or an EAP over LAN (EAPOL) request identifier message. For a complete list of the patterns that are supported in the current operating system, see the **NDIS_PM_CAPABILITIES** reference page.

NumTotalWoLPatterns
A **ULONG** value that contains the total number of WOL patterns that a network adapter supports. This is the sum of "number of supported WOL protocol patterns" and "number of supported WOL bitmap patterns."

For example, if your driver supports 8 flexible bitmap patterns, IPv4 TCP SYN (via preset filter), and magic packet, then you would report 9 in NumTotalWoLPatterns. (8 bitmaps + 1 IPv4 TCP SYN = 9)

Note The total number of WOL patterns does not include the magic packet wake-up pattern.

For more information about WOL protocol patterns, see **NDIS_PM_WOL_PATTERN**.

MaxWoLPatternSize
Contains the maximum number of bytes that can be compared with a pattern.

MaxWoLPatternOffset
Contains the number of bytes in a packet that can be examined, which starts from the beginning of the MAC header.

MaxWoLPacketSaveBuffer
Contains the number of bytes of a WOL protocol pattern that a miniport driver can save to a buffer and indicate up the driver stack.

SupportedProtocolOffloads
Contains flags that specify the power management protocol offload features that a network adapter supports. Miniport drivers use these flags to report the low power

protocol offload capabilities of a network adapter. For example, the network adapter can support IPv4 ARP offload, IPv6 Neighbor Solicitation (NS), or IEEE 802.11 robust secure network (RSN) 4-way and 2-way handshake. For a complete list of the protocol offloads that are supported in the current operating system, see the NDIS_PM_CAPABILITIES reference page.

NumArpOffloadIPv4Addresses
Contains the number of ARP offload IPv4 addresses.

NumNSOffloadIPv6Addresses
Contains the number of network solicitation (NS) offload IPv6 requests that the network adapter supports.

MinMagicPacketWakeUp
Specifies the lowest device power state from which a network adapter can signal a wake-up event on receipt of a *magic packet*. (A *magic packet* is a packet that contains 16 contiguous copies of the receiving network adapter's Ethernet address.)

MinPatternWakeUp
Specifies the lowest device power state from which a network adapter can signal a wake-up event on receipt of a network frame that contains a pattern that is specified by the protocol driver.

MinLinkChangeWakeUp
Specifies the lowest device power state from which a network adapter can signal a wake-up event when there is a link change (media connect or disconnect).

SupportedWakeUpEvents
Specifies the media-independent wake-up events that a network adapter supports. These events are not specific to media type. For example, these wake-up events include link change events.

MediaSpecificWakeUpEvents
Specifies the media-specific wake-up events that a network adapter supports. For example, these events include following:

- The 802.11 network adapter disassociates with the access point (AP).

- The mobile broadband (MB) network adapter detects a change in its registration state to the MB Service.

If a miniport driver supports offloading protocols to a network adapter in a low power state, it must support the same low power state for the protocol offload that it supports for a pattern match WOL event; that is, the value that is specified in the **MinPatternWakeUp** or **MinMagicPacketWakeUp** member.

NDIS initializes an **NDIS_PM_CAPABILITIES** structure with the currently available power management capabilities of the underlying network adapter and passes it the protocol overlying protocol drivers during the bind operation. NDIS sets the **PowerManagementCapabilitiesEx** member of the **NDIS_BIND_PARAMETERS** structure to point to the NDIS_PM_CAPABILITIES structure.

Overlying drivers can use the OID_PM_HARDWARE_CAPABILITIES OID query to obtain the hardware power management capabilities of the network adapter. NDIS handles this OID request on behalf of the miniport driver. NDIS miniport drivers are not required to support the OID_PM_HARDWARE_CAPABILITIES OID request.

Overlying drivers can use the OID_PM_CURRENT_CAPABILITIES OID to query the currently available power management capabilities of a network adapter. NDIS handles this OID request on behalf of the miniport driver. NDIS miniport drivers are not required to support the OID_PM_CURRENT_CAPABILITIES OID request.

Obtaining and Updating Power Management Parameters

Article • 12/15/2021

Protocol drivers can use the OID_PM_PARAMETERS OID to query the hardware capabilities of a network adapter that is currently enabled. After a successful return from the query, the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to an **NDIS_PM_PARAMETERS** structure.

Protocol drivers can also use OID_PM_PARAMETERS as a set request to enable or disable the current hardware capabilities of a network adapter. The protocol driver provides a pointer to an NDIS_PM_PARAMETERS structure in the **InformationBuffer** member of the NDIS_OID_REQUEST structure.

Note Protocol drives cannot disable capabilities that were enabled by other protocol drivers. If none of the protocol drivers enable a capability, that capability is unused.

Note NDIS enables magic packet and low power on disconnect capabilities based on the user settings, and these capabilities cannot be disabled by protocol drivers.

NDIS_PM_PARAMETERS includes the following information:

EnabledWoLPacketPatterns
Contains flags that correspond to capabilities that the miniport driver reported in the **SupportedWoLPacketPatterns** member of the **NDIS_PM_CAPABILITIES** structure. For example, the network adapter is enabled to generate a wake-up event when it receives a bitmap, a WOL magic packet, or an EAP over LAN (EAPOL) request identifier message. For a complete list of the patterns that are possible in the current operating system, see the **NDIS_PM_PARAMETERS** reference page.

EnabledProtocolOffloads
Contains flags that correspond to capabilities that the miniport driver reported in the **SupportedProtocolOffloads** member of the **NDIS_PM_CAPABILITIES** structure. NDIS uses these flags to enable or disable the low power protocol offload capabilities on a network adapter. For example, the network adapter offload for IPv4 ARP, IPv6 Neighbor Solicitation (NS), or IEEE 802.11 robust secure network (RSN) 4-way and 2-way handshake is enabled. For a complete list of the protocol offloads that are supported in the current operating system, see the **NDIS_PM_PARAMETERS** reference page.

WakeUpFlags
Contains flags that NDIS uses to enable or disable wake-up capabilities on a network

adapter.

For NDIS 6.20, the NDIS_PM_WAKE_ON_LINK_CHANGE_ENABLED flag enables the capability to wake on a link change (media connect). For more information about this flag, see Low Power on Media Disconnect.

Starting with NDIS 6.30, the NDIS_PM_SELECTIVE_SUSPEND_ENABLED flag enables the support for NDIS selective suspend on underlying USB network adapters. For more information, see NDIS Selective Suspend.

When a driver sets the OID_PM_PARAMETERS OID, NDIS completes the request without forwarding it to the miniport driver. NDIS stores the requested settings and combines them with the settings from other such requests.

Before NDIS transitions the network adapter to the low power state, NDIS sends a set request to the miniport driver that contains the combined settings from all of the requests that NDIS stored. For more information about setting a low power state, see Low Power for Wake on LAN.

The capabilities that are currently enabled can be a subset of the capabilities that the hardware supports. For more information about the capabilities that the hardware supports, see Reporting Power Management Capabilities.

Adding and Deleting Wake on LAN Patterns

Article • 12/15/2021

To add a wake-on-LAN (WOL) pattern, NDIS protocol drivers issue an OID set request of OID_PM_ADD_WOL_PATTERN. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to an **NDIS_PM_WOL_PATTERN** structure. Protocol drivers should specify a WOL packet if that WOL packet is supported by a network adapter. When the network adapter does not support the WOL packet, the protocol driver should use the WOL bitmap wake method.

NDIS_PM_WOL_PATTERN includes the following information:

Priority
Contains the priority of the WOL pattern. If an overlying driver adds a higher priority WOL pattern when there are no resources available for more WOL patterns, NDIS might remove a lower priority WOL pattern to free resources. Miniport drivers should ignore this member. A protocol driver can specify any priority that is within the pre-defined range from NDIS_PM_WOL_PRIORITY_LOWEST to NDIS_PM_WOL_PRIORITY_HIGHEST.

WoLPacketType
Contains an **NDIS_PM_WOL_PACKET** enumeration value that specifies the type of the WOL packet.

FriendlyName
Contains an **NDIS_PM_COUNTED_STRING** structure that contains the user-readable description of the WOL packet.

PatternId
Contains an NDIS-provided value that identifies the WOL pattern. Before NDIS sends the OID_PM_ADD_WOL_PATTERN OID request down to the underlying NDIS drivers or completes the request to the overlying driver, NDIS sets **PatternId** to a value that is unique among the WOL patterns on a network adapter.

NextWoLPatternOffset
Contains the offset (from the beginning of the OID request **InformationBuffer**) of one **NDIS_PM_WOL_PATTERN** structure to the next NDIS_PM_WOL_PATTERN structure in a list for the OID_PM_WOL_PATTERN_LIST OID. For more information about OID_PM_WOL_PATTERN_LIST, see Obtaining the Current Settings of WOL Patterns.

WoLPattern
Contains one of the **IPv4TcpSynParameters**, **IPv6TcpSynParameters**, **EapolRequestIdMessageParameters**, or **WoLBitMapPattern** structures in a union.

IPv4TcpSynParameters
Contains IPv4 TCP synchronize (SYN) information.

IPv6TcpSynParameters
Contains IPv6 TCP SYN information.

EapolRequestIdMessageParameters
Contains 802.1X EAP over LAN (EAPOL) request identity message parameters.

WoLBitMapPattern
Contains a WOL bitmap pattern specification.

NDIS assigns an identifier that is unique for network adapter to every WOL pattern. The pattern identifier is a unique value for each of the patterns that are set on a network adapter. However, the pattern identifier is not globally unique across all network adapters. NDIS passes the identifier to the underlying network adapter when NDIS sends the OID_PM_ADD_WOL_PATTERN OID request to the miniport driver. If adding the WOL pattern is successful, NDIS returns the identifier to the overlying driver that added the WOL pattern. The overlying driver uses the identifier to remove a previously added WOL pattern. The pattern identifier is also used in status indications to the overlying drivers when a WOL pattern is removed from a network adapter.

Protocol drivers must issue the OID set request of OID_PM_REMOVE_WOL_PATTERN to remove all of the patterns that they added to a network adapter before they close a binding to that network adapter. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to a pattern identifier.

User-mode applications use the GUID_PM_REMOVE_WOL_PATTERN WMI GUID to remove a previously added WOL pattern from a network adapter. NDIS translates this WMI request to the OID set request of OID_PM_REMOVE_WOL_PATTERN for the network adapter. NDIS deletes all of the WOL patterns that an application added from the network adapter before it halts the network adapter.

NDIS allows multiple NDIS protocol drivers to add WOL patterns to the same network adapter. To ensure that the right set of WOL patterns have been set when the number of requested WOL patterns is higher than what a network adapter can support, protocol drivers assign a priority to each requested WOL pattern in the **Priority** member of the NDIS_PM_WOL_PATTERN structure. When NDIS cannot add a new high priority WOL pattern because the network adapter is out of resources, NDIS deletes one of the lower priority patterns (if any) and attempts to add the high priority pattern again.

Note A miniport driver should fail a pattern add request and return the STATUS_NDIS_PM_WOL_PATTERN_LIST_FULL status code to allow NDIS to re-prioritize the patterns.

If NDIS deletes one of the lower priority patterns, it notifies the overlying driver that set the deleted pattern with an NDIS_STATUS_PM_WOL_PATTERN_REJECTED status indication. The **StatusBuffer** member of the NDIS_STATUS_INDICATION structure contains a ULONG for the WOL pattern identifier of the rejected WOL pattern. NDIS provided the WOL pattern identifier in the **PatternId** member of the NDIS_PM_WOL_PATTERN structure.

For wireless network adapter's that might use an infrastructure element to offload the patterns as it roams across the infrastructure, a new infrastructure element might not support the same capabilities and the miniport driver can send an NDIS_STATUS_PM_WOL_PATTERN_REJECTED status indication with an appropriate status code.

Obtaining the Current Settings of WOL Patterns

Article • 12/15/2021

Overlying drivers can use the OID_PM_WOL_PATTERN_LIST OID query request to enumerate the wake-on-LAN (WOL) patterns that are set on an underlying network adapter. After a successful return from the query, the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to a list of **NDIS_PM_WOL_PATTERN** structures that describe the currently added WOL patterns. For information about the contents of the **NDIS_PM_WOL_PATTERN** structure, see Adding and Deleting Wake on LAN Patterns.

NDIS handles OID_PM_WOL_PATTERN_LIST OID requests on behalf of the miniport driver. Therefore, NDIS miniport drivers are not required to support OID_PM_WOL_PATTERN_LIST OID request.

Adding and Deleting Low Power Protocol Offloads

Article • 12/15/2021

To add a low power protocol offload, NDIS protocol drivers issue an OID set request of OID_PM_ADD_PROTOCOL_OFFLOAD. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to an **NDIS_PM_PROTOCOL_OFFLOAD** structure.

Note If an incoming packet matches both an offloaded protocol and a pattern (for example, because of a configuration error), the network adapter should respond to the packet and wake up the computer.

The **NDIS_PM_PROTOCOL_OFFLOAD** structure includes the following information:

Member	Description
Priority	Contains the priority of the protocol offload. If an overlying driver adds a higher priority protocol offload when there are no resources available for more protocol offloads, NDIS might remove a lower priority protocol offload to free resources. Miniport drivers should ignore this member. Protocol drivers can provide any value within the predefined range from NDIS_PM_PROTOCOL_OFFLOAD_PRIORITY_LOWEST to NDIS_PM_PROTOCOL_OFFLOAD_PRIORITY_HIGHEST.
ProtocolOffloadType	Contains an **NDIS_PM_PROTOCOL_OFFLOAD_TYPE** value that specifies the type of protocol offload.
FriendlyName	Contains an **NDIS_PM_COUNTED_STRING** structure that contains the user-readable description of the low power protocol offload.
ProtocolOffloadId	Contains an NDIS-provided value that identifies the offloaded protocol. Before NDIS sends the OID request of OID_PM_ADD_PROTOCOL_OFFLOAD down to the underlying NDIS drivers or completes the request to the overlying driver, NDIS sets **ProtocolOffloadId** to a value that is unique among the protocol offloads on a network adapter.

<table>
<tr><th>Member</th><th>Description</th></tr>
<tr><td><b>NextProtocolOffloadOffset</b></td><td>Contains the offset, the beginning of the OID request <i>InformationBuffer</i>, to the next <b>NDIS_PM_PROTOCOL_OFFLOAD</b> structure in a list for the OID_PM_PROTOCOL_OFFLOAD_LIST OID. For more information about OID_PM_PROTOCOL_OFFLOAD_LIST, see Obtaining the Current Parameter Settings of Low Power Protocol Offloads.</td></tr>
<tr><td><b>ProtocolOffloadParameters</b></td><td>Contains one of the <b>IPv4ARPParameters</b>, <b>IPv6NSParameters</b>, or <b>Dot11RSNRekeyParameters</b> structures in a union.
<table>
<tr><th>Term</th><th>Description</th></tr>
<tr><td>IPv4ARPParameters</td><td>Contains IPv4 ARP parameters.</td></tr>
<tr><td>IPv6NSParameters</td><td>Contains IPv6 Neighbor Solicitation (NS) parameters.</td></tr>
<tr><td>Dot11RSNRekeyParameters</td><td>Contains IEEE 802.11 robust secure network (RSN) handshake parameters</td></tr>
</table>
</td></tr>
</table>

NDIS assigns an identifier that is unique for a network adapter to every offloaded protocol. The protocol offload identifier is a unique value for each of the protocols that are offloaded on a network adapter. However, the protocol offload identifier is not globally unique across all network adapters. NDIS passes this identifier to the underlying miniport driver when NDIS sends the OID_PM_ADD_PROTOCOL_OFFLOAD OID request to the miniport driver. If offloading the protocol is successful, NDIS returns the identifier to the overlying driver that offloaded the protocol. The overlying driver uses the identifier to remove a previously offloaded protocol. The protocol offload identifier is also used in status indications to the upper layer drivers when an offloaded protocol is removed from a network adapter.

Protocol drivers must remove all of the offloaded protocols from a network adapter before closing the binding to that network adapter. To remove a low power protocol offload, a protocol driver sends an OID set request of

OID_PM_REMOVE_PROTOCOL_OFFLOAD. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to a protocol offload identifier.

NDIS allows multiple NDIS protocol drivers to add protocol offloads to the same network adapter. To ensure that the right set of protocols have been offloaded to a network adapter when the number of requested offloaded protocols is higher than what a network adapter can support, protocol drivers assign a priority to each offloaded protocol. When NDIS cannot offload a new high priority protocol because the network adapter is out of resources, NDIS deletes one of the lower priority offloaded protocols (if any) and attempts to offload the high priority protocol again.

Note A miniport driver should fail a low power protocol offload add request and return the STATUS_NDIS_PM_PROTOCOL_OFFLOAD_LIST_FULL status code to allow NDIS to re-prioritize the protocol offloads.

If as a result of offloading a high priority protocol, one of the lower priority offloaded protocols is deleted, NDIS sends an **NDIS_STATUS_PM_OFFLOAD_REJECTED** status indication to notify the overlying driver that set the deleted protocol offload. The **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure contains a protocol offload identifier of the rejected protocol offload. NDIS provided the protocol offload identifier in the **ProtocolOffloadId** member of the **NDIS_PM_PROTOCOL_OFFLOAD** structure.

Implementing IPv6 NS Offload

Article • 12/15/2021

An NDIS protocol driver sends an IPv6 neighbor solicitation (NS) offload request as an OID_PM_ADD_PROTOCOL_OFFLOAD OID request. To support these NS offload requests, miniports should do the following.

Indicating How Many Offload Requests the Miniport Adapter Supports

A miniport driver sets the **NumNSOffloadIPv6Addresses** member of the **NDIS_PM_CAPABILITIES** structure to indicate how many NS offload requests the miniport adapter supports.

Note Despite its name, the **NumNSOffloadIPv6Addresses** member contains the number of supported requests, not the number of addresses.

Note Some Windows Hardware Certification requirements, such as **Device.Network.LAN.PM.PowMgmtNDIS** and **Device.Network.WLAN.WoWLAN.ImplementWakeOnWLAN**, specify that the miniport adapter must support at least 2 NS offload requests. (In other words, to meet these requirements, the value of **NumNSOffloadIPv6Addresses** must be at least 2.) For more information, see the Windows 8 Hardware Certification Requirements.

Each NS offload request can contain 1 or 2 target addresses.

In addition, there are 2 types of NS messages: unicast and multicast. Miniport drivers must be prepared to match both types of NS message for each target address.

Example

If a miniport driver sets the **NDIS_PM_CAPABILITIES** member of the **NumNSOffloadIPv6Addresses** structure to 3, then NDIS may send up to 3 OID_PM_ADD_PROTOCOL_OFFLOAD requests of type **NdisPMProtocolOffloadIdIPv6NS**. Each OID_PM_ADD_PROTOCOL_OFFLOAD request may have exactly 1 or 2 addresses in the **TargetIPv6Addresses** member of the **NDIS_PM_PROTOCOL_OFFLOAD** structure. Therefore, the miniport must support a 3 x 2 = 6 target addresses.

Because the miniport must match both unicast and multicast NS messages for each target address, the miniport should be able to match a total of 6 x 2 = 12 NS message patterns.

Matching the NS Message

The NS message format is specified in RFC 4861 section 4.3, "Neighbor Solicitation Message Format". The miniport should match the fields in the following table.

Field	Match value	Notes
Ethernet.EtherType	0x86dd (IPv6)	Adjust as needed for non-Ethernet media types.
IPv6.Version	6	
IPv6.NextHeader	58 (ICMPv6)	
IPv6.HopLimit	255	
IPv6.Destination	**OID.TargetIPv6Addresses[x]** or **OID.SolicitedNodeIPv6Address**	The miniport must match both options for this field: **OID.TargetIPv6Addresses[x]** and **OID.SolicitedNodeIPv6Address**. If this field is **OID.TargetIPv6Addresses[x]**, the NS message is a unicast message. If this field is **OID.SolicitedNodeIPv6Address**, the NS message is a multicast message. **OID.TargetIPv6Addresses** is an array that can contain 1 or 2 addresses. If it contains 2 addresses, the miniport must match both of them. If the second address is "0::0", it must be ignored, and a second match pattern must not be created.
IPv6.ICMPv6.Type	135 (NS)	
IPv6.ICMPv6.Code	0	
IPv6.ICMPv6.TargetAddress	**OID.TargetIPv6Addresses[x]**	**OID.TargetIPv6Addresses[x]** is an array that can contain 1 or 2 addresses.

Field	Match value	Notes
IPv6.Source	OID.RemoteIPv6Address	If **OID.RemoteIPv6Address** is "0::0", this field should be ignored.

Sending the NA Message

Upon receiving the NS message, device firmware should perform the validation steps called out in RFC 4861 section 7.1, "Message Validation", including validating checksums. If the incoming NS message passes all validation, then an NA message must be generated and sent as a reply. Its format is specified in RFC 4861 section 4.4, "Neighbor Advertisement Message Format". The miniport should set the fields in the following table.

Field	Value	Notes
Ethernet.Destination	**Ethernet.Source**	Copy this value from the NS frame. Adjust as needed for non-Ethernet media types.
Ethernet.Source	The miniport's current MAC address	
IPv6.HopLimit	255	
IPv6.Source	**IPv6.ICMPv6.TargetAddress**	Copy this value from the NS frame.
IPv6.Destination	**IPv6.Source**	Copy this value from the NS frame, unless the value of **IPv6.Source** was "0::0". If the value of **IPv6.Source** was "0::0" set this field to "FF02::1".
IPv6.ICMPv6.Type	136 (NA)	
IPv6.ICMPv6.Code	0	
IPv6.ICMPv6.RouterFlag	0	

Field	Value	Notes
IPv6.ICMPv6.SolicitedFlag	0	If the value of **IPv6.Source** in the NS frame was "0::0", set this field to 1.
IPv6.ICMPv6.OverrideFlag	1	
IPv6.ICMPv6.TargetAddress	**IPv6.ICMPv6.TargetAddress**	Copy this value from the NS frame.
IPv6.ICMPv6.TLLAOption.Type	2 (Target Link-layer Address)	
IPv6.ICMPv6.TLLAOption.Length	1	
IPv6.ICMPv6.TLLAOption.LinkLayerAddress	**OID.MacAddress**	

Obtaining the Current Parameter Settings of Low Power Protocol Offloads

Article • 12/15/2021

A protocol driver can use OID_PM_PROTOCOL_OFFLOAD_LIST OID query to get a list of all the protocols that have been offloaded by that protocol on a network adapter. After a successful return from the query, the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to a list of **NDIS_PM_PROTOCOL_OFFLOAD** structures that describe the currently active protocol offloads. For information about the contents of the **NDIS_PM_PROTOCOL_OFFLOAD** structure, see Adding and Deleting Low Power Protocol Offloads.

NDIS handles OID_PM_PROTOCOL_OFFLOAD_LIST OID and GUID_PM_PROTOCOL_OFFLOAD_LIST WMI requests on behalf of the miniport driver. Therefore, NDIS miniport drivers are not required to support OID_PM_PROTOCOL_OFFLOAD_LIST OID request.

Overlying drivers can use the OID_PM_GET_PROTOCOL_OFFLOAD method OID to get parameter settings for a low power protocol offload from a miniport driver. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure initially contains a pointer to a protocol offload identifier. After a successful return from the method request, the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains a pointer to an **NDIS_PM_PROTOCOL_OFFLOAD** structure.

Low Power for Wake on LAN

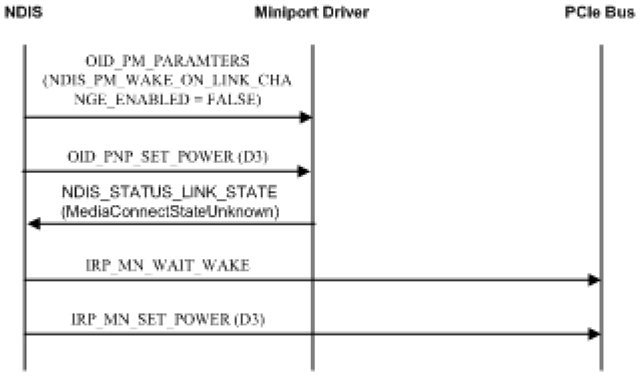
Article • 12/15/2021

The wake on LAN (WOL) feature wakes the computer from a low power state when a network adapter detects a WOL event.

A miniport driver reports network adapter WOL capabilities during initialization. For more information about reporting WOL capabilities, see Reporting Power Management Capabilities.

Note that the lower power on the media disconnect (D3 on disconnect) feature is canceled when the computer enters a sleep state in order to prevent waking the computer when the link state is externally cycled; that is, when a switch is turned off and on. For more information about D3 on disconnect, see Low Power on Media Disconnect.

The following figure illustrates the sequence of events that occurs to set a network adapter to a low power state.



NDIS
Miniport Driver
PCIe Bus
OID_PM_PARAMTERS (NDIS_PM_WAKE_ON_LINK_CHANGE_ENABLED = FALSE)
OID_PNP_SET_POWER (D3)
NDIS_STATUS_LINK_STATE (MediaConnectStateUnknown)
IRP_MN_WAIT_WAKE
IRP_MN_SET_POWER (D3)

When NDIS puts a network adapter in a low power state, the following sequence occurs:

1. NDIS uses OID_PM_PARAMETERS to enable wake on LAN and to disable wake on media connect. NDIS_PM_WAKE_ON_LINK_CHANGE_ENABLED is cleared in the **WakeUpFlags** member.

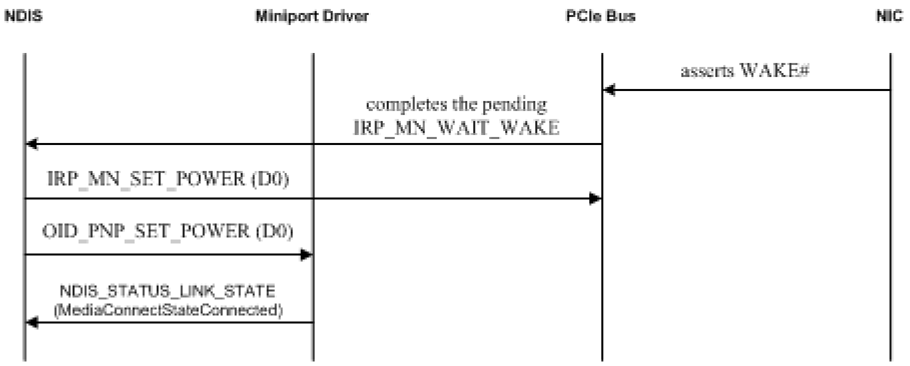
2. NDIS uses OID_PNP_SET_POWER to notify the miniport driver of the new power state (D3).

3. The miniport driver may indicate an unknown media connect state using the **NDIS_STATUS_LINK_STATE** status indication. The **MediaConnectStateUnknown** value is set in the **MediaConnectState** member of the **NDIS_LINK_STATE** structure. For more information, see the **NDIS_STATUS_LINK_STATE** documentation.

4. NDIS sends the PCI Express (PCIe) bus an **IRP_MN_WAIT_WAKE** IRP to wait for a WOL event.

5. NDIS sends the PCIe bus an **IRP_MN_SET_POWER** IRP to set the bus to the D3 state.

The following figure illustrates the sequence of events that occurs to restore full power to a network adapter after a WOL event.



NDIS
Miniport Driver
PCIe Bus
NIC
asserts WAKE#
completes the pending IRP_MN_WAIT_WAKE
IRP_MN_SET_POWER (D0)
OID_PNP_SET_POWER (D0)
NDIS_STATUS_LINK_STATE (MediaConnectStateConnected)

When the network adapter is waking the computer the following sequence occurs:

1. The network adapter wakes the system by asserting WAKE# on the PCIe bus or PME# on the PCI bus.
2. The bus completes the pending **IRP_MN_WAIT_WAKE** IRP. The IRP is pending completion from the last step in the power down sequence.
3. NDIS sets the bus to full power (D0) with the **IRP_MN_SET_POWER** IRP.
4. NDIS notifies the miniport driver that the network adapter is at full power (D0) with the OID set request of OID_PNP_SET_POWER.
5. The network adapter notifies NDIS of a media connect event with the **NDIS_STATUS_LINK_STATE** status indication. The **MediaConnectStateConnected** value is set in the **MediaConnectState** member of the **NDIS_LINK_STATE** structure.

Starting with NDIS 6.30, if the miniport driver supports **NDIS_STATUS_PM_WAKE_REASON** status indications, it must issue this status notification if the network adapter wakes the system. The driver issues this status notification while it is handling the OID set request of OID_PNP_SET_POWER for the transition to a full-power (D0) state.

For more information, see NDIS Wake Reason Status Indications.

Low Power on Media Disconnect

Article • 12/15/2021

The low power on media disconnect (D3 on disconnect) feature saves power by placing a network adapter in a low-power state (D3) when the media is disconnected. When the media is reconnected, the network adapter is brought back up to the full-power state (D0).

NDIS uses the D3 on disconnect feature under these conditions:

- The network adapter hardware must be able to generate a wake event on media connect.
- The miniport driver must report the wake event capability of the network adapter in the **MinLinkChangeWakeUp** member of the NDIS_PM_CAPABILITIES structure.
- The value of **MinLinkChangeWakeUp** must correspond to the value of the **DeviceWake** member of the DEVICE_CAPABILITIES structure that is reported by the IRP_MN_QUERY_CAPABILITIES IRP.
- The miniport driver must register as an NDIS 6.20 driver or later version.
- The network adapter must be an Ethernet PCI adapter.
- The wake event capability must be enabled by the ***DeviceSleepOnDisconnect** standard INF file keyword.
- The computer chipset must be able to correctly propagate the wake event while the computer is fully powered. NDIS validates this by querying the DEVPKEY_PciDevice_S0WakeupSupported PCI property.

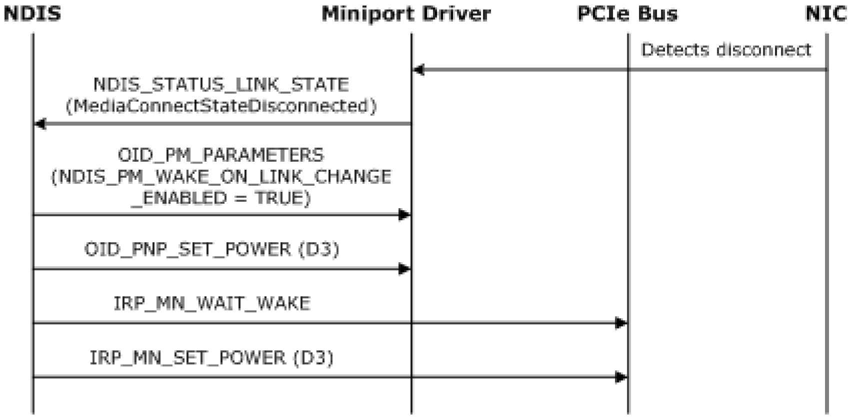
Note that D3 on disconnect is only available while the computer is fully powered in the working state (S0). This feature is canceled when the computer enters a sleep state to prevent waking the computer when the link state is externally cycled; that is, when a switch is turned off and on. For more information about the setting the low-power state when a computer enters a sleep state, see Low Power for Wake on LAN.

A miniport driver reports D3 on disconnect capabilities during initialization. For more information about reporting D3 on disconnect capabilities, see Reporting Power Management Capabilities.

The ***DeviceSleepOnDisconnect** standard INF file keyword specifies whether the device has enabled or disabled support for D3 on disconnect. For more information about this INF keyword, see Standardized INF Keywords for Power Management.

During initialization, a miniport drivers that supports D3 on disconnect must report the lowest power level where it can support the ability to notify the operating system of media connect event. The miniport driver reports the power level in the **MinLinkChangeWakeUp** member of the NDIS_PM_CAPABILITIES structure. For example, the miniport driver can report **NdisDeviceStateD3**.

The following figure illustrates the sequence of events to set a network adapter to a low-power state after a media disconnect event.



NDIS
Miniport Driver
PCIe Bus
NIC
Detects disconnect
NDIS_STATUS_LINK_STATE (MediaConnectStateDisconnected)
OID_PM_PARAMETERS (NDIS_PM_WAKE_ON_LINK_CHANGE _ENABLED = TRUE)
OID_PNP_SET_POWER (D3)
IRP_MN_WAIT_WAKE
IRP_MN_SET_POWER (D3)

When the adapter detects a media disconnect, the following sequence occurs:

1. The network adapter hardware detects a media disconnect event and passes the information to the miniport driver.

2. The miniport driver notifies NDIS of a media disconnect event using the NDIS_STATUS_LINK_STATE status indication. The **StatusBuffer** member of the NDIS_STATUS_INDICATION structure contains an NDIS_LINK_STATE structure. The MediaConnectStateDisconnected value is set in the **MediaConnectState** member of the **NDIS_LINK_STATE** structure.

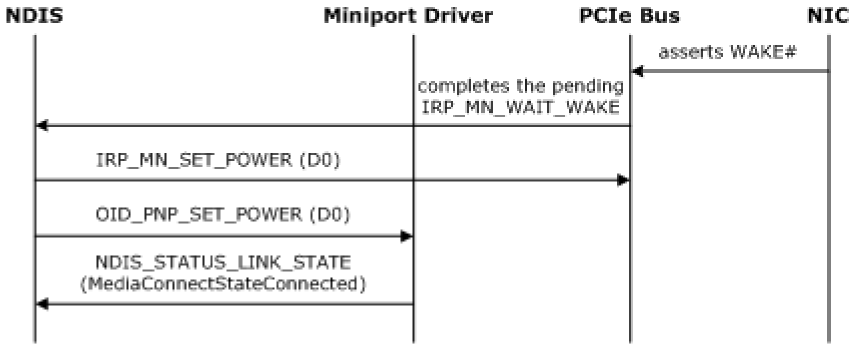
3. NDIS uses OID_PM_PARAMETERS to disable Wake-on-LAN and to enable wake on media connect (NDIS_PM_WAKE_ON_LINK_CHANGE_ENABLED is set in the **WakeUpFlags** member).

4. NDIS uses the OID_PNP_SET_POWER OID to notify the miniport driver of the new power state (D3).

5. NDIS sends the PCIe bus an IRP_MN_WAIT_WAKE IRP to wait for a reconnect event.

6. NDIS sets the PCIe bus to the D3 state with the IRP_MN_SET_POWER IRP.

The following figure illustrates the sequence of events to restore full power to a network adapter after a media connect event.



NDIS
Miniport Driver
PCIe Bus
NIC
asserts WAKE#
completes the pending IRP_MN_WAIT_WAKE
IRP_MN_SET_POWER (D0)
OID_PNP_SET_POWER (D0)
NDIS_STATUS_LINK_STATE (MediaConnectStateConnected)

When the media is reconnected the following sequence occurs:

1. The network adapter wakes the system by asserting WAKE# on the PCIe bus or PME# on the PCI bus.

2. The bus completes the pending **IRP_MN_WAIT_WAKE** IRP. The IRP is pending completion from the last step in the disconnect sequence.

3. NDIS sets the bus to full power (D0) with the **IRP_MN_SET_POWER** IRP.

4. NDIS notifies the miniport driver that the network adapter is in the full power (D0) state with the OID set request of OID_PNP_SET_POWER.

5. The network adapter notifies NDIS of a media connect event with the **NDIS_STATUS_LINK_STATE** status indication. The **MediaConnectStateConnected** value is set in the **MediaConnectState** member of the **NDIS_LINK_STATE** structure.

Starting with NDIS 6.30, if the miniport driver supports **NDIS_STATUS_PM_WAKE_REASON** status indications, it must issue this status notification if the network adapter wakes the system. The driver issues this status notification while it is handling the OID set request of OID_PNP_SET_POWER for the transition to a full-power (D0) state.

For more information, see NDIS Wake Reason Status Indications.

Note If the miniport driver issues an **NDIS_STATUS_PM_WAKE_REASON** status indication, it must do this before it issues the **NDIS_STATUS_LINK_STATE** status indication.

NDIS_STATUS_PM_CAPABILITIES_CHANGE

Article • 03/14/2023

The NDIS_STATUS_PM_CAPABILITIES_CHANGE status indicates a change in the power management capabilities of a network adapter to overlying drivers.

Remarks

NDIS generates an NDIS_STATUS_PM_CAPABILITIES_CHANGE status indication when an update to the previously reported power management capabilities is required.

The **StatusBuffer** member of the NDIS_STATUS_INDICATION structure contains a pointer to an NDIS_PM_CAPABILITIES structure with the updated power management capabilities.

Requirements

Version	Supported in NDIS 6.20 and later.
Header	Ndis.h (include Ndis.h)

See also

NDIS_PM_CAPABILITIES

NDIS_STATUS_INDICATION

NDIS_STATUS_PM_HARDWARE_CAPABILITIES

Article • 03/14/2023

The **NDIS_STATUS_PM_HARDWARE_CAPABILITIES** status indicates to overlying drivers that a change in the power management (PM) hardware capabilities of a network adapter has occurred.

Remarks

The miniport driver generates an **NDIS_STATUS_PM_HARDWARE_CAPABILITIES** status indication when an update to the previously reported power management capabilities is required.

The miniport driver for an 802.11 network adapter can generate this status indication.

A MUX intermediate driver that provides load balancing failover (LBFO) support can also generate this status indication. The MUX driver aggregates the PM capabilities of the underlying network adapters that are part of the LBFO team. If the PM capabilities change because an adapter has been either added or removed from the team, the MUX driver must generate this status indication. For more information on LBFO MUX intermediate drivers, see NDIS MUX Intermediate Drivers.

The **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure contains a pointer to an **NDIS_PM_CAPABILITIES** structure with the updated power management capabilities.

Requirements

Version	Supported in NDIS 6.30 and later.
Header	Ndis.h (include Ndis.h)

NDIS_STATUS_INDICATION

NDIS_STATUS_PM_OFFLOAD_REJECTED

Article • 03/14/2023

The NDIS_STATUS_PM_OFFLOAD_REJECTED status indicates to overlying drivers that a power management protocol offload was rejected.

Remarks

NDIS or miniport drivers can generate the NDIS_STATUS_PM_OFFLOAD_REJECTED status indication when either of them removes an offloaded protocol. The **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure contains a ULONG for the protocol offload identifier of the rejected protocol offload. NDIS provided the protocol offload identifier in the **ProtocolOffloadId** member of the **NDIS_PM_PROTOCOL_OFFLOAD** structure.

NDIS generates an NDIS_STATUS_PM_OFFLOAD_REJECTED status indication when it has to remove a previously offloaded protocol from a network adapter. For example, NDIS might remove the protocol offload to free resources for a higher priority protocol offload. NDIS sends the status indication to the binding that offloaded the rejected protocol offload, but does not send it to other bindings.

Miniport drivers report this status indication to reject a previously accepted protocol offload. For example, for a WiFi WOL case, the miniport driver must make an NDIS_STATUS_PM_OFFLOAD_REJECTED status indication when PTK/GTK rotation is not required to support WOL (due to vendor specific infrastructure support).

For wireless network adapters that use infrastructure elements to offload protocols and roam across the infrastructure, it is possible that a new infrastructure element might not support the same capabilities as the previous one. In this case, the miniport driver can issue a status indication to NDIS, and NDIS will issue NDIS_STATUS_PM_OFFLOAD_REJECTED with a specific error code.

A WiFi driver might cache protocol offload requests locally. When the driver processes an OID for adding or deleting a protocol offload, the driver can choose to only update its local cache. The driver can defer the update of the infrastructure until it receives the OID_PM_PARAMETERS OID.

The infrastructure might not have enough resources to accommodate all of the protocol offloads. In this case, the infrastructure can accept a partial list of the protocol offloads. When the miniport driver completes the OID_PM_PARAMETERS set request, the miniport driver must make NDIS_STATUS_PM_OFFLOAD_REJECTED status indications for each of the protocol offloads that the AP rejects.

For example, a network adapter can use the AP's proxy ARP to support ARP offload.

Requirements

Version	Supported in NDIS 6.20 and later.
Header	Ndis.h (include Ndis.h)

NDIS_STATUS_INDICATION

OID_PM_PARAMETERS

NDIS_STATUS_PM_WOL_PATTERN_REJECTED

Article • 03/14/2023

The NDIS_STATUS_PM_WOL_PATTERN_REJECTED status indicates to overlying drivers that a power management wake on LAN (WOL) pattern was rejected.

Remarks

NDIS or miniport drivers can generate the NDIS_STATUS_PM_WOL_PATTERN_REJECTED status indication when either of them removes a WOL pattern. The **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure contains a ULONG for the WOL pattern identifier of the rejected WOL pattern. NDIS provided the WOL pattern identifier in the **PatternId** member of the **NDIS_PM_WOL_PATTERN** structure.

NDIS generates an NDIS_STATUS_PM_WOL_PATTERN_REJECTED status indication when it must remove a previously added WOL pattern from a network adapter. For example, NDIS might remove the WOL pattern to free resources for a higher priority WOL pattern. The notification event will only be sent to the binding that added the removed pattern.

For wireless network adapters that use infrastructure elements to offload the patterns and roam across the infrastructure, it is possible that a new infrastructure element might not support the same capabilities as the previous one. In this case, the miniport driver can issue a status indication to NDIS, and NDIS will issue NDIS_STATUS_PM_WOL_PATTERN_REJECTED with a specific error code.

A WiFi driver might cache wake-up patterns locally. When the driver processes an OID for adding or deleting a wake-up pattern, the driver can choose to only update its local cache. The driver can defer the update of the infrastructure until it receives the OID_PM_PARAMETERS OID.

The infrastructure might not have enough resources to accommodate all of the wake-up patterns. In this case, the infrastructure can accept a partial list of the wake-up patterns. When the miniport driver completes the OID_PM_PARAMETERS set request, the driver must make NDIS_STATUS_PM_WOL_PATTERN_REJECTED status indications for each of the WOL patterns that the access point (AP) rejects.

Requirements

Version	Supported in NDIS 6.20 and later.
Header	Ndis.h (include Ndis.h)

OID_PM_PARAMETERS

Required and Optional OIDs for Power Management

Article • 12/15/2021

For a miniport driver, supporting power management involves supporting power management object identifiers (OIDs). For a detailed description of how miniport drivers process queries and sets to OIDs, see Obtaining and SettingMiniport Driver Information and NDIS Support for WMI.

There are two levels of power management support for miniport drivers:

1. A miniport driver can support a network adapter making a transition between power states. This support is the minimum level of power management support. For a description of device power states for network adapters, see Device Power States for Network Adapters.

2. A miniport driver can also support one or more network wake-up events.

Miniport drivers report power management capabilities during initialization. For more information about power management capabilities that are reported during initialization, see **NDIS_MINIPORT_ADAPTER_ATTRIBUTES** and the related attributes structures.

A miniport driver must support the following OIDs directly or in attributes for a network adapter to make a transition between power states:

- OID_PNP_CAPABILITIES

  Intermediate drivers must respond to this OID query. NDIS responds to OID_PNP_CAPABILITIES requests on behalf of physical network adapters. For more information about responding to this OID in an intermediate driver, see Handling PnP Events and Power Management Events in an Intermediate Driver.

- OID_PNP_QUERY_POWER

  This OID specifies a device power state to which the network adapter should prepare to transition. A miniport driver must always return NDIS_STATUS_SUCCESS in response to a query of OID_PNP_QUERY_POWER. By returning NDIS_STATUS_SUCCESS in response to this OID request, the miniport driver guarantees that it will transition the network adapter to the specified device power state on receipt of a subsequent OID_PNP_SET_POWER request. The miniport driver, in this case, must do nothing to jeopardize the transition.

- OID_PNP_SET_POWER

  This OID indicates that the network adapter must transition to the indicated device power state. A miniport driver must set the network adapter to the specified state before the driver returns NDIS_STATUS_SUCCESS. A miniport driver must always return NDIS_STATUS_SUCCESS in response to this OID. If OID_PNP_SET_POWER sets a network adapter to working power state and the miniport driver fails this OID, NDIS assumes that the device is in a unrecoverable state.

To support network wake-up events, a miniport driver must also support the OID_PNP_ENABLE_WAKE_UP OID. Both protocol drivers and NDIS use this OID to enable a network adapter's wake-up capabilities. For more information, see Enabling Wake-Up Events.

To support network wake-up frames (see Network Wake-Up Events), a miniport driver must also support the following OIDs that are related to wake-up events:

- OID_PNP_ADD_WAKE_UP_PATTERN

  A protocol driver uses this OID to add a wake-up pattern to a list that either the network adapter or miniport driver or both maintain.

- OID_PNP_REMOVE_WAKE_UP_PATTERN

  A protocol driver uses this OID to delete a wake-up pattern that it previously specified with OID_PNP_ADD_WAKE_UP_PATTERN.

NDIS miniport drivers that support network wake-up events can optionally support the following statistical OIDs that are related to wake-up events:

- OID_PNP_WAKE_UP_ERROR

  Protocol drivers query this OID to determine the number of false wake-ups signaled by the miniport driver's network adapter.

- OID_PNP_WAKE_UP_OK

  Protocol drivers query this OID to determine the number of valid wake-ups that are signaled by the miniport driver's network adapter.

Device Power States for Network Adapters

Article • 12/15/2021

A device power state for a network adapter describes a network adapter's level of power consumption and computing activity.

There are four device power states: D0, D1, D2, and D3. D0 is the highest-powered state. D1, D2, and D3 are the sleeping states. D3 is subdivided into D3hot and D3cold.

The state number is inversely related to power consumption: higher-numbered states use less power. Power might be fully removed from the network adapter in the D3 state.

For a thorough description of device states, see the following topics:

- Device Power States
- Device Working State D0
- Device Low-Power States
- Required Support for Device Power States

Note NDIS processes power management IRPs, but NDIS drivers do not.

The device power states for network adapters are defined as follows:

Device Working State D0

This power state is described for all devices in Device Working State D0. For network adapters and miniport drivers:

Power consumption
The network adapter is fully powered and delivering full functionality and performance.

Device context
The hardware device context is maintained by either the network adapter or miniport driver or both.

Miniport driver and network adapter behavior
The network adapter is fully compliant with the requirements of the attached network. The operation of the miniport driver and network adapter is not restricted because of low-power requirements.

Restore time
Not applicable.

Device Power State D1

This power state is described for all devices in Device Low-Power States. For network adapters and miniport drivers:

Power consumption
This state is the highest-powered sleeping state. Power consumption is less than that in the D0 state and greater than or equal to that in the D2 state.

Device context
The miniport driver should preserve any hardware device context that might be lost. The miniport driver should restore such context when the device returns to the D0 state.

Miniport driver and network adapter behavior
The miniport driver does not receive transmission requests from protocol drivers. NDIS either notifies a bound protocol driver of the network adapter's transition to the sleeping state or, if the protocol driver is an old driver that is not power management-aware, NDIS disables transmission requests from the protocol driver. However, the miniport driver should be able to handle the case in which it does receive transmission requests when it is in this low-power state. In this case, the miniport driver should fail all transmission requests.

The miniport driver does not indicate up any packets that the network adapter might receive while it is in this state.

The network adapter does not generate interrupts. However, the miniport driver must be able to handle interrupts, because a shared interrupt could be generated on the bus.

Restore time
The time to restore the network adapter to the D0 state is less than that required when the network adapter is in the D2 state.

Device Power State D2

This power state is described for all devices in Device Low-Power States. For network adapters and miniport drivers:

Power consumption
An intermediate sleeping state. Power consumption is less than that in the D1 state and greater than or equal to that in the D3 state.

Device context
Same as for D1.

Miniport driver and network adapter behavior
Same as for D1.

Restore time
The time to restore the network adapter to the D0 state is greater than that required when the network adapter is in the D1 state and less than that required when the network adapter is in the D3 state.

Device Power State D3

This power state is described for all devices in Device Low-Power States. For network adapters and miniport drivers:

Power consumption
The sleeping state with the least amount of power. The amount of power may be nonzero (D3hot) or it may be exactly zero (D3cold). For more information about D3hot and D3cold, see Device Low-Power States.

Device context
Same as for D1.

Miniport driver and network adapter behavior
Same as for D1.

Restore time
The time to restore the network adapter to the D0 state is greater than that required when the network adapter is in the D2 state.

Before a network adapter can transition to a sleeping state, its miniport driver must disable everything under the miniport driver's control: interrupts must be disabled, timers must be canceled, and so on. A miniport driver cannot access the network adapter hardware after the bus driver sets the network adapter to the D3 state.

Transitions Allowed Between Device Power States

The only transitions allowed between device power states are from the highest-powered state (D0) to a sleeping state (D1, D2, D3), or from a sleeping state to the highest-powered state. NDIS never commands a network adapter to transition directly from one sleeping state to another.

About Network Wake-Up Events

Article • 08/23/2022

A *network wake-up event* is an external event that causes a network adapter to wake the system. A network adapter wakes the system by asserting a bus-specific wake-up signal that eventually results in the system making a transition from a sleeping state to the working state.

NDIS defines the following two network wake-up events:

- Receipt of a network wake-up frame that contains a pattern that was specified by a bound protocol driver.

- Receipt of a Magic Packet.

A network adapter can support any combination of network wake-up events, including none at all. NDIS treats the miniport driver as not power management-aware if the miniport driver sets the **PowerManagementCapabilities** member of NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES to **NULL**.

Depending on the capabilities of the network adapter, a network wake-up event can occur from any device power state, including the highest-powered state (D0).

Network Wake-Up Frames

If, during initialization, a miniport driver indicates that a network adapter can signal a wake-up on the receipt of a packet that contains a specified pattern, a bound protocol can enable the pattern-based wake up method on the network adapter and specify wake-up patterns. To enable this type of wake-up, a protocol driver sets the NDIS_PNP_WAKE_UP_PATTERN_MATCH flag in OID_PNP_ENABLE_WAKE_UP.

A protocol driver uses OID_PNP_ADD_WAKE_UP_PATTERN to specify a wake-up pattern, along with a mask that indicates which bytes of an incoming packet should be compared with the pattern. A protocol driver can remove a wake-up pattern with OID_PNP_REMOVE_WAKE_UP_PATTERN.

Magic-Packet Wake-Up

A *Magic Packet* is a packet that contains 16 contiguous copies of the receiving network adapter's MAC address.

This section includes:

Enabling Wake-Up Events

Handling Wake-Up Events

Enabling Wake-Up Events

Article • 12/15/2021

A protocol driver can send an OID_PNP_ENABLE_WAKE_UP request to enable one or more of the network adapter's wake-up capabilities. NDIS does not immediately enable these wake-up capabilities. Instead, NDIS keeps track of the wake-up capabilities that are enabled by the protocol driver and, just before the miniport driver transitions to a sleeping state, sends an OID_PNP_ENABLE_WAKE_UP to the miniport driver to enable the appropriate wake-up events. After the miniport driver initializes the network adapter, or when it resumes from a low-power state, the miniport driver must disable any wake up methods that are set on the network adapter.

Before the miniport driver transitions to a low-power state (that is, before NDIS sends the miniport driver an OID_PNP_SET_POWER request), NDIS sends the miniport driver an OID_PNP_ENABLE_WAKE_UP request to enable the network adapter's wake-up capabilities.

Handling Wake-Up Events

Article • 12/15/2021

A miniport driver does not handle a wake-up event detected by a NIC. When a NIC detects an enabled wake-up event, it asserts a bus-specific wake-up line. The power manager then sends a power IRP to NDIS, which, in response, sends the miniport driver an OID_PNP_SET_POWER OID that requests the miniport driver to put a NIC in the highest-powered (D0) state.

Handling an OID_PNP_QUERY_POWER OID

Article • 12/15/2021

The OID_PNP_QUERY_POWER OID requests a miniport driver to indicate whether it can transition a network adapter to a low-power state. A miniport driver must always return NDIS_STATUS_SUCCESS in response to a query of OID_PNP_QUERY_POWER. By returning NDIS_STATUS_SUCCESS to this OID request, the miniport driver guarantees that it will transition the network adapter to the specified device power state on receipt of a subsequent OID_PNP_SET_POWER request. The miniport driver, in this case, must do nothing to jeopardize the transition.

An OID_PNP_QUERY_POWER request is always followed by an OID_PNP_SET_POWER request. The OID_PNP_SET_POWER request can immediately follow the OID_PNP_QUERY_POWER request or can arrive at an unspecified interval after the OID_PNP_QUERY_POWER request. A device state of D0, which is specified in the OID_PNP_SET_POWER request, effectively cancels a preceding OID_PNP_QUERY_POWER request.

Transitioning to a Sleeping State

Article • 12/15/2021

If a miniport driver supports wake-up events, NDIS sends the driver an OID_PNP_ENABLE_WAKE_UP request before sending an OID_PNP_SET_POWER request. For more information, see Enabling Wake-Up Events. A miniport driver must not fail an OID_PNP_SET_POWER request.

Before returning NDIS_STATUS_SUCCESS in response to an OID_PNP_SET_POWER request, the miniport driver must:

- Perform the device-dependent operations that are needed to prepare the network adapter for the sleeping state.

- Save any packet filters, multicast addresses, the current MAC address, wake-up patterns, and any other hardware context that the network adapter cannot preserve in a sleeping state.

- Disable interrupts and the network adapter's DMA engine. A miniport driver cannot access the network adapter hardware after the network adapter has been set to the D3 state by the bus driver.

Transitioning to the Working State

Article • 12/15/2021

NDIS initiates the transition to the working power state (D0) by sending the miniport driver an OID_PNP_SET_POWER request that specifies state D0. The miniport driver must then perform any device-dependent operations needed to restore the network adapter to a working state. The miniport driver must also restore any hardware context--packet filters, multicast addresses, the current media access control (MAC) address, or wake-up patterns--that the network adapter might have lost.

Note Starting with NDIS 6.30, the miniport driver that support NDIS packet coalescing must clear its coalesced packet counter. The driver must also configure the network adapter to flush any packets that it coalesced before the low-power transition. For more information, see Handling Packet Coalescing Receive Filters.

Before the miniport driver returns NDIS_STATUS_SUCCESS in response to the OID_PNP_SET_POWER request, the miniport driver and a network adapter must be ready for normal operation.

Power Management Considerations for Gigabit Ethernet Network Adapters

Article • 12/15/2021

When a gigabit Ethernet network adapter is operating at 1000 megabits per second (Mbps), it draws a lot of electrical power. Before such a network adapter transitions to a low-power state, its link speed is typically reduced so that the network adapter draws less power. The reduced link speed enables the network adapter to transition to a low-power state. While changing link speeds during the transition to a low-power state, the network adapter typically loses network connectivity for a short time.

Conversely, when a gigabit Ethernet network adapter transitions to the fully-on state from a low-power state, the network adapter's link speed is increased to its fully operational rate. During this transition, the network adapter might also lose connectivity for a short time.

While a miniport driver's underlying network adapter is transitioning to or from a low-power state, the miniport must not indicate either a change in link speed or a change in connection status. For more information about indicating a change in link speed, see **NDIS_STATUS_LINK_STATE**. For more information about indicating a change in connection status, see Indicating Connection Status.

Power Management for Old Miniport Drivers

Article • 12/15/2021

NDIS treats a miniport driver as an old miniport driver that is not power management-aware if:

- During initialization, the bus driver indicates that the system or the NIC is not power management-aware.
- The miniport driver returns NDIS_STATUS_UNSUPPORTED in response to the OID_PNP_CAPABILITIES query. Only NDIS 5.1 and earlier miniport drivers or intermediate drivers receive this OID query.
- The user disables power management in the user interface.

NDIS supports only two device power states for old miniport drivers that do not support power manegement: the highest-powered (D0) state and the D3 state.

During initialization, an old miniport driver can indicate that NDIS should not halt it before the system transitions to the sleeping (D3) state. A miniport driver makes such an indication by setting the NDIS_ATTRIBUTE_NO_HALT_ON_SUSPEND flag in the *AttributeFlags* parameter that the miniport driver passes to the **NdisMSetMiniportAttributes** function. An old miniport driver should set this flag only if it can:

- Save all hardware context that it might require.
- Put a NIC in an appropriate state for the sleeping state (D3).
- Reactivate the NIC to the highest-powered state (D0).

If NDIS determines from the bus driver that the NIC is not power management-aware and if the miniport driver did not set the NDIS_ATTRIBUTE_NO_HALT_ON_SUSPEND flag, NDIS will not query the miniport driver's power management capabilities. However, if the miniport driver set the NDIS_ATTRIBUTE_NO_HALT_ON_SUSPEND flag, NDIS issues an OID_PNP_CAPABILITIES request to the miniport driver. In this case, the miniport driver should succeed the OID_PNP_CAPABILITIES request with NDIS_STATUS_SUCCESS. In the NDIS_PM_WAKE_UP_CAPABILITIES structure that the miniport driver returns in response to this request, the miniport driver must also specify a device power state of **NdisDeviceStateUnspecified** for each wake-up capability.

NDIS provides the following power management support for old miniport drivers:

- NDIS succeeds all **IRP_MN_QUERY_POWER** requests that the system power manager sends to the device object that represents the NIC. That is, NDIS guarantees that the miniport driver's NIC will transition to the D3 state in response to any IRP_MN_QUERY_POWER request from the system.

- If the miniport driver did not set the NDIS_ATTRIBUTE_NO_HALT_ON_SUSPEND flag during initialization, NDIS calls the miniport driver's *MiniportHaltEx* function before the miniport driver's NIC transitions to state D3. The miniport driver's NIC loses all hardware context information.

- If the miniport driver set the NDIS_ATTRIBUTE_NO_HALT_ON_SUSPEND flag during initialization, NDIS does not halt the miniport driver before the system transitions to state D3. Instead, NDIS issues the miniport driver an OID_PNP_SET_POWER request to D3 state. The miniport driver must save any hardware context that it uses and put a NIC in a state appropriate for the D3 state.

- While the system is transitioning to the S0 system power states, NDIS calls the miniport driver's *MiniportInitializeEx* function if NDIS halted the miniport driver. If NDIS did not halt the miniport driver, NDIS issues the miniport driver an OID_PNP_SET_POWER request to D0 state. The miniport driver must put a NIC in a state appropriate for the D0 state.

- If the miniport driver was halted and reinitialized, NDIS restores all the appropriate miniport driver settings, such as packet filters and multicast address lists, by issuing OID requests. If the miniport driver was not halted and then reinitialized, the miniport driver must restore such settings.

How NDIS Sets the Power Policy for a Network Adapter

Article • 03/14/2023

NDIS serves as the device power policy owner for each network device. As such, NDIS sets and administers the power policy for each network device. For more information about managing device power policy, see Managing Device Power Policy.

NDIS uses the following information to set the power policy for a NIC:

- The **DEVICE_CAPABILITIES** structure that the bus driver returns in response to an **IRP_MN_QUERY_CAPABILITIES** request that NDIS issued.
- The miniport driver's response to an OID_PNP_CAPABILITIES request issued by NDIS.
- User input from the user interface (UI).

Using the DEVICE_CAPABILITIES Structure

When a NIC is enumerated, NDIS queries the NIC's capabilities by issuing, in addition to other requests, an **IRP_MN_QUERY_CAPABILITIES** request. In response to this request, the bus driver returns a **DEVICE_CAPABILITIES** structure. NDIS copies this structure and uses the following information from this structure when setting the power policy for the NIC.

Member	Description
DeviceD1 and DeviceD2	TRUE if the device supports the D1 power state.
DeviceD1 and DeviceD2	TRUE if the device supports the D2 power state.
WakeFromD0, WakeFromD1, WakeFromD2, and WakeFromD3	TRUE if the device can respond to an external wake signal while in the D0 power state.
WakeFromD0, WakeFromD1, WakeFromD2, and WakeFromD3	TRUE if the device can respond to an external wake signal while in the D1 power state.
WakeFromD0, WakeFromD1, WakeFromD2, and WakeFromD3	TRUE if the device can respond to an external wake signal while in the D2 power state.
WakeFromD0, WakeFromD1, WakeFromD2, and WakeFromD3	TRUE if the device can respond to an external wake signal while in the D3 power state.

Member	Description
DeviceState[**PowerSystemMaximum**]	Specifies the highest-powered device state that this device can maintain for each system power state, from **PowerSystemUnspecified** to **PowerSystemShutdown**.
SystemWake	Specifies lowest-powered system power state (S0 through S4) from which the device can signal a wake event.
DeviceWake	Specifies lowest-powered device power state (D0 through D3) from which the device can signal a wake event.

NDIS uses the DEVICE_CAPABILITIES information to determine if:

- Both the system and the NIC support power management, and if so, which device power states the NIC can be in for each system power state.

- Both the system and the NIC support wake-on-LAN, and if so, from which device power states the NIC can wake the system.

WakeFromD0 through **WakeFromD3** indicate the device power states from which the NIC can wake the system.

The **DeviceState** array indicates, for each system power state, the highest-powered device power state in which the NIC can be and still support that system power state. For example, consider the following array values.

```C++
DeviceState[PowerSystemWorking] PowerDeviceD0
DeviceState[PowerSystemSleeping1] PowerDeviceD1
DeviceState[PowerSystemSleeping2] PowerDeviceD2
DeviceState[PowerSystemSleeping3] PowerDeviceD2
DeviceState[PowerSystemHibernate] PowerDeviceD3
DeviceState[PowerSystemShutdown] PowerDeviceD3
```

As indicated by the preceding array of sample values, when the system is in system power state S1, the NIC can be in device power state D1, D2, or D3. When the system is in system power state S2 or S3, the NIC can be in device power state D2 or D3.

To determine whether both the system and NIC support wake-on-LAN, NDIS examines both the **SystemWake** and **DeviceWake** members. If both **SystemWake** and **DeviceWake** are set to **PowerSystemUnspecified**, NDIS treats the NIC as capable of power management. In this case, or if the miniport driver set the

NDIS_ATTRIBUTE_NO_HALT_ON_SUSPEND flag during initialization, NDIS subsequently issues the miniport driver an OID_PNP_CAPABILITIES request to obtain more information about the NIC's wake-up capabilities.

Using OID_PNP_CAPABILITIES

After a miniport driver successfully returns from its *MiniportInitializeEx* function, NDIS sends an OID_PNP_CAPABILITIES request to the driver if either of the following is true:

- Both the **SystemWake** and **DeviceWake** members of the **DEVICE_CAPABILITIES** structure that is returned by the bus driver are *not* set to **PowerSystemUnspecified**.
- The miniport driver set the NDIS_ATTRIBUTE_NO_HALT_ON_SUSPEND flag when it called **NdisMSetMiniportAttributes** during initialization.

Note that NDIS issues an OID_PNP_CAPABILITIES request regardless of whether the user has enabled wake-on-LAN in the user interface.

If the miniport driver returns NDIS_STATUS_SUCCESS in response to a query of OID_PNP_CAPABILITIES, NDIS treats the miniport driver as power management-capable. If the miniport driver returns NDIS_STATUS_NOT_SUPPORTED, NDIS treats the miniport driver as an old miniport driver that is not power management-capable. For more information about power management for such drivers, see Power Management for Old Miniport Drivers.

A miniport driver that succeeds an OID_PNP_CAPABILITIES request returns the following information to NDIS in response to the request:

- The lowest device power state from which the NIC can wake the system on receipt of a Magic Packet.
- The lowest device power state from which the NIC can wake the system on receipt of a network frame that contains a pattern that the protocol driver specifies.

As soon as NDIS gets this information, it determines, for each system power state, the device power states to which it can set the NIC if wake-on-LAN is enabled by the user in the UI. If there are no allowable low-power device states from which the NIC can generate a wake-up signal (that is, if all the low-power device power states specified in the **DeviceState** array of DEVICE_CAPABILITIES structures are lower than lowest device power states from which the NIC can wake the system), NDIS makes the **Allow the device to bring the computer out of standby** option in the **Power Management** tab unavailable for the NIC. Then, the user cannot enable wake-on-LAN.

Note Wake-on-LAN is possible only if both the NIC and the system are power management-capable. If the system is not power management-capable, NDIS will not query a NIC's power management capabilities.

Using User Input

For a power management-capable NIC, Microsoft Windows 2000 and later versions provide the following options in the **Power Management** tab of a NIC's **Properties** dialog box:

Allow the computer to turn off this device to save power

Allow the device to bring the computer out of standby

The first option is selected by default to enable power management for the NIC. If the user clears the option, NDIS treats the NIC as an old NIC with regard to power management. For more information, see Power Management for Old Miniport Drivers.

The second option is clear by default. If NDIS determines that there is no allowable low-power state from which the NIC can generate a wake-up signal, NDIS makes the second option unavailable. For example, if the **DeviceState** array member of the DEVICE_CAPABILITIES structure indicates that the NIC must be in D3 for all low-power system states, and if **DeviceWake** indicates that the lowest-powered device state from which the NIC can wake the system is D2, then NDIS shades makes the second check box unavailable.

In addition to the preceding two options, Windows XP and Windows Vista provide a third option in the **Power Management** tab for a NIC:

Only allow management stations to bring the computer out of standby

This option, which is subordinate to the second option that is described earlier, is available only if:

- The user selected the second option to enable wake-on-LAN.
- The miniport driver, in responding to the OID_PNP_CAPABILITIES, indicated that the NIC could wake the system on receipt of a Magic Packet.

The **Only allow management stations to bring the computer out of standby** option is clear by default. The user can select this option to specify that only the receipt of a Magic Packet will cause the NIC to generate a wake-up signal to the system.

Whenever a user selects or clears a power management option for a NIC, the system notifies NDIS of the change. NDIS writes the new setting to the registry so that the changed setting persists across restarts.

Avoiding NDIS Power Management Problems

Article • 03/14/2023

The following rules will help you avoid power-management problems with your network adapter:

- A network adapter must always report its power management capabilities to the bus driver.
- Do not try to enable or disable power management for a network adapter based on registry settings. NDIS obtains power management information about the network adapter from the bus driver before the network adapter's miniport driver is initialized. If the information obtained from the bus driver indicates that the network adapter is not power management-capable, NDIS treats the network adapter as an old network adapter and does not issue an OID_PNP_CAPABILITIES request to the network adapter's miniport driver.
- Do not attempt to provide custom power-management controls in the user interface.

Introduction to NDIS QoS for Data Center Bridging

Article • 03/14/2023

This section describes NDIS Quality of Service (QoS) for the IEEE 802.1 Data Center Bridging (DCB) interface. Miniport drivers use NDIS QoS for traffic prioritization of transmit, or *egress*, packets over a DCB-compliant network adapter.

NDIS QoS for DCB was introduced with NDIS 6.30 in Windows Server 2012.

This section includes the following topics:

Overview of Data Center Bridging

Article • 05/31/2022

IEEE 802.1 Data Center Bridging (DCB) is a collection of standards that defines a unified 802.3 Ethernet media interface, or *fabric*, for local area network (LAN) and storage area network (SAN) technologies. DCB extends the current 802.1 bridging specification to support the coexistence of LAN-based and SAN-based applications over the same networking fabric within a data center. DCB also supports technologies, such as Fibre Channel over Ethernet (FCoE) and iSCSI, by defining link-level policies that prevent packet loss.

DCB consists of the following 802.1 draft standards that specify how networking devices can interoperate within a unified data center fabric:

Priority-based Flow Control (PFC)

PFC is specified in the IEEE 802.1Qbb draft standard. This standard is part of the framework for the DCB interface.

PFC supports the reliable delivery of data by substantially reducing packet loss due to congestion. This allows loss-sensitive protocols, such as FCoE, to coexist with traditional loss-insensitive protocols over the same unified fabric.

PFC specifies a link-level flow control mechanism between directly connected peers. PFC is similar to IEEE 802.3 PAUSE frames but operates on individual 802.1p priority levels instead. This allows a receiver to pause a transmitter on any priority level.

For more information on PFC, see Priority-based Flow Control (PFC).

Enhanced Transmission Selection (ETS)

ETS is a transmission selection algorithm (TSA) that is specified in the IEEE 802.1Qaz draft standard. This standard is part of the framework for the DCB interface.

ETS allocates bandwidth between traffic classes that are assigned to different IEEE 802.1p priority levels. Each traffic class is allocated a percentage of available bandwidth on the data link between directlyconnected peers. If a traffic class doesn't use its allocated bandwidth, ETS allows other traffic classes to use the available bandwidth that the traffic class is not using.

For more information on ETS, see Enhanced Transmission Selection (ETS) Algorithm.

Data Center Bridging Exchange (DCBX) Protocol

The Data Center Bridging Exchange (DCBX) protocol is also specified in the IEEE 802.1Qaz draft standard. DCBX allows DCB configuration parameters to be exchanged between two directlyconnected peers. This allows these peers to adapt and tune Quality of Service (QoS) parameters to optimize data transfer over the connection.

DCBX is also used to detect conflicting QoS parameter settings between the network adapter (*local peer*) and the remote peer. Based on the local and remote QoS parameter settings, the miniport driver resolves the conflicts and derives a set of operational QoS parameters. The network adapter uses these operational parameters for the prioritized transmission of packets to the remote peer. For more information about how the driver resolves its operational NDIS QoS parameter settings, see Resolving Operational NDIS QoS Parameters.

DCBX consists of DCB type-length-value (TLV) settings that are carried over the Link Layer Discovery Protocol (LLDP) packets. LLDP is specified in the IEEE 802.1AB-2005 standard.

> ⓘ **Note**
>
> DCBX specifies that the local peer maintain configuration parameters from only one remote peer at any given time. As a result, the network adapter maintains only one set of local, remote, and operational NDIS QoS parameters.

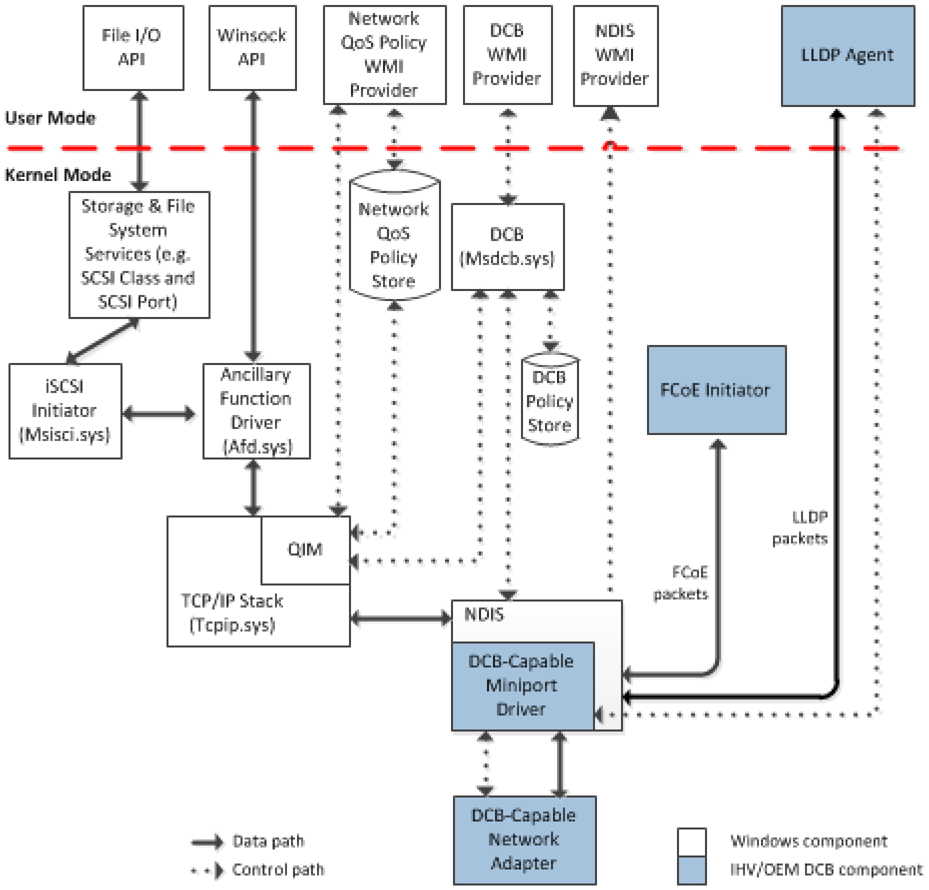
Each ETS traffic class and PFC configuration setting is associated with an IEEE 802.1p priority level. The priority level is specified as a 3-bit value within a packet's 802.1Q tag. For NDIS packets, the 802.1p priority level is specified by the **UserPriority** member of the **NDIS_NET_BUFFER_LIST_8021Q_INFO** structure that is associated with a packet's **NET_BUFFER_LIST** structure.

For more information about priority levels, see IEEE 802.1p Priority Levels.

NDIS QoS Architecture for Data Center Bridging

Article • 03/14/2023

This section describes the various components that are part of the NDIS Quality of Service (QoS) architecture for IEEE 802.1 Data Center Bridging (DCB). These components are shown in the following diagram.



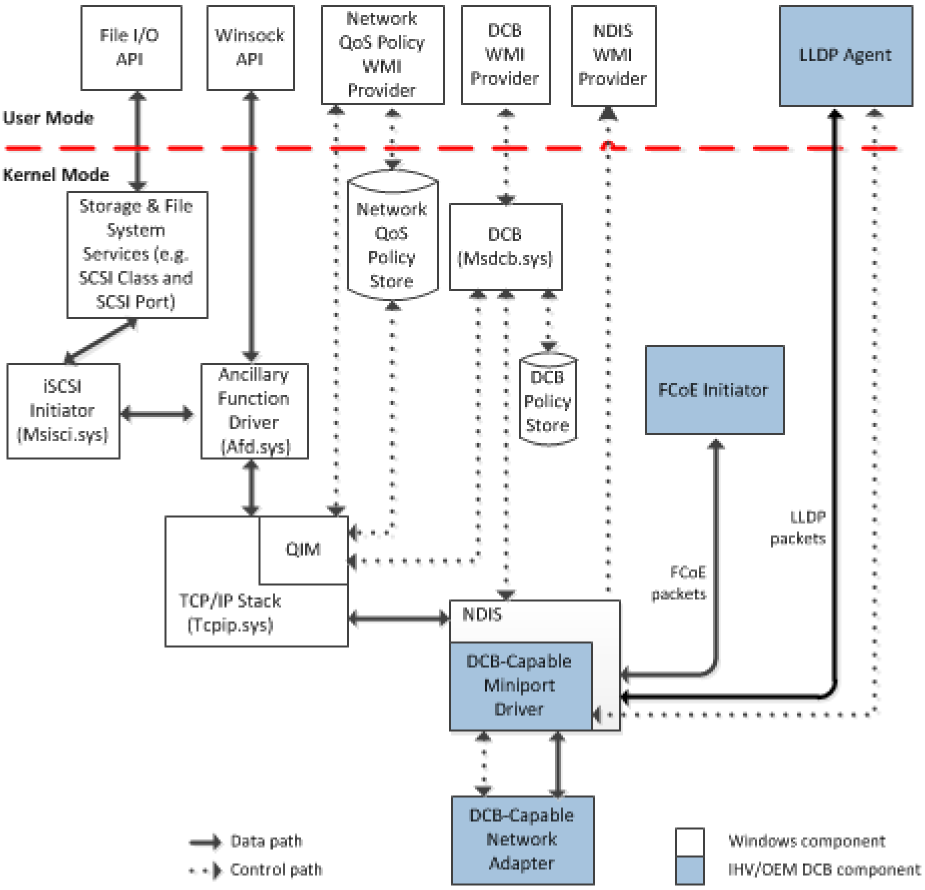
The unshaded boxes in the diagram represent components that the Windows operating system provides, including components that support DCB. For more information about these components, see System-Provided DCB Components.

The shaded boxes in the diagram represent DCB components that independent hardware vendors (IHVs) and original equipment manufacturers (OEMs) provide. For more information about these components, see Vendor-Provided DCB Components.

System-Provided DCB Components

Article • 12/15/2021

This section describes the various components that are part of the NDIS Quality of Service (QoS) architecture for IEEE 802.1 Data Center Bridging (DCB). These components are shown in the following diagram.



The unshaded boxes in the diagram represent modules that the Windows operating system provides. In particular, the operating system provides the following modules that support DCB:

Network QoS Policy WMI Provider
This module provides an interface for Windows Management Instrumentation (WMI) clients to query and set QoS-based network policies within the operating system's network stack. These policies allow specific types of network traffic to be assigned to DCB traffic classes for transmit, or *egress*, management and prioritized delivery.

A network policy defines a set of conditions and actions. An egress packet that matches a condition, such as a TCP or UDP port number, is assigned the action related to the condition. Starting with NDIS 6.30, policy actions specify an 802.1p priority level to which a DCB traffic class has been assigned.

Network QoS policies are a superset of NDIS QoS classifications. A policy defined by using the Network Policy WMI Provider may be automatically migrated to NDIS QoS as long as the policy conditions and actions match the restrictions of an NDIS QoS classification element. For more information about these elements, see NDIS QoS Traffic Classifications.

This WMI provider saves the network policies within a separate store in the system registry.

DCB WMI Provider
This component provides an interface for WMI clients to query and set NDIS QoS parameters on the underlying miniport driver. Through WMI-based PowerShell cmdlets and WMI methods, clients can configure DCB functionality, such as Priority-based Flow Control (PFC) and Enhanced Transmission Selection (ETS), on the miniport driver that supports DCB.

DCB
The DCB component (Msdcb.sys) configures the DCB-capable miniport driver with DCB parameter settings. The DCB component obtains these settings from the following sources:

- Persistent settings from the DCB policy store in the system registry.
- Dynamic settings from the DCB WMI user-mode provider. These settings are delivered over a private I/O control (IOCTL) interface between the DCB WMI provider and the DCB module.

The DCB component also relays QOS classification settings from the QIM component to miniport drivers that support NDIS QoS.

QoS Inspection Module (QIM)
The QIM component is part of the packet inspection layer in the core TCP/IP network stack (Tcpip.sys). Starting with Windows Server 2012, this component performs QoS-based packet classification for traffic prioritization.

The QIM component exposes a private Network Programming Interface (NPI). When the DCB component sets QoS parameters on the underlying miniport driver, it relays those settings to the QIM component over this NPI interface. This allows DCB to create QoS policies in QIM that are based on DCB application priority settings. For more information about the NPI interface, see Network Programming Interface.

The QIM component also processes networking QoS policies from the policy store in the registry. If those policies are compatible with NDIS QoS classification elements, the QIM component migrates the policies and issues them to the DCB component over the NPI interface.

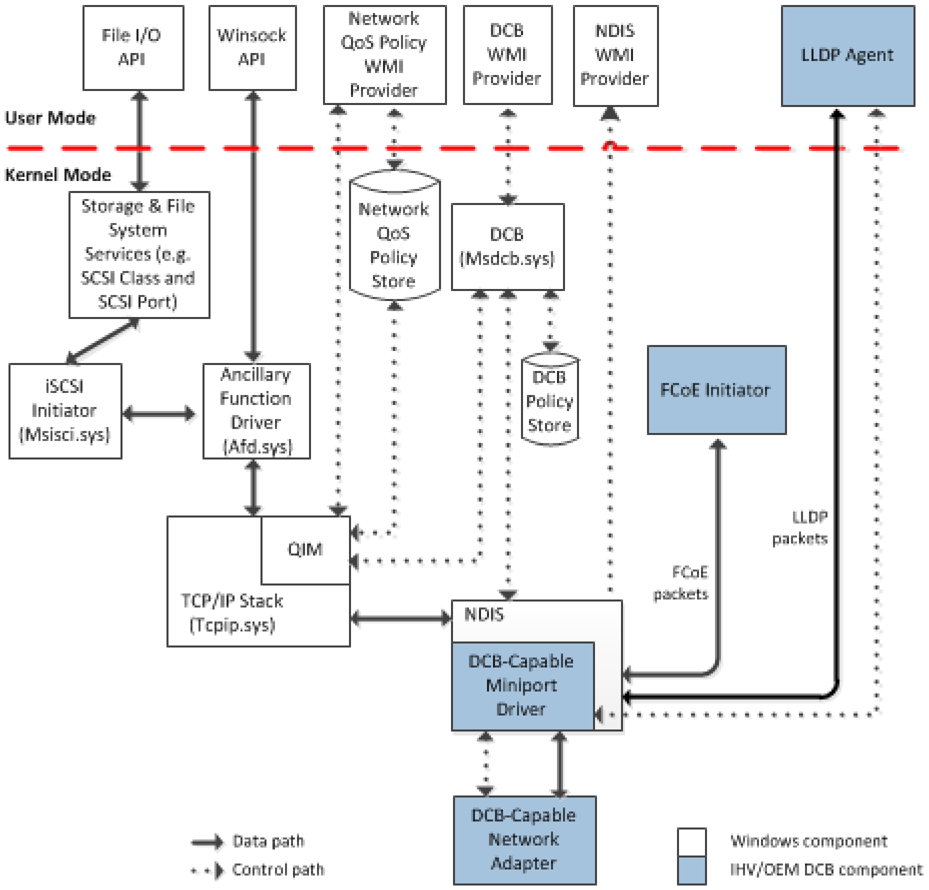
Note The policies that are created by the QIM component go into the active store and do not persist through a system restart.

Note Starting with Windows Server 2012, the DCB and DCB WMI provider components are not installed by default. These components are installed and enabled through the installation of the Microsoft DCB server feature. This feature is installed by using the Add Roles and Features wizard of the Server Manager.

Vendor-Provided DCB Components

Article • 12/15/2021

This section describes the various components that are part of the NDIS Quality of Service (QoS) architecture for IEEE 802.1 Data Center Bridging (DCB). These components are shown in the following diagram.



The shaded boxes in the diagram represent DCB components that independent hardware vendors (IHVs) and original equipment manufacturers (OEMs) provide. The following list describes these components:

Link Layer Discovery Protocol (LLDP) Agent
Starting with Windows Server 2012, vendors that support the IEEE 802.1Qaz DCB Exchange (DCBX) protocol can provide support for the IEEE 802.1Qab LLDP protocol over which DCBX is carried. This LLDP support can be provided through either the miniport driver or an LLDP agent.

Typically, the LLDP agent and the DCB-capable miniport driver communicate over a private control path, such as a private I/O control (IOCTL) interface.

If the vendor provides an LLDP agent, we highly recommend that the agent reside in user mode to mitigate the general stability risks associated with processing network packets.

Fibre Channel over Ethernet (FCoE) Initiator
The Windows operating system does not natively support FCoE. To support FCoE, the vendor must provide an FCoE initiator stack that is used to connect to remote storage devices.

DCB-Capable Miniport Driver and Network Adapter
To support NDIS QoS for DCB, the miniport driver and network adapter must support the requirements described in NDIS QoS Requirements for Data Center Bridging.

NDIS QoS Requirements for Data Center Bridging

Article • 03/14/2023

To support NDIS Quality of Service (QoS) for IEEE 802.1 Data Center Bridging (DCB), the miniport driver and network adapter must support the following:

- The miniport driver and network adapter must support Priority-based Flow Control (PFC) as specified by the IEEE 802.1Qbb draft standard.

- The miniport driver and network adapter must support the Enhanced Transmission Selection (ETS) algorithm as specified by the IEEE 802.1Qaz draft standard.

- The miniport driver and network adapter must support a minimum of three NDIS QoS traffic classes, and must support a minimum of two ETS-based traffic classes. Of these two, at least one ETS-based traffic class must support PFC.

  For more information about traffic classes, see NDIS QoS Traffic Classes.

- The miniport driver and network adapter must support the strict priority algorithm for transmission selection as specified by the IEEE 802.1Q-2005 standard.

For NDIS QoS, the miniport driver and network adapter can optionally support the Data Center Bridging Exchange (DCBX) protocol as specified by the IEEE 802.1Qaz draft standard. To support DCBX, the miniport driver and adapter must also support the Link Layer Discovery Protocol (LLDP) protocol as specified in the IEEE 802.1AB-2005 standard.

In addition, the miniport driver itself must support the following for NDIS QoS:

- The miniport driver must support NDIS 6.30 or later versions of NDIS.

- The miniport driver must support object identifier (OID) method requests of OID_QOS_PARAMETERS for setting NDIS QoS parameters. For more information, see Setting Local NDIS QoS Parameters.

  Note NDIS handles most of the NDIS QoS OID requests for the miniport driver with the exception of OID_QOS_PARAMETERS.

- The miniport driver must be able to resolve conflicting NDIS QoS parameter settings that were received over a DCBX frame that was sent from the remote peer. The driver resolves conflicts between its local and remote NDIS QoS parameters to determine its operational NDIS QoS parameters that the network adapter uses for prioritized packet transmission. For more information about this process, see Resolving Operational NDIS QoS Parameters.

- The miniport driver must be able to issue NDIS status indications when its operational NDIS QoS parameters change. For more information about this process, see Indicating Changes to the Operational NDIS QoS Parameters.
- The miniport driver must be able to issue NDIS status indications when it detects a change in the NDIS QoS parameters on the remote peer. For more information about this process, see Indicating Changes to the Remote NDIS QoS Parameters.

NDIS QoS Traffic Classes

Article • 03/14/2023

NDIS Quality of Service (QoS) traffic classes specify a set of policies that determine how the network adapter handles transmit, or *egress*, packets for prioritized delivery. Each traffic class specifies the following policies that are applied to egress packets:

Priority Level and Flow Control
This policy defines the IEEE 802.1p priority level and optional flow control algorithms for the egress traffic.

For more information, see Priority Levels and Flow Control.

Traffic Selection Algorithms (TSAs)
This policy specifies how the network adapter selects egress traffic for delivery from its transmit queues. For example, the adapter could select egress packets based on IEEE 802.1p priority or the percentage of the egress bandwidth that is allocated to each traffic class.

For more information, see Transmission Selection Algorithms (TSAs).

Note Bandwidth allocation is only supported for the Enhanced Transmission Selection (ETS) TSA. For more information, see Enhanced Transmission Selection (ETS) Algorithm.

Traffic classes are specified through object identifier (OID) method requests of OID_QOS_PARAMETERS. This OID request contains an **NDIS_QOS_PARAMETERS** structure that specifies the following NDIS QoS parameters:

- The number of traffic classes to be configured on the network adapter. Each traffic class is identified by a value in the range from zero to (**NumTrafficClasses**–1), where **NumTrafficClasses** is a member of the **NDIS_QOS_PARAMETERS** structure.

  Note Starting with NDIS 6.30, NDIS QoS supports a maximum of NDIS_QOS_MAXIMUM_TRAFFIC_CLASSES (8) traffic classes. The network adapter must support a minimum of three traffic classes.

- The 802.1p priority level associated with the traffic class.

- The TSA associated with the traffic class.

- The transmit bandwidth allocated to each traffic class that uses the ETS TSA.

OID method requests of OID_QOS_PARAMETERS also specify traffic classifications. These classifications define the relationship between egress packets and IEEE 802.1p priority levels. For more information, see NDIS QoS Traffic Classifications.

IEEE 802.1p Priority Levels

Article • 12/15/2021

IEEE 802.1p was specified by an IEEE 802.1 Task Group to address traffic prioritization for Quality of Service (QoS). 802.1p is not a separate IEEE 802.1 standard, but is defined in Annex G of the IEEE 802.1Q-2005 standard.

IEEE 802.1p defines a 3-bit field called the Priority Code Point (PCP) within an IEEE 802.1Q tag. For NDIS packets, the 802.1p PCP value is specified by the **UserPriority** member of the NDIS_NET_BUFFER_LIST_8021Q_INFO structure that is associated with a packet's NET_BUFFER_LIST structure.

The PCP value defines 8 priority levels, with 7 the highest priority and 1 the lowest priority. The priority level of 0 is the default. Each priority level defines a *class of service* that identifies separate traffic classes of transmitted packets.

Priority-based Flow Control (PFC)

Article • 12/15/2021

Priority-based Flow Control (PFC) is specified in the IEEE 802.1Qbb draft standard. This standard is part of the framework for the IEEE 802.1 Data Center Bridging (DCB) interface.

PFC enables flow control over a unified 802.3 Ethernet media interface, or *fabric*, for local area network (LAN) and storage area network (SAN) technologies. PFC is intended to eliminate packet loss due to congestion on a network link. This allows loss-sensitive protocols, such as Fibre Channel over Ethernet (FCoE), to coexist with traditional loss-insensitive protocols over the same unified fabric.

PFC specifies a link-layer flow control mechanism between directly connected peers. PFC is similar to IEEE 802.3 PAUSE frames but operates on individual 802.1p priority levels instead. This allows a receiver to pause a transmitter on any 802.1p priority level.

PFC uses the 802.3 PAUSE frame, and extends it with the following PFC fields:

- An 8-bit mask that specifies which 802.1p priority levels should be paused.
- A timer value for each priority specifying how long the traffic for that priority level should be paused.

When the receiver sends an 802.3 PAUSE frame with PFC data, the switch blocks the transmit of frames with the specified priority level to the port on which the receiver is connected. When the timer value expires, the switch resumes the transmit of paused frames on the port.

NDIS Quality of Service (QoS) parameters are specified through the **NDIS_QOS_PARAMETERS** structure. The **PfcEnable** member contains a bitmap, in which each bit specifies whether PFC is enabled for a 802.1p priority level.

For more information about priority levels, see IEEE 802.1p Priority Levels.

Transmission Selection Algorithms (TSAs)

Article • 12/15/2021

This section provides an overview of the traffic selection algorithms (TSAs) that are used by NDIS Quality of Service (QoS) for the IEEE 802.1 Data Center Bridging (DCB) interface.

This section includes the following topics:

Strict Priority Algorithm

Enhanced Transmission Selection (ETS) Algorithm

Strict Priority Algorithm

Article • 12/15/2021

Strict priority is a transmission selection algorithm (TSA) that is specified in the IEEE 802.1Q-2005 standard. This standard is part of the framework for the IEEE 802.1 Data Center Bridging (DCB) interface.

When the network adapter employs the strict priority TSA, it selects packets for transmission based solely on the packet's specified IEEE 802.1p priority level. As a result, packets with higher priority levels are always transmitted before packets with lower priority levels.

The miniport driver specifies its support for the strict priority TSA by setting NDIS_QOS_CAPABILITIES_STRICT_TSA_SUPPORTED in the **Flags** member of the **NDIS_QOS_CAPABILITIES** structure. The driver uses this structure to register its NDIS QoS and DCB capabilities in the call to **NdisMSetMiniportAttributes**.

For more information about priority levels, see IEEE 802.1p Priority Levels.

Note Starting with NDIS 6.30, the miniport driver that supports NDIS Quality of Service (QoS) for the DCB interface must advertise support for the strict priority TSA.

Enhanced Transmission Selection (ETS) Algorithm

Article • 12/15/2021

Enhanced Transmission Selection (ETS) is a transmission selection algorithm (TSA) that is specified by the IEEE 802.1Qaz draft standard. This standard is part of the framework for the IEEE 802.1 Data Center Bridging (DCB) interface.

Transmission selection based solely on IEEE 802.1p priority levels can lead to situations in which higher-priority traffic blocks lower-priority traffic. ETS ensures fairness by allowing a minimum amount of bandwidth to be allocated to traffic classes that are assigned to different 802.1p priority levels.

Each traffic class is allocated a percentage of the available bandwidth on the data link between directly connected peers. If a traffic class doesn't use its allocated bandwidth, ETS allows other traffic classes to use the available bandwidth that the traffic class is not using.

NDIS Quality of Service (QoS) traffic classes are defined through OID method requests of OID_QOS_PARAMETERS. This OID request contains an **NDIS_QOS_PARAMETERS** structure which specifies the following traffic class attributes:

- The number of traffic classes that is specified by the **NumTrafficClasses** member.

- The TSA used by the traffic class. This is specified by the **TsaAssignmentTable** member. If the table element for the traffic class is set to NDIS_QOS_TSA_ETS, the traffic class uses the ETS TSA.

- The 802.1p priority that is assigned to the traffic class. A traffic class can be assigned to one or more priority levels. However, each priority level can only be assigned to one traffic class.

  For more information, see Traffic Class Priority Assignment.

- The bandwidth allocated for the traffic class. This is specified by the **TcBandwidthAssignmentTable** member. This table is only valid for traffic classes that use the ETS TSA.

  For more information about ETS bandwidth allocation, see Bandwidth Allocation.

For more information about priority levels, see IEEE 802.1p Priority Levels.

Traffic Class Priority Assignment

Article • 12/15/2021

The Enhanced Transmission Selection (ETS) algorithm specifies a method by which a traffic class is assigned an 802.1p priority level. ETS is specified in the IEEE 802.1Qaz draft standard. This standard is part of the framework for the IEEE 802.1 Data Center Bridging (DCB) interface.

NDIS Quality of Service (QoS) traffic classes specify a set of policies that determine how the network adapter handles transmit, or *egress*, packets. Under ETS, each traffic class is assigned an IEEE 802.1p priority level in which to transmit packets. A traffic class can be assigned to one or more IEEE 802.1p priority levels. However, each IEEE 802.1p priority level can only be assigned to one traffic class.

NDIS QoS parameters are specified through the **NDIS_QOS_PARAMETERS** structure. The **PriorityAssignmentTable** member contains an array that specifies the priority assignments for each traffic class.

For more information about priority levels, see IEEE 802.1p Priority Levels.

Bandwidth Allocation

Article • 12/15/2021

Bandwidth allocation is a component of the Enhanced Transmission Selection (ETS) algorithm. ETS is specified in the IEEE 802.1Qaz draft standard. This standard is part of the framework for the IEEE 802.1 Data Center Bridging (DCB) interface.

Under ETS, each traffic class is assigned a percentage of the bandwidth that is available to transmit packets between two directly connected peers. If the bandwidth allocated to a traffic class is not completely used, ETS allows the unused bandwidth to be shared by traffic classes that have different IEEE 802.1p priority levels.

NDIS Quality of Service (QoS) parameters are specified through the **NDIS_QOS_PARAMETERS** structure. The **TcBandwidthAssignmentTable** member contains an array that specifies the bandwidth allocation for traffic classes that use the ETS algorithm.

For more information about priority levels, see IEEE 802.1p Priority Levels.

NDIS QoS Traffic Classifications

Article • 03/14/2023

NDIS Quality of Service (QoS) classifies transmit, or *egress*, packets for prioritized delivery by the network adapter. Each traffic classification specifies the following:

- A classification *condition* that is based on a data pattern within the egress packet data.

  Starting with NDIS 6.30, classification conditions are based on a 16-bit value, such as a UDP or TCP destination port or a media access control (MAC) EtherType.

- A classification *action* that defines the traffic class to be used to handle the egress packet.

  Starting with NDIS 6.30, classification actions specify an 802.1p priority level.

Note Traffic classifications are also known as "application priorities" in the IEEE 802.1 specifications.

NDIS QoS traffic classifications are intended for the following types of egress packet traffic:

- Packets based on traffic that is offloaded to the miniport driver, such as Fibre Channel over Ethernet (FCoE) or iSCSI packets.

- Packets based on connections that are managed and enforced by the miniport driver, such as RDMA.

Because NDIS QoS traffic classifications are not intended for TCP/IP traffic generated by the operating system, the miniport driver does not need to perform packet inspection. Instead, if a classification condition matches a packet type that has been offloaded or managed by the driver, it can simply apply the classification action to all packets that belong to that type. For example, if the miniport driver is enabled for FCoE offloads and the classification condition specifies the iSCSI TCP port number (860 or 3260), the driver prioritizes all egress iSCSI packets with the priority level defined for the classification action.

The DCB component (Msdcb.sys) specifies traffic classifications through OID method requests of OID_QOS_PARAMETERS. This OID request contains an **NDIS_QOS_PARAMETERS** structure that specifies an array of **NDIS_QOS_CLASSIFICATION_ELEMENT** structures. Each of these structures defines a traffic classification.

The DCB component specifies a *default* traffic classification that is applied to all egress packets that do not match other classification conditions. In this case, the network adapter assigns the IEEE 802.1p priority level that is associated with the default classification to these egress packets. The default traffic classification has the following attributes:

- It has a traffic classification condition of type NDIS_QOS_CONDITION_DEFAULT.
- It is the first traffic classification defined in the array of **NDIS_QOS_CLASSIFICATION_ELEMENT** structures.

For more information on the DCB component, see NDIS QoS Architecture for Data Center Bridging.

Registering NDIS QoS Capabilities

Article • 03/14/2023

Miniport drivers regsiter the following Quality of Service (QoS) capabilities with NDIS during network adapter initialization:

- The NDIS QoS hardware capabilities that the network adapter supports.

  Note Starting with NDIS 6.30, the miniport driver must register the NDIS QoS hardware capabilities that the adapter supports only if the***QOS** INF keyword setting is present in the registry. In this case, the driver must register its NDIS QoS hardware capabilities regardless of whether those capabilities are enabled or disabled on the adapter.

- The NDIS QoS hardware capabilities that are currently enabled on the network adapter.

  Note A miniport driver's NDIS QoS hardware capabilities can be enabled or disabled through the ***QOS** INF keyword setting in the registry. This setting is displayed on the **Advanced** property page for the network adapter.

For more information about the NDIS QoS INF keyword settings, see Standardized INF Keywords for NDIS QoS.

The miniport driver reports the hardware NDIS QoS capabilities of the underlying network adapter through an **NDIS_QOS_CAPABILITIES** structure that is initialized in the following way:

1. The miniport driver initializes the **Header** member. The driver sets the **Type** member of **Header** to NDIS_OBJECT_TYPE_QOS_CAPABILITIES.

   Starting with NDIS 6.30, the miniport driver sets the **Revision** member of **Header** to NDIS_QOS_CAPABILITIES_REVISION_1 and the **Size** member to NDIS_SIZEOF_QOS_CAPABILITIES_REVISION_1.

2. If the network adapter supports the strict priority transmission selection algorithm (TSA), the miniport driver sets the NDIS_QOS_CAPABILITIES_STRICT_TSA_SUPPORTED flag in the **Flags** member. For more information on this algorithm, see Strict Priority Algorithm.

   Note Starting with NDIS 6.30, the miniport driver and network adapter that support NDIS QoS for IEEE Data Center Bridging (DCB) must support the strict priority TSA.

3. If the network adapter supports the ability to bypass media access control security (MACsec) processing, the miniport driver sets the NDIS_QOS_CAPABILITIES_MACSEC_BYPASS_SUPPORTED flag in the **Flags** member. For more information about MACsec, refer to the IEEE 802.1AE-2006 standard.

   Note Starting with NDIS 6.30, the network adapter does not need to support the bypass of MACsec processing.

4. The miniport driver sets the **MaxNumTrafficClasses** member to the maximum number of NDIS QoS traffic classes that the network adapter supports. A traffic class defines the transmit, or *egress* policies for QoS, such as IEEE 802.1p priority level and bandwidth allocation. For more information about traffic classes, see NDIS QoS Traffic Classes.

   Note Starting with NDIS 6.30, the network adapter must support a minimum of three traffic classes.

5. The miniport driver sets the **MaxNumEtsCapableTrafficClasses** member to the maximum number of NDIS QoS traffic classes that the network adapter can use with the Enhanced Transmission Selection (ETS) algorithm. This value must be less than or equal to the value of the **MaxNumTrafficClasses** member.

   For more information on ETS, see Enhanced Transmission Selection (ETS) Algorithm.

   Note For the network adapter to support NDIS QoS, it must support a minimum of two ETS-capable traffic classes.

6. The miniport driver sets the **MaxNumPfcEnabledTrafficClasses** member to the maximum number of NDIS QoS traffic classes that the network adapter can use with the Priority-based Flow Control (PFC) algorithm. This value must be less than or equal to the value of the **MaxNumTrafficClasses** member.

   For more information on PFC, see Priority-based Flow Control (PFC).

   Note For the network adapter to support NDIS QoS, it must support at least one PFC-capable traffic class.

When NDIS calls the miniport driver's *MiniportInitializeEx* function, the driver registers the NDIS QoS attributes of the network adapter by following these steps:

1. The miniport driver initializes an **NDIS_MINIPORT_ADAPTER_HARDWARE_ASSIST_ATTRIBUTES** structure.

The miniport driver sets the **HardwareQOSCapabilities** member to a pointer to the previouslyinitialized NDIS_QOS_CAPABILITIES structure.

If the registry setting for the ***QOS** INF keyword has a value of one, the NDIS QoS capabilities are enabled on the network adapter. The miniport driver sets the **CurrentQOSCapabilities** members to a pointer to the same NDIS_QOS_CAPABILITIES structure.

If the registry setting for the ***QOS** INF keyword has a value of zero, the NDIS QoS capabilities are disabled on the network adapter. The miniport driver must set the **CurrentQOSCapabilities** member to NULL.

2. The driver calls NdisMSetMiniportAttributes and sets the *MiniportAttributes* parameter to a pointer to the NDIS_MINIPORT_ADAPTER_HARDWARE_ASSIST_ATTRIBUTES structure.

For more information about the adapter initialization process, see Initializing a Miniport Adapter.

Querying NDIS QoS Capabilities

Article • 03/14/2023

Overlying protocol and filter drivers can query the NDIS Quality of Service (QoS) capabilities of a network adapter in the following way:

- The overlying driver can query the hardware NDIS QoS capabilities supported by the network adapter through an object identifier (OID) query request of OID_QOS_HARDWARE_CAPABILITIES.

- The overlying driver can query the hardware NDIS QoS capabilities that are currently enabled on the network adapter through an OID query request of OID_QOS_CURRENT_CAPABILITIES.

NDIS handles these OID requests for the miniport driver. When the miniport driver registers the hardware and currently enabled NDIS QoS capabilities for the network adapter during network adapter initialization, NDIS caches this information. NDIS then returns this data when it handles the OID requests from an overlying driver.

For more information about how the miniport driver registers the NDIS QoS capabilities, see Registering NDIS QoS Capabilities.

Overview of NDIS QoS Parameters

Article • 03/14/2023

NDIS Quality of Service (QoS) parameters specify the policies and settings of traffic classes that the network adapter uses for transmit, or *egress*, packet delivery. NDIS QoS parameters contain the following settings:

- Priority level and flow control settings. These settings define the IEEE 802.1p priority level and optional flow control algorithms for the transmit, or *egress*, traffic.

  For more information, see Priority Levels and Flow Control.

- Traffic selection algorithm (TSA) settings. These settings define how the network adapter selects egress traffic from its transmit queues. For example, the adapter could use the strict priority TSA and select egress packets based only on IEEE 802.1p priority. The adapter could also use the Enhanced Transmission Selection (ETS) TSA that moderates egress traffic among traffic classes based on their bandwidth allocation.

  For more information, see Transmission Selection Algorithms (TSAs).

- Traffic classifications that specify the assignment of IEEE 802.1p priority levels to packets that contain data that matches a classification condition, such as an EtherType or destination TCP port. For more information, see NDIS QoS Traffic Classifications.

  Note Traffic classifications are also known as "application priorities" in the IEEE 802.1 specifications.

NDIS QoS defines the following types of parameters:

Local NDIS QoS Parameters
Local NDIS QoS parameters specify the core QoS settings for a miniport driver and its network adapter. These parameters persist in the system registry, and are administered locally to the miniport driver in the following way:

- Through an NDIS object identifier (OID) method request of OID_QOS_PARAMETERS that is issued by the DCB component. This OID request contains an **NDIS_QOS_PARAMETERS** structure that specifies the local NDIS QoS parameters.

  For more information on the DCB component, see NDIS QoS Architecture for Data Center Bridging.

- Through proprietary registry settings for the network adapter. The miniport driver reads these settings when its *MiniportInitializeEx* function is called by NDIS.

- Through settings issued to the miniport driver through a management application developed by the independent hardware vendor (IHV).

For more information about how the miniport driver obtains its local NDIS QoS parameters, see Setting Local NDIS QoS Parameters.

Remote NDIS QoS Parameters
Remote NDIS QoS parameters are those that are configured on a remote peer that the network adapter is connected to over the data link. The miniport driver discovers these parameters through the Data Center Bridging Exchange (DCBX) protocol that is specified by the IEEE 802.1Qaz draft standard.

DCBX requires that the miniport driver maintain only one set of remote QoS parameters that were received from a single data-link peer. The miniport driver must issue an NDIS status indication when its remote QoS parameters are either received from a peer for the first time or change later. For example, the driver may change its remote NDIS QoS parameters because it received a different set of QoS parameters from its remote peer. For more information on this process, see Indicating Changes to the Remote NDIS QoS Parameters.

For more information about how the miniport driver obtains its remote NDIS QoS parameters, see Receiving Remote NDIS QoS Parameters.

Operational NDIS QoS Parameters
Operational NDIS QoS parameters are those that the miniport driver resolves for traffic prioritization over the data-link connection to a remote peer. The miniport driver resolves its operational NDIS QoS parameters from its local or remote NDIS QoS parameters.

The miniport driver must issue an NDIS status indication when its operational QoS parameters are either resolved for the first time or change later. For example, the driver may change its operational NDIS QoS parameters because it received a different set of QoS parameters from its remote peer. For more information on how to generate this status indication, see Indicating Changes to the Operational NDIS QoS Parameters.

For more information about how the miniport driver resolves its operational NDIS QoS parameters, see Resolving Operational NDIS QoS Parameters.

Managing the Local DCBX Willing State

Article • 12/15/2021

The IEEE 802.1Qaz draft standard defines the Data Center Bridging Exchange (DCBX) protocol. This protocol allows DCB configuration parameters to be exchanged between the network adapter (local peer) and a directly connected remote peer. This allows these peers to adapt and tune Quality of Service (QoS) parameters to optimize data transfer over the connection.

Based on the local and remote QoS parameter settings, the miniport driver resolves the conflicts and derives a set of operational QoS parameters. The network adapter uses these operational parameters for the prioritized transmission of packets to the remote peer. For more information about how the driver resolves its operational NDIS QoS parameter settings, see Resolving Operational NDIS QoS Parameters.

DCBX consists of DCB type-length-value (TLV) settings that are carried over Link Layer Discovery Protocol (LLDP) packets. A separate TLV is defined for the following types of QoS parameters:

- Enhanced Transmission Selection (ETS)
- Priority-based Flow Control (PFC)

The TLVs for ETS and PFC define a bit known as the *Willing* bit. If the network adapter sends its TLV settings to the remote peer with the Willing bit set to one, it indicates that the adapter is willing to accept QoS parameters from the remote peer.

The ability to set individual Willing bits in these TLVs depends on the local DCBX Willing state that is managed by the miniport driver. The miniport driver must follow these guidelines for managing the local DCBX Willing state:

- If the local DCBX Willing state is disabled, the local Willing bit must be set to zero in the DCBX TLVs. In this case, the operational QoS parameters are always resolved from the local QoS parameters. For more information on these parameters, see Setting Local NDIS QoS Parameters.

- If the local DCBX Willing state is enabled, the local Willing bit must be set to one in the DCBX TLVs. In this case, the operational QoS parameters must be resolved from the remote QoS parameters. For more information on these parameters, see Receiving Remote NDIS QoS Parameters.

  Note If local DCBX Willing state is enabled, the miniport driver can also resolve its operational QoS parameters based on any proprietary QoS settings that are defined by the independent hardware vendor (IHV). The driver can only do this for QoS parameters that are not configured remotely by the peer or locally by the operating system.

The miniport driver manages the local DCBX Willing state in the following way:

- When the miniport driver is initialized through a call to its *MiniportInitializeEx* function, it should enable the local DCBX Willing state based on proprietary QoS settings that are defined by the IHV.
- The DCB component (Msdcb.sys) issues an object identifier (OID) method request of OID_QOS_PARAMETERS to configure the local QoS parameters on a network adapter. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure for this OID request contains a pointer to an **NDIS_QOS_PARAMETERS** structure.

  If the **NDIS_QOS_PARAMETERS_WILLING** flag is set in the **Flags** member of this structure, the miniport driver enables the DCBX Willing state. If this bit is not set, the miniport driver disabled the DCBX Willing state.

For more information about LLDP, refer to the IEEE 802.1AB-2005 standard.

For more information about the local DCBX Willing bits and TLVs, refer to the IEEE 802.1Qaz draft standard.

Note Starting with Windows Server 2012, the DCB component can be configured through a PowerShell cmdlet to set or clear the **NDIS_QOS_PARAMETERS_WILLING** flag when it issues an OID_QOS_PARAMETERS request. This causes the miniport driver to respectively enable or disable the local DCBX Willing state.

Setting Local NDIS QoS Parameters

Article • 03/14/2023

Local NDIS Quality of Service (QoS) parameters specify the locally provisioned QoS settings for a miniport driver and its network adapter. Miniport drivers obtain the local NDIS QoS parameters in the following ways:

- Through an object identifier (OID) method request of OID_QOS_PARAMETERS that is issued by the Data Center Bridging (DCB) component (Msdcb.sys). This OID request contains an **NDIS_QOS_PARAMETERS** structure that specifies the local NDIS QoS parameters.

  For more information on the DCB component, see NDIS QoS Architecture for Data Center Bridging.

  Note Starting with Windows Server 2012, the DCB component is installed and enabled with the Microsoft Data Center Bridging (DCB) server feature. This feature is not installed by default.

- Through proprietary settings that are stored in the system registry and defined by the independent hardware vendor (IHV) for the network adapter. The miniport driver reads these settings when its *MiniportInitializeEx* function is called by NDIS.

- Through proprietary settings issued to the miniport driver through a management application developed by the IHV.

When the DCB component issues an OID method request of OID_QOS_PARAMETERS, the **NDIS_QOS_PARAMETERS_WILLING** flag of the **NDIS_QOS_PARAMETERS.Flags** member specifies how the miniport driver resolves its operational QoS parameters from the local NDIS QoS parameters. Based on this flag, the driver resolves the local QoS parameters in the following ways:

- If the **NDIS_QOS_PARAMETERS_WILLING** flag is set, the miniport driver must enable the local DCB Exchange (DCBX) Willing state. This allows the driver to be remotely configured with QoS parameters. In this case, the driver resolves its operational QoS parameters based on the remote QoS parameters.

  The miniport driver can also resolve its operational QoS parameters based on any proprietary QoS settings that are defined by the IHV. The driver can only do this for QoS parameters that are not configured remotely by the peer or locally by the operating system.

For more information about this procedure, see Receiving Remote NDIS QoS Parameters.

- If the **NDIS_QOS_PARAMETERS_WILLING** flag is not set, the miniport driver must disable the local DCBX Willing state. This allows the driver to resolve its operational QoS parameters from its local QoS parameters instead of remote QoS parameters.

  Note If the local DCBX Willing state is disabled, the miniport driver can still accept the remote QoS parameters but cannot use them to resolve its operational QoS parameters.

If the local DCBX Willing state is disabled, the miniport driver must follow these guidelines when it manages its local QoS parameters:

- The miniport driver must disable or override any local QoS parameter for which the related **NDIS_QOS_PARAMETERS_*Xxx*_CONFIGURED** flag is not set in the **NDIS_QOS_PARAMETERS.Flags** member.

  For example, the miniport driver can override an unconfigured local QoS parameter with its proprietary settings for the QoS parameter that are defined by the IHV. If there are no proprietary settings for local QoS parameters that are not specified with an **NDIS_QOS_PARAMETERS_*Xxx*_CONFIGURED** flag, the driver must disable the use of these QoS parameters on the network adapter.

  Note NDIS guarantees that both the **NDIS_QOS_PARAMETERS_ETS_CONFIGURED** and **NDIS_QOS_PARAMETERS_PFC_CONFIGURED** flags are set or cleared together.

- The miniport driver should *apply* the local QoS parameters that are contained in the **NDIS_QOS_PARAMETERS** structure when it resolves its operational NDIS QoS parameters. If the driver applies these local QoS parameters, it must not use any remote QoS parameters that it received from the remote peer.

  For more information on this procedure, see Resolving Operational NDIS QoS Parameters.

For more information about the local DCBX Willing state, see Managing the Local DCBX Willing State.

Receiving Remote NDIS QoS Parameters

Article • 03/14/2023

Remote NDIS Quality of Service (QoS) parameters are those that are received from a remote peer that the network adapter is connected to over the data link. The miniport driver discovers these parameters through the Data Center Bridging Exchange (DCBX) protocol that is specified by the IEEE 802.1Qaz draft standard.

The driver must follow these guidelines for managing remote QoS parameters:

- The miniport driver must issue an **NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE** status indication when its remote NDIS QoS parameters are either received from a peer for the first time or change later. For more information on this procedure, see Indicating Changes to the Remote NDIS QoS Parameters.

- The miniport driver can use the remote NDIS QoS parameters to resolve its operational NDIS QoS parameters only if the local Data Center Bridging Exchange (DCBX) Willing state is enabled on the network adapter. The miniport driver can also resolve its operational QoS parameters based on any proprietary QoS settings that are defined by the independent hardware vendor (IHV).

  For more information about this procedure, see Resolving Operational NDIS QoS Parameters.

  For more information about the local DCBX Willing state, see Managing the Local DCBX Willing State.

For more information about NDIS QoS parameters, see Overview of NDIS QoS Parameters.

Resolving Operational NDIS QoS Parameters

Article • 03/14/2023

Operational NDIS Quality of Service (QoS) parameters are those that the miniport driver uses for traffic prioritization over the data-link connection to a remote peer. The miniport driver derives, or *resolves*, its operational NDIS QoS parameters from one of the following:

- The local NDIS QoS parameters that are administered locally on the miniport driver. For more information about how the miniport driver obtains its local QoS parameters, see Setting Local NDIS QoS Parameters.

- The remote NDIS QoS parameters that the miniport driver receives from a remote peer on the data link. For more information about how the miniport driver obtains its remote QoS parameters, see Receiving Remote NDIS QoS Parameters.

Local, remote, and operational NDIS QoS parameters consist of the following types of data:

- Priority level and flow control settings. These settings define the IEEE 802.1p priority level and optional flow control algorithms for the transmit, or *egress*, traffic.

  For more information, see Priority Levels and Flow Control.

- Traffic selection algorithm (TSA) settings. These settings define how the network adapter selects egress traffic from its transmit queues.

  For example, the adapter could use the strict priority TSA and select egress packets based only on IEEE 802.1p priority. The adapter could also use the Enhanced Transmission Selection (ETS) TSA that moderates egress traffic among traffic classes based on their bandwidth allocation.

  For more information, see Transmission Selection Algorithms (TSAs).

- Traffic classifications that specify the assignment of IEEE 802.1p priority levels to packets that contain data which matches a classification condition, such as an EtherType or destination TCP port. For more information, see NDIS QoS Traffic Classifications.

  Note Traffic classifications are also known as "application priorities" in the IEEE 802.1 specifications.

The miniport driver resolves its operational settings from its local or remote NDIS QoS parameters by following these guidelines:

- If the local Data Center Bridging Exchange (DCBX) Willing state is enabled, the miniport driver must resolve its operational QoS parameters from its remote QoS parameters.

  For more information about how the miniport driver handles remote NDIS QoS parameters, see Receiving Remote NDIS QoS Parameters.

- If the local DCBX Willing state is disabled, the miniport driver must resolve its operational QoS parameters from its local QoS parameters.

  For more information about how the miniport driver handles local NDIS QoS parameters, see Setting Local NDIS QoS Parameters.

- The miniport driver can also resolve its operational QoS parameters based on any proprietary QoS settings that are defined by the independent hardware vendor (IHV). The driver can only do this for QoS parameters that are not configured remotely by the peer or locally by the operating system.

- The miniport driver must issue an NDIS status indication when its operational QoS parameters are either resolved for the first time or change later. For example, the driver may change its operational NDIS QoS parameters because it received a different set of QoS parameters from its remote peer. For more information on how to generate this status indication, see Indicating Changes to the Operational NDIS QoS Parameters.

For more information about the local DCBX Willing state, see Managing the Local DCBX Willing State.

For more information on the methods used to resolve QoS operational parameters, refer to the IEEE 802.1Qaz draft standard.

Querying NDIS QoS Parameters

Article • 03/14/2023

Overlying protocol and filter drivers can query the NDIS Quality of Service (QoS) parameters of a network adapter in the following ways:

- The overlying driver can query the operational NDIS QoS parameters through an object identifier (OID) query request of OID_QOS_OPERATIONAL_PARAMETERS.
- The overlying driver can query the remote NDIS QoS parameters through an OID query request of OID_QOS_REMOTE_PARAMETERS.

Note Overlying drivers cannot query the local NDIS QoS parameters.

For more information about local, remote, and operational NDIS QoS parameters, see Overview of NDIS QoS Parameters.

NDIS handles these OID requests for the miniport driver and returns the requested QoS parameters within an **NDIS_QOS_PARAMETERS** structure. NDIS handles these OID requests in the following ways:

- When NDIS handles the OID query request of OID_QOS_OPERATIONAL_PARAMETERS, it returns the operational NDIS QoS parameters that it had cached from the previous **NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE** status indication that was issued by the miniport driver. The driver issues this status indication when its operational QoS parameters are either resolved for the first time or change later.

  If the overlying driver issues the OID query request before the miniport driver issues the **NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE** status indication, NDIS returns an **NDIS_QOS_PARAMETERS** structure with all the members (with the exception of the **Header** member) set to zero.

  Note NDIS also returns this structure if the miniport driver issues an **NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE** status indication with an **NDIS_QOS_PARAMETERS** structure whose members (with the exception of the **Header** member) are set to zero.

- When NDIS handles the OID query request of OID_QOS_REMOTE_PARAMETERS, it returns the remote NDIS QoS parameters that it had cached from the previous **NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE** status indication that was issued by the miniport driver. The driver issues this status indication when its remote QoS parameters are either resolved for the first time or change later.

If the overlying driver issues the OID query request before the miniport driver issues the NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indication, NDIS returns an NDIS_QOS_PARAMETERS structure with all the members (with the exception of the **Header** member) set to zero.

Note NDIS also returns this structure if the miniport driver issues an NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indication with an NDIS_QOS_PARAMETERS structure whose members (with the exception of the **Header** member) are set to zero.

Indicating NDIS QoS Parameter Status

Article • 03/14/2023

A miniport driver that supports NDIS Quality of Service (QoS) for the IEEE 802.1 Data Center Bridging (DCB) interface must issue NDIS status indications whenever one of the following events occurs:

- The driver's operational NDIS QoS parameters are either resolved for the first time or change later.

  For more information about how to issue this type of NDIS status indication, see Indicating Changes to the Operational NDIS QoS Parameters.

- The driver's remote NDIS QoS parameters are either received from a data-link peer for the first time or change later.

  For more information about how to issue this type of NDIS status indication, see Indicating Changes to the Remote NDIS QoS Parameters.

For more information about operational and remote NDIS QoS parameters, see Overview of NDIS QoS Parameters.

Indicating Changes to the Operational NDIS QoS Parameters

Article • 03/14/2023

The miniport driver that supports NDIS Quality of Service (QoS) issues an NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indication when the driver's operational NDIS QoS parameters are resolved for the first time or when they change later. The miniport driver configures the network adapter with these operational parameters to perform QoS packet transmission.

The miniport driver must follow these guidelines for issuing an NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indication:

- The miniport driver must issue an NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indication after it has resolved its operational NDIS QoS parameters and configured the network adapter with them.

  Note If the miniport driver is provisioned with proprietary local NDIS QoS parameters in the registry, the driver must issue an NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indication during or immediately after the call to *MiniportInitializeEx*. In this case, the driver initializes an NDIS_QOS_PARAMETERS structure with its proprietary local NDIS QoS parameter settings.

  For more information about how the driver resolves its operational NDIS QoS parameter settings, see Resolving Operational NDIS QoS Parameters.

- After this initial status indication, the miniport driver should issue an NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indication when its operational NDIS QoS parameters are changed. For example, the operational NDIS QoS parameters could change under the following conditions:

  - The operational NDIS QoS parameters change because of changes to the local NDIS QoS parameters. These parameters could change through an OID method request of OID_QOS_PARAMETERS or through a management application developed by the independent hardware vendor (IHV).

  - The operational NDIS QoS parameters change because of conflicts with the QoS settings from the remote peer.

    The miniport driver uses the IEEE 802.1Qaz Data Center Bridging Exchange (DCBX) protocol to discover the QoS parameters for a remote peer. If the DCBX Willing state is enabled, the driver must resolve the differences between its QoS parameters and the remote peer's QoS parameters by following the procedures that are defined for the DCBX state engine. For more information about this state engine, refer to the IEEE 802.1Qaz draft standard.

    For more information about the local DCBX Willing state, see Managing the Local DCBX Willing State.

Note When the miniport driver receives local or remote NDIS QoS parameters, it should not issue an NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indication if there have been no changes to the operational NDIS QoS parameters. If the driver makes this unnecessary status indication, NDIS may not pass the indication to overlying drivers.

- The miniport driver should issue an NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indication when it needs to override the local NDIS QoS parameters that were used to resolve the operational NDIS QoS parameters.

  The miniport driver notifies NDIS and the overlying driver that it has overridden the local NDIS QoS parameters by issuing an NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indication. For this type of indication, the driver must set the appropriate **NDIS_QOS_PARAMETERS_*Xxx*_CHANGED** flags in the **Flags** member of the NDIS_QOS_PARAMETERS structure to specify the reason for overriding the local NDIS QoS parameters.

  For more information on how the miniport driver manages the local QoS parameters, see Setting Local NDIS QoS Parameters.

  For more information on how the miniport driver resolves its operational QoS parameters, see Resolving Operational NDIS QoS Parameters.

Note The miniport driver must issue NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indications if its NDIS QoS capabilities are currently enabled through the ***QOS** keyword standardized INF keyword. For more information, see Standardized INF Keywords for NDIS QoS.

Guidelines for Issuing the NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE Status Indication

The miniport driver follows these steps when it issues the NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indication:

1. The miniport driver allocates a buffer that is large enough to contain the following:

   - An NDIS_QOS_PARAMETERS structure that contains the NDIS QoS configuration settings as well as global operational parameters for the NDIS QoS traffic classes.

   - An array of NDIS_QOS_CLASSIFICATION_ELEMENT structures. Each of these structures specifies a traffic classification as defined by a packet data pattern (*condition*) and associated IEEE 802.1p priority level (*action*). If the network adapter finds a pattern in the transmit, or *egress*, packet that matches a condition, it assigns the associated priority level to the packet. The adapter also applies the other NDIS QoS policies to the packet based on the priority level.

2. The miniport initializes the NDIS_QOS_PARAMETERS structure with the operational NDIS QoS parameters. The driver must provide the complete set of operational parameters, including those parameters that may not be configured on the network adapter.

When the miniport driver initializes the **Header** member, it sets the **Type** member of **Header** to NDIS_OBJECT_TYPE_QOS_PARAMETERS. The miniport driver sets the **Revision** member of **Header** to NDIS_QOS_PARAMETERS_REVISION_1 and the **Size** member to NDIS_SIZEOF_QOS_PARAMETERS_REVISION_1.

The miniport driver sets the appropriate **NDIS_QOS_PARAMETERS_*Xxx*_CHANGED** flags in the **Flags** member if the corresponding members contain data that has changed since the miniport driverissued an NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indication.

Note Setting the **NDIS_QOS_PARAMETERS_*Xxx*_CHANGED** flags is optional. NDIS always assumes that the members of the NDIS_QOS_PARAMETERS are current even if they have not changed from the previous NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE status indication.

For more information on how to set the **Flags** member, see Guidelines for Setting the **Flags** Member.

3. The miniport driver initializes an NDIS_QOS_CLASSIFICATION_ELEMENT structure for each traffic classification from the operational NDIS QoS parameters. The driver adds these elements at the end of the NDIS_QOS_PARAMETERS structure in the buffer.

   Note The miniport driver must not set the NDIS_QOS_CLASSIFICATION_ENFORCED_BY_MINIPORT flag in the **Flags** member of any NDIS_QOS_CLASSIFICATION_ELEMENT structures.

   The driver sets the **NumClassificationElements** member of the NDIS_QOS_PARAMETERS structure to the number of classification elements in the array. The driver sets the **FirstClassificationElementOffset** member to the byte offset of the first element from the start of the buffer. The driver also sets the **ClassificationElementSize** member to the length, in bytes, of each element in the array.

   Note Starting with NDIS 6.30, the miniport driver must set the **ClassificationElementSize** member to `sizeof(NDIS_QOS_CLASSIFICATION_ELEMENT)`.

4. The miniport driver initializes an NDIS_STATUS_INDICATION structure for the status indication in the following way:

   - The **StatusCode** member must be set to NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE.

   - The **StatusBuffer** member must be set to the pointer to the buffer that contains the operational NDIS QoS parameters.

   - The **StatusBufferSize** member must be set to the length, in bytes, of the buffer.

5. The miniport driver issues the status indication by calling NdisMIndicateStatusEx. The driver must pass a pointer to the NDIS_STATUS_INDICATION structure to the *StatusIndication* parameter.

Guidelines for Setting the Flags Member

The miniport driver sets the following flags in the **Flags** member of the NDIS_QOS_PARAMETERS structure to specify which operational NDIS QoS parameters have been configured or changed on the network adapter:

NDIS_QOS_PARAMETERS_ETS_CONFIGURED
If this flag is set, the miniport driver has configured the network adapter with the ETS parameters contained in the following members:

- **NumTrafficClasses**
- **PriorityAssignmentTable**
- **TcBandwidthAssignmentTable**
- **TsaAssignmentTable**

Note The miniport driver must support ETS in order to support NDIS QoS for DCB. However, the setting of this flag does not specify whether the network adapter supports ETS. Instead, the setting of this flag specifies only whether ETS parameters are configured on the network adapter.

NDIS_QOS_PARAMETERS_ETS_CHANGED
If this flag is set, one or more ETS parameters have changed in the following members:

- **NumTrafficClasses**
- **PriorityAssignmentTable**
- **TcBandwidthAssignmentTable**
- **TsaAssignmentTable**

NDIS_QOS_PARAMETERS_PFC_CONFIGURED
If this flag is set, the miniport driver has configured the network adapter with the PFC settings contained in the **PfcEnable** member.

Note The miniport driver must support PFC in order to support NDIS QoS for DCB. The setting of this flag does not specify whether the network adapter supports PFC. Instead, the setting of this flag specifies only whether PFC parameters are enabled on the network adapter.

NDIS_QOS_PARAMETERS_PFC_CHANGED
If this flag is set, one or more PFC settings have changed in the **PfcEnable** member.

NDIS_QOS_PARAMETERS_CLASSIFICATION_CONFIGURED
If this flag is set, the miniport driver has configured the network adapter with the QoS traffic classifications parameters specified in the following members:

- **NumClassificationElements**
- **ClassificationElementSize**
- **FirstClassificationElementOffset**

NDIS_QOS_PARAMETERS_CLASSIFICATION_CHANGED
If this flag is set, one or more QoS traffic classification parameters have changed in the following members:

- **NumClassificationElements**
- **ClassificationElementSize**
- **FirstClassificationElementOffset**

Note The **NDIS_QOS_PARAMETERS_*Xxx*_CONFIGURED** flags must be set if the NDIS_QOS_PARAMETERS structure contains NDIS QoS parameter settings. The miniport driver must set these flags regardless of whether the settings have changed. However, the driver must set the **NDIS_QOS_PARAMETERS_*Xxx*_CHANGED** flags only for those settings that have changed.

Indicating Changes to the Remote NDIS QoS Parameters

Article • 03/14/2023

The miniport driver that supports NDIS Quality of Service (QoS) issues an NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indication when its remote NDIS QoS parameters are either received from a peer for the first time or change later. The miniport driver receives these QoS parameters from a remote peer through the IEEE 802.1Qaz Data Center Bridging Exchange (DCBX) protocol.

The miniport driver must follow these guidelines for issuing an NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indication:

- If the miniport driver has not received a DCBX frame from a remote peer, it must not issue an NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indication.

- The miniport driver must issue an NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indication after it has first received the QoS settings from a remote peer.

  Note The miniport driver must issue this status indication if the network adapter receives remote QoS parameter settings from a peer before the driver's local QoS parameters are set. For more information, see Setting Local NDIS QoS Parameters.

- After this initial status indication, the miniport driver should only issue an NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indication when it determines a change in the QoS settings on the remote peer.

  Note Miniport drivers should not issue an NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indication if there have been no changes to the remote NDIS QoS parameters. If the driver does make this type of status indication, NDIS may not pass the indication to overlying drivers.

Note The miniport driver must issue NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indications if its NDIS QoS capabilities are currently enabled. Starting with Windows Server 2012, these indications allow system administrators to view NDIS QoS and Data Center Bridging (DCB) settings regardless of whether the Microsoft DCB server feature is installed.

Guidelines for Issuing the NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE

Status Indication

The miniport driver follows these steps when it issues the NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indication:

1. The miniport driver allocates a buffer that is large enough to contain the following:

    - An NDIS_QOS_PARAMETERS structure that contains the NDIS QoS configuration settings as well as global operational parameters for the NDIS QoS traffic classes.

    - An array of NDIS_QOS_CLASSIFICATION_ELEMENT structures. Each of these structures specifies a traffic classification as defined by a packet data pattern (*condition*) and associated IEEE 802.1p priority level (*action*). If the network adapter finds a pattern in the transmit, or *egress*, packet that matches a condition, it assigns the associated priority level to the packet. The adapter also applies the other NDIS QoS policies to the packet based on the priority level.

2. The miniport initializes the NDIS_QOS_PARAMETERS structure with the remote NDIS QoS parameters. The driver must provide the complete set of remote parameters that were received from the DCBX frame sent by the remote peer.

    When the miniport driver initializes the **Header** member, it sets the **Type** member of **Header** to NDIS_OBJECT_TYPE_QOS_PARAMETERS. The miniport driver sets the **Revision** member of **Header** to NDIS_QOS_PARAMETERS_REVISION_1 and the **Size** member to NDIS_SIZEOF_QOS_PARAMETERS_REVISION_1.

    The miniport driver sets the appropriate **NDIS_QOS_PARAMETERS_*Xxx*_CHANGED** flags if the corresponding members contain data that has changed since the miniport driver previously issued an NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indication.

    Note Setting these **NDIS_QOS_PARAMETERS_*Xxx*_CHANGED** flags is optional. NDIS always assumes that the members of the NDIS_QOS_PARAMETERS are specified even if they have not changed from the previous NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indication.

    The miniport driver sets the **Flags** member to specify status information for the data that is contained in the NDIS_QOS_PARAMETERS structure members.

    For example, the miniport driver sets the appropriate **NDIS_QOS_PARAMETERS_*Xxx*_CHANGED** flags in the **Flags** member for those members which contain data that has changed since the miniport driver previously issued an NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indication.

For more information on how to set the **Flags** member, see Guidelines for Setting the **Flags** Member.

3. The miniport driver initializes an NDIS_QOS_CLASSIFICATION_ELEMENT structure for each traffic classification from the remote NDIS QoS parameters. The driver adds these elements past the end of the NDIS_QOS_PARAMETERS structure in the buffer.

   Note The miniport driver must not set the NDIS_QOS_CLASSIFICATION_ENFORCED_BY_MINIPORT flag in the **Flags** member of any NDIS_QOS_CLASSIFICATION_ELEMENT structures.

   The driver sets the **NumClassificationElements** member of the NDIS_QOS_PARAMETERS structure to the number of classification elements in the array. The driver sets the **FirstClassificationElementOffset** member to the byte offset of the first element from the start of the buffer. The driver also sets the **ClassificationElementSize** member to the length, in bytes, of each element in the array.

   Note Starting with NDIS 6.30, the miniport driver must set the **ClassificationElementSize** member to `sizeof(NDIS_QOS_CLASSIFICATION_ELEMENT)`.

4. The miniport driver initializes an NDIS_STATUS_INDICATION structure for the status indication in the following way:

   - The **StatusCode** member must be set to NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE.

   - The **StatusBuffer** member must be set to the pointer to the buffer that contains the remote NDIS QoS parameters.

   - The **StatusBufferSize** member must be set to the length, in bytes, of the buffer.

5. The miniport driver issues the status indication by calling **NdisMIndicateStatusEx**. The driver must pass a pointer to the NDIS_STATUS_INDICATION structure to the *StatusIndication* parameter.

Guidelines for Setting the Flags Member

The miniport driver sets the following flags in the **Flags** member of the NDIS_QOS_PARAMETERS structure to specify which operational NDIS QoS parameters have been configured or changed on the network adapter:

NDIS_QOS_PARAMETERS_ETS_CONFIGURED
If this flag is set, the miniport driver has configured the network adapter with the ETS parameters contained in the following members:

- **NumTrafficClasses**
- **PriorityAssignmentTable**
- **TcBandwidthAssignmentTable**
- **TsaAssignmentTable**

Note The miniport driver must support ETS in order to support NDIS QoS for DCB. However, the setting of this flag does not specify whether the network adapter supports ETS. Instead, the setting of this flag specifies only whether ETS parameters are configured on the network adapter.

NDIS_QOS_PARAMETERS_ETS_CHANGED
If this flag is set, one or more ETS parameters have changed in the following members:

- **NumTrafficClasses**
- **PriorityAssignmentTable**
- **TcBandwidthAssignmentTable**
- **TsaAssignmentTable**

NDIS_QOS_PARAMETERS_PFC_CONFIGURED
If this flag is set, the miniport driver has configured the network adapter with the PFC settings contained in the **PfcEnable** member.

Note The miniport driver must support PFC in order to support NDIS QoS for DCB. The setting of this flag does not specify whether the network adapter supports PFC. Instead, the setting of this flag specifies only whether PFC parameters are enabled on the network adapter.

NDIS_QOS_PARAMETERS_PFC_CHANGED
If this flag is set, one or more PFC settings have changed in the **PfcEnable** member.

NDIS_QOS_PARAMETERS_CLASSIFICATION_CONFIGURED
If this flag is set, the miniport driver has configured the network adapter with the QoS traffic classifications parameters specified in the following members:

- **NumClassificationElements**
- **ClassificationElementSize**
- **FirstClassificationElementOffset**

NDIS_QOS_PARAMETERS_CLASSIFICATION_CHANGED
If this flag is set, one or more QoS traffic classification parameters have changed in the

following members:

- **NumClassificationElements**
- **ClassificationElementSize**
- **FirstClassificationElementOffset**

Note The **NDIS_QOS_PARAMETERS_*Xxx*_CONFIGURED** flags must be set if the NDIS_QOS_PARAMETERS structure contains NDIS QoS parameter settings. The miniport driver must set these flags regardless of whether the settings have changed. However, the driver must only set the **NDIS_QOS_PARAMETERS_*Xxx*_CHANGED** flags for those settings that have changed.

Guidelines for Indicating Invalid Remote NDIS QoS Parameters

The miniport driver must invalidate its remote QoS parameters if the following conditions are true:

- The time-to-live (TTL) value expires for the remote QoS parameters.

  Note DCBX is carried over the Link Layer Discovery Protocol (LLDP) protocol as specified in the IEEE 802.1AB-2005 standard. LLDP frames always contain a TTL field.

- Another data-link peer sends a DCBX frame before the TTL value expires. This scenario is known as a *multi-peer* condition. DCBX requires that the miniport driver maintain only one set of remote QoS parameters that were received from a single data-link peer.

  When a multi-peer condition occurs, the miniport driver must invalidate all of the remote QoS parameters until the TTL value expires for all of the received DCBX frames.

When the miniport driver invalidates its remote NDIS QoS parameters, it must follow these steps when it issues the NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE status indication:

1. Because the miniport driver is not reporting any valid remote NDIS QoS parameters, it must first fill an NDIS_QOS_PARAMETERS structure with zeros.

   When the miniport driver initializes the **Header** member of this structure, it sets the **Type** member of **Header** to NDIS_OBJECT_TYPE_QOS_PARAMETERS. The miniport driver sets the **Revision** member of **Header** to NDIS_QOS_PARAMETERS_REVISION_1 and the **Size** member to NDIS_SIZEOF_QOS_PARAMETERS_REVISION_1.

The miniport driver sets the appropriate **NDIS_QOS_PARAMETERS_*Xxx*_CHANGED** flags in the **Flags** member.

2. The miniport driver initializes an NDIS_STATUS_INDICATION structure for the status indication in the following way:

   - The **StatusCode** member must be set to NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE.

   - The **StatusBuffer** member must be set to the address of the NDIS_QOS_PARAMETERS structure.

   - The **StatusBufferSize** member must be set to `sizeof(NDIS_QOS_PARAMETERS)`.

3. The miniport driver issues the status indication by calling NdisMIndicateStatusEx. The driver must pass a pointer to the NDIS_STATUS_INDICATION structure to the *StatusIndication* parameter.

Standardized INF Keywords for NDIS QoS

Article • 03/14/2023

A standardized INF keyword is defined to enable or disable support for NDIS Quality of Service (QoS) on a miniport driver.

The INF file for the miniport driver of an adapter that supports NDIS QoS must specify the ***QOS** standardized INF keyword. After the driver is installed, administrators can update the ***QOS** keyword value in the **Advanced** property page for the adapter. For more information about advanced properties, see Specifying Configuration Parameters for the Advanced Properties Page.

Note The miniport driver is automatically restarted after a change is made in the **Advanced** property page for the adapter.

The ***QOS** INF keyword is an enumeration keyword. The following table describes the possible INF entries for the ***QOS** INF keyword. The columns in this table describe the following attributes for an enumeration keyword:

SubkeyName
The name of the keyword that you must specify in the INF file. This name also appears in the registry under the **NDI\params\** key for the network adapter.

ParamDesc
The display text that is associated with SubkeyName.

Note The independent hardware vendor (IHV) can define any descriptive text for SubkeyName.

Value
The enumeration integer value that is associated with each SubkeyName in the list.

EnumDesc
The display text that is associated with each value that appears in the menu.

SubkeyName	ParamDesc	Value	EnumDesc
***QOS**	NDIS QoS	0	QoS Disabled
		1 (Default)	QoS Enabled

When NDIS calls the miniport driver's *MiniportInitializeEx* function, the driver must do the following:

- The miniport driver must register the NDIS QoS hardware capabilities that the network adapter supports.
- The miniport driver must also read the ***QOS** keyword value in the registry to register the current status of the adapter's NDIS QoS hardware capabilities.

The miniport driver must follow these guidelines when it registers the current status of the NDIS QoS hardware capabilities:

- If the ***QOS** keyword has a value of one, the miniport driver must register all NDIS QoS hardware capabilities as currently enabled. The driver must enable its NDIS QoS hardware capabilities regardless of the following:

    - Whether the Microsoft Data Center Bridging (DCB) server feature is installed or enabled on Windows Server 2012 and later versions of Windows Server. For more information about this server feature and related components, see NDIS QoS Architecture for Data Center Bridging.
    - Whether the local Data Center Bridging Exchange (DCBX) Willing state is enabled on the network adapter. When this state is enabled, the network adapter and miniport driver can resolve its operational NDIS QoS parameters from remote NDIS QoS parameters that were received from the remote peer. For more information, see Managing the Local DCBX Willing State.

    For more information on how to register QoS hardware and current capabilities, see Registering NDIS QoS Capabilities.

    Note The miniport driver must always issue **NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE** and **NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE** status indications if its NDIS QoS hardware capabilities are currently enabled. Starting with Windows Server 2012, these status indications report on the current operational and remote QoS parameter settings, respectively. These indications allow system administrators to view NDIS QoS and DCB settings regardless of whether the Microsoft DCB server feature is installed. For more information, see Indicating NDIS QoS Parameter Status.

- If the ***QOS** keyword has a value of zero, the miniport driver must report all NDIS QoS hardware capabilities as currently disabled. In this case, the operating system will not configure the driver with NDIS QoS capabilities.

Note The driver must disable DCB and DCBX on the network adapter if the ***QOS** keyword has a value of zero.

- If the ***QOS** keyword is not present in the registry, the miniport driver must not report any NDIS QoS hardware capabilities. In this case, the operating system will not configure the driver with NDIS QoS capabilities.

  Note The driver must disable DCB and DCBX on the network adapter if the ***QOS** keyword is not present in the registry.

In addition to the ***QOS** keyword, the miniport driver must read the ***PriorityVLANTag** keyword. This keyword specifies whether the network adapter is enabled to insert the 802.1Q tags for packet priority and virtual LANs (VLANs).

The following table summarizes the relationship between the ***QOS** and ***PriorityVLANTag** keyword values.

QOS keyword setting	**PriorityVLANTag keyword setting**	***PriorityVLANTag setting description**
0 or not present	0	Packet priority & VLAN disabled
0 or not present	1	Packet priority enabled
0 or not present	2	VLAN Enabled
0 or not present	3 (Default)	Packet priority and VLAN enabled
1	0	Packet priority enabled
1	1	Packet priority enabled
1	2	Packet priority and VLAN enabled
1	3 (Default)	Packet priority and VLAN enabled

For more information about the ***PriorityVLANTag** keyword, see Enumeration Keywords.

For more information about standardized INF keywords, see Standardized INF Keywords for Network Devices.

For more information on how to register NDIS QoS capabilities, see Registering NDIS QoS Capabilities.

Initializing NDIS Timers

Article • 03/14/2023

The NDIS_TIMER_CHARACTERISTICS structure defines characteristics of a one-shot or periodic timer. Any NDIS driver can have more than one timer. Each timer object is associated with a different NetTimerCallback function that is specified in the **TimerFunction** member. NDIS calls the associated *NetTimerCallback* function when the timer expires.

To allocate and initialize a timer, your driver should call the NdisAllocateTimerObject function and provide a driver-allocated NDIS_TIMER_CHARACTERISTICS structure. The timer does not start until the driver calls the NdisSetTimerObject function.

To free a timer object, your driver should call the NdisFreeTimerObject function.

Setting and Clearing Timers

Article • 12/15/2021

After allocating and initializing a timer with the NdisAllocateTimerObject function, an NDIS 6.0 driver calls the NdisSetTimerObject function to set a timer object to fire after a specified interval or periodically.

The *DueTime* parameter of **NdisSetTimerObject** specifies the interval to elapse before a timer fires and NDIS calls the associated NetTimerCallback function. The expiration time is expressed in system time units (100-nanosecond intervals).

If the *MillisecondsPeriod* parameter of **NdisSetTimerObject** is not zero, the timer fires periodically and *MillisecondsPeriod* specifies the periodic time interval, in milliseconds, that elapses between each time a periodic timer fires and the next call to the *NetTimerCallback* function.

Your driver can call the NdisCancelTimerObject function to cancel a timer that is associated with a previous call to the **NdisSetTimerObject** function. NDIS might still call *NetTimerCallback* if the timeout has already expired before the call to **NdisCancelTimerObject**.

Servicing Timers

Article • 12/15/2021

NDIS calls the NetTimerCallback function when an NDIS 6.0 timer fires. The *FunctionContext* parameter of this function contains a pointer to a driver-supplied context area. The default value for *FunctionContext* is specified in an NDIS_TIMER_CHARACTERISTICS structure. The driver passed the structure to the NdisAllocateTimerObject function to allocate and initialize the associated timer object.

If the driver specified a non-NULL value in the *FunctionContext* parameter that is passed to the NdisSetTimerObject function, NDIS passes that value to the *FunctionContext* parameter of the *NetTimerCallback* function. Otherwise, NDIS passes the default value that is specified in the NDIS_TIMER_CHARACTERISTICS structure.

Any NDIS driver can have more than one *NetTimerCallback* function. Each such *NetTimerCallback* function must be associated with a different driver-allocated and initialized timer object.

A call to the NdisSetTimerObject function causes the *NetTimerCallback* function that is associated with the timer object to be run after a specified interval or periodically.

To stop calls to a *NetTimerCallback* function, call the NdisCancelTimerObject function. NDIS might still call *NetTimerCallback* if the timeout has already expired before the call to **NdisCancelTimerObject**.

If a *NetTimerCallback* function shares resources with other driver functions, the driver should synchronize access to those resources with a spin lock.

NDIS Configuration Functions

Article • 03/14/2023

NDIS includes the following functions to simplify driver configuration:

NdisOpenConfigurationEx

NdisMGetBusData

NdisMSetBusData

To obtain configuration information for an adapter, an NDIS miniport driver calls **NdisOpenConfigurationEx** and NdisReadConfiguration. The driver can call **NdisMGetBusData** to obtain bus-specific information. The driver can call **NdisMSetBusData** to set bus-specific information.

A protocol driver uses a registry path to an adapter name to read configuration parameters that are specific to the binding between the driver and the underlying adapter. NDIS provides the registry path in the call to the *ProtocolBindAdapterEx* function. The driver can pass this registry path to the NdisOpenProtocolConfiguration function or to direct registry calls. As an alternative, the driver can pass a *BindParameters* structure to the **NdisOpenConfigurationEx** function to read the same parameters.

NDIS Objects

Article • 03/14/2023

Components that do not have an NDIS handle use the **NdisAllocateGenericObject** function to allocate a generic NDIS object. A component must call the **NdisFreeGenericObject** function to free a generic object that was created with **NdisAllocateGenericObject**.

For information about using generic objects, see Obtaining Pool Handles.

NDIS I/O Work Items

Article • 03/14/2023

Drivers can queue I/O work item callback functions for later execution. NDIS calls the driver-specified callback function at IRQL = PASSIVE_LEVEL. This improves system performance by allowing the current function to return immediately and the driver to do work later at a lower IRQL.

NDIS 6.0 and later provide wrapper functions for the kernel I/O work item routines **IoAllocateWorkItem**, **IoFreeWorkItem**, and **IoQueueWorkItem**. Instead of the private **IO_WORKITEM** structure, NDIS uses the private **NDIS_IO_WORKITEM** structure.

NDIS 6.0 drivers call the **NdisAllocateIoWorkItem** function to allocate a work item. NDIS miniport drivers pass **NdisAllocateIoWorkItem** the adapter handle that NDIS passed to the *MiniportInitializeEx* function. **NdisAllocateIoWorkItem** gets the device object associated with the handle and passes the device object to the **IoAllocateWorkItem** routine. Filter drivers pass in a filter handle.

Note Protocol drivers cannot use **NdisAllocateIoWorkItem** because NDIS does not associate protocol drivers with device objects.

NDIS drivers call the **NdisQueueIoWorkItem** function to queue work items. NDIS work items use the **CriticalWorkQueue** queue type.

NDIS drivers must call the **NdisFreeIoWorkItem** function to free the resources associated with a work item that **NdisAllocateIoWorkItem** allocated.

Components and Files Used for Network Component Installation

Article • 05/30/2023

The following components and files are used to install network drivers:

- One or more information (INF) files
- A required class installer and optional co-installer for miniport drivers
- INetCfg for protocol and filter drivers
- An optional notify object

In addition to one or more of the above components, a vendor also optionally supplies the following files:

- One or more device driver image (.sys) files and driver library (.dll) files
- A driver catalog file
- A text-mode setup information file (txtsetup.oem)

INF files

Each network component must have an information (INF) file that the network class installer uses to install the component. Network INF files are based on the common INF file format. For more information about the INF file format, see INF File Sections and Directives.

For detailed information about creating INF files for network components, see Creating Network INF Files.

Starting with Windows OS build version 25319, you can create a network driver package that can be executed from the Driver Store. An INF that is using 'run from Driver Store' means that the INF uses **DIRID 13** to specify the location for driver package files on install.

You can't install a driver package through the network configuration interfaces and use the driver store feature on older Windows versions. To successfully install the driver package in this scenario, you need to have a minimum OS build number of 25319. For more information, see Manufacturer Section in a Network INF File.

INetCfg

Currently, NDIS protocol and filter drivers are installed by calling into the `INetCfg` family of Network Configuration Interfaces. For example, to install or remove network components, a driver writer calls into the INetCfgClassSetup interface.

Driver writers can either call into this interface programmatically or they can use netcfg.exe, which calls `INetCfg` on their behalf.

For more information about protocol driver installation, see NDIS protocol driver installation.

For more information about filter driver installation, see NDIS Filter Driver Installation.

Notify object

A software component, such as a network protocol, client, or service, can have a *notify object*. A notify object can display a user interface, notify the component of binding events so that the component can exercise some control over the binding process, and conditionally install or remove software components. On older versions of Windows you can't create a driver package with a notify object that is executed from the Driver Store. To successfully install a driver package in this scenario, you need to have a minimum OS build number of 25341. For more information about notify objects, see Notify Objects for Network Components.

A network adapter can't have a notify object. It can have co-installers. For more information about co-installers, see Writing a Co-installer.

Vendor-supplied files

A vendor supplies one or more drivers for the device, which typically consists of a driver image (.sys) file and a driver library (.dll) file. A vendor may also supply an optional driver *catalog file*. A vendor gets a digital signature by submitting its driver package to the Windows Hardware Quality Lab (WHQL) for testing and signing. WHQL returns the package with a catalog (.cat) file. The vendor must list the catalog file in the INF file for the device.

An optional text-mode setup information file (txtsetup.oem) may also be supplied by the vendor. If a network device is required to boot the machine, the driver or drivers for the device must be included in the operating system kit or the vendor of such a device must provide a txtsetup.oem file. The txtsetup.oem file contains information that is used by the system setup components to install the device during text-mode setup.

Creating Network INF Files

Article • 12/15/2021

A *network INF file* is based on the standard INF file format but also includes network-specific items, such as network-specific sections, directives, section entries, and values. The following description of network INF files assumes an understanding of base INF files. Read the description of base INF files before attempting to create a network INF file. For more information about base INF files, see INF File Sections and Directives.

A single INF file can be used to install a network component on various Windows platforms. For more information, see INF File Sections and Directives.

The INF file requirements vary by type of network component. For more information about the INF file requirements for each type of network component, see Summary of Installation Requirements for Network Components.

This section includes:

In this section

Version Section in a Network INF File

Article • 12/15/2021

The **Version** section in a network INF file is based on the generic **INF Version section**.

The **Version** section in a network INF file has the following network-specific entries:

- Class
- ClassGuid
- Signature and Operating System Entries
- PnpLockDown
- CatalogFile
- Version Section Example

Class

The **Version** section should contain a **Class** entry which identifies the class of network component that is installed by the file.

There are four network classes:

Net
Specifies a physical or virtual network adapter. NDIS intermediate drivers, which export virtual network adapters, are included in the Net class.

NetTrans
Specifies a network protocol, such as TCP/IP, IPX, a connection-oriented client, or a connection-oriented call manager.

NetClient
Specifies a network client, such as the Microsoft Client for Networks or the NetWare Client. A NetClient component is considered to be a network provider and, if it provides print services over the network, it is also considered to be a print provider.

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

NetService
Specifies a network service, such as a file service or a print service.

Note Infrared Data Association (IrDA) compliant devices are not categorized as any of the previous four network classes, even though they are installed by the network class installer. An INF file that is used to install an IrDA device should have a **Class** value of **Infrared**. This class includes both Serial-IR and Fast-IR devices.

Note Support for IrDA miniport drivers has been removed from NDIS 6.30 (Windows 8) and later.

ClassGuid

The **Version** section must contain a **ClassGuid** entry. The network class installer uses the **ClassGuid** entry to determine the class of network component being installed.

There are four network **ClassGuid** values, each of which corresponds to a network class:

Network class	ClassGuid
Net	{4D36E972-E325-11CE-BFC1-08002BE10318}
NetTrans	{4D36E975-E325-11CE-BFC1-08002BE10318}
NetClient	{4D36E973-E325-11CE-BFC1-08002BE10318}
NetService	{4D36E974-E325-11CE-BFC1-08002BE10318}

An INF file for an IrDA device should have a **ClassGuid** value of

{6bdd1fc5-81d0-bec7-08002be2092f}.

Signature and Operating System Entries

The **Signature** entry must be **$Windows NT$**.

PnpLockDown

The **PnpLockDown** entry should be set to 1 to prevent applications from directly modifying the files that your driver package's INF file specifies. For more information about this entry, see INF Version Section.

CatalogFile

The **CatalogFile** entry is used to declare an optional driver-supplied .cat file. For more information, see the Vendor-supplied files section of Components and Files Used for Network Component Installation.

Version Section Example

The following is an example of a **Version** section for an INF file that installs a network adapter:

INF

```
[Version]
Signature = $Windows NT$
Class=Net
ClassGuid = {4D36E972-E325-11CE-BFC1-08002BE10318}
Provider = %Msft%
DriverVer=06/22/2010,6.1.7065.0
PnpLockDown = 1
CatalogFile = netvmini630.cat
```

Note The **Provider** entry indicates the developer of the INF file, not the developer of the component that is installed by the INF file.

Manufacturer Section in a Network INF File

Article • 05/30/2023

The Manufacturer section in a network INF file is based on the generic **INF Manufacturer section**.

Starting with Windows OS build version 25319, you can create a network driver package that can be executed from the Driver Store. An INF that is using 'run from Driver Store' means that the INF uses **DIRID 13** to specify the location for driver package files on install.

You can't install a driver package through the network configuration interfaces and use the driver store feature on older Windows versions. To successfully install the driver package in this scenario, you need to have a minimum OS build number of 25319.

To use DIRID 13 for installation in newer builds, it's useful to create an INF Manufacturer section that includes multiple *models-section-name* entries that specify target operating system versions. Different **INF *Models* sections** can be specified for different versions of the operating system. The *models-section-name* entries indicate operating system versions with which the INF ***Models*** sections are used.

The following example shows how to create an OS-specific INF Manufacturer section using two *models-section-name* entries. OS builds 25319 and later will use `MyMfg.NT$ARCH$.10.0...25319`. All other builds will use `MyMfg.NT$ARCH$`. This example uses build 25319 because it's the first build that allows for installation using DIRID 13.

INF

```
[Manufacturer]
%ManufacturerName%=Standard,NT$ARCH$,NT$ARCH$.10.0...25319

[Standard.NT$ARCH$.10.0...25319]
%NDISPROT_Desc%=InstallA, MS_NDISPROT

[Standard.NT$ARCH$]
%NDISPROT_Desc%=InstallB, MS_NDISPROT

[InstallA]    ; OS build numbers 25319 and higher
AddReg=Inst_Ndi
Characteristics=0x0 ;
CopyFiles=CpyFiles_Sys_A

[InstallB]    ; OS build numbers lower than 25319
AddReg=Inst_Ndi
```

```
Characteristics=0x0 ;
CopyFiles=CpyFiles_Sys_B
```

For an example of how an OS-specific Manufacturer section can allow for installation using DIRID 13 for new builds and DIRID 12 for older builds, see the Sample NDIS Protocol Driver.

Models Section in a Network INF File

Article • 12/15/2021

The **Models** section in a network INF file is based on the generic **INF Models section**.

The **Models** section in an INF file contains an entry of the following format for each type of component installed by the INF file:

[*device-description*= *install-section.name*, *hw-id*[, *compatible-id*...]

For a detailed description of this entry, see Creating an INF File.

The *hw-id* (also known as the device, hardware, or component ID) for a network adapter must match the hardware ID supplied by the adapter to the PnP manager.

The *hw-id* for a network software component should consist of a provider name, followed by an underscore, and a manufacturer name or the product name, for example:

- MS_DLC
- MS_IBMDLC

A *provider name* identifies the provider of the INF file. A *manufacturer name* identifies the manufacturer of the software component. The *product name* identifies the software component.

DDInstall Section in a Network INF File

Article • 12/15/2021

A *DDInstall* section in a network INF file is based on the generic **INF DDInstall section**.

A *DDInstall* section in a network INF file has the following network-specific entries:

- Characteristics
- BusType
- Port1DeviceNumber and Port1FunctionNumber

Characteristics

Each *DDInstall* section in a network INF file must have a **Characteristics** entry. The **Characteristics** entry specifies certain characteristics of the network component being installed and may limit the user's actions regarding that component. For example, the **Characteristics** entry can specify whether the component supports a user interface, whether it can be removed, or whether it is hidden from the user.

The **Characteristics** entry can have one or more of the following values (multiple values are summed together):

Hex value	Name	Description
0x1	NCF_VIRTUAL	Component is a virtual adapter. The device is not on a physical bus, such as the PCI bus or USB, but is on the root bus. This flag is only applicable to drivers which use the Net device setup class.
0x2	NCF_SOFTWARE_ENUMERATED	Component is a software-enumerated adapter. This flag is only applicable to drivers which use the Net device setup class.

Hex value	Name	Description
0x4	NCF_PHYSICAL	Component is a physical adapter that the driver communicates with directly (for example, through the PCI bus) or indirectly (for example, through USB). Select this option if the driver supports a physical network interface.[1] This flag is only applicable to drivers which use the Net device setup class.
0x8	NCF_HIDDEN	Component should not be shown in any user interface.
0x10	NCF_NO_SERVICE	Component does not have an associated service (device driver).
0x20	NCF_NOT_USER_ REMOVABLE	Component cannot be removed by the user (for example, through Control Panel or Device Manager).
0x80	NCF_HAS_UI	Component supports a user interface (for example, the Advanced Page or a custom properties sheet).
0x400	NCF_FILTER	Component is a Filter Intermediate driver. Filter Intermediate drivers are not supported in Windows 10 or later.
0x4000	NCF_NDIS_PROTOCOL	Component requires the unload event that is provided by the binding engine to the **NetTrans** device setup class (typically used by filter Intermediate drivers which use the **NetService** device setup class).

Hex value	Name	Description
0x40000	NCF_LW_FILTER	Component is a lightweight filter driver. This flag is only applicable to drivers which use the NetService device setup class.

[1] When using Windows Server 2012 R2, at least one network interface on the system must be marked with NCF_PHYSICAL in order to be eligible for DHCPv6 client.

The following combinations of **Characteristics** values are not allowed:

- NCF_VIRTUAL, NCF_SOFTWARE_ENUMERATED, and NCF_PHYSICAL are mutually exclusive.

- NCF_NO_SERVICE cannot be used with NCF_VIRTUAL, NCF_SOFTWARE_ENUMERATED, or NCF_PHYSICAL. A virtual, software-enumerated, or physical adapter must always have an associated service (device driver).

The following is an example of a **Characteristics** entry for a physical adapter that supports a user interface:

INF

```
Characteristics = 0x84; NCF_PHYSICAL, NCF_HAS_UI
```

BusType

A *DDInstall* section for a physical network adapter must contain a **BusType** entry that specifies the type of bus (such as PCI or ISA) on which the adapter can function. The possible values for the **BusType** entry are specified by the INTERFACE_TYPE enumeration in the NDIS header file (ndis.h) as follows:

BusType Entry	Value
ISA	1
EISA	2
MicroChannel	3
TurboChannel	4
PCIBus	5

BusType Entry	Value
VMEbus	6
NuBus	7
PCMCIABus	8
Cbus	9
MPIBus	10
MPSABus	11
PNPISABus	14
PNPBus	15

Note If an adapter can function on more than one type of bus, the INF file that installs that adapter should contain a *DDInstall* section for each bus type.

For example, if an adapter can function on both the ISA bus and the PnPISA bus, the INF file for that adapter should contain a *DDInstall* section for ISA and a *DDInstall* section for PnPISA. The **BusType** entry in each such *DDInstall* section should specify the appropriate bus type for that section as follows:

INF

```
[a1.isa]
BusType=1

[a1.pnpisa]
BusType=14
```

Port1DeviceNumber and Port1FunctionNumber

The *DDInstall* section of an INF file that installs a multiport network adapter must include either a **Port1DeviceNumber** entry or a **Port1FunctionNumber** entry. Specifying such an entry causes the adapter's port information to be displayed in the **Connection Properties** dialog box (which is accessed through the **Network** and **Dial-Up Connections** folder) when you select the adapter name or icon.

- If an adapter's port numbers map sequentially to PCI device numbers, use the **Port1DeviceNumber** entry. Set **Port1DeviceNumber** to the first PCI device number in the sequence. For example, if PCI device number 4 maps to port 1, PCI device number 5 maps to port 2, PCI device number 6 maps to port 3, and so forth, use the following entry:

```INF
Port1DeviceNumber = 4
```

- If an adapter's port numbers map sequentially to PCI function numbers, use the **Port1FunctionNumber** entry. Set **Port1FunctionNumber** to the first PCI function number in the sequence. For example, if PCI function number 2 maps to port 1, PCI function number 3 maps to port 2, PCI function number 4 maps to port 3, and so forth, use the following entry:

```INF
Port1FunctionNumber = 2
```

Note It is assumed that the mapping of PCI device numbers or PCI functions to port numbers is static. It is also assumed that the adapter's ports are numbered sequentially.

The **Port1DeviceNumber** and **Port1FunctionNumber** entries are mutually exclusive. If both entries are present in a given *DDInstall* Section, only the **Port1DeviceNumber** entry is used.

Remove Section in a Network INF File

Article • 12/15/2021

Remove sections are supported for **NetClient**, **NetTrans**, and **NetService** components but not for **Net** components (adapters).

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

The network class installer does not keep track of adapter instances. A **Remove** section that removes files that are shared by other adapters or by multiple instances of an adapter could render those adapters or adapter instances inoperative. If it is necessary to remove a driver file that is used by a **Net** component, use a co-installer that keeps track of all drivers that are using the file. Such a co-installer should also track multiple instances of the same device, as well as drivers for multiple devices. For more information about co-installers, see Creating an INF File.

ControlFlags Section in a Network INF File

Article • 12/15/2021

A **ControlFlags** section in a network INF file is based on the generic **INF ControlFlags section**.

The **ControlFlags** section in a network INF file typically has one or more **ExcludeFromSelect** entries. Each **ExcludeFromSelect** entry specifies a network component that will not be displayed to the end user as an option during a manual installation.

The **ControlFlags** section in a network INF file must contain an **ExcludeFromSelect** entry for each Plug and Play adapter that it installs, and for any software component that should be added programmatically rather than manually by the user.

Adapters that are not compatible with Plug and Play must be added manually by the user and therefore should not be listed in the *ControlFlags* section. For example, non-PnP ISA adapters and EISA adapters must be manually added by the user. Note that Windows XP and later operating systems do not support non-PnP ISA adapters and EISA adapters.

Note An **ExcludeFromSelect** entry performs a different function than does the NCF_HIDDEN value of the **Characteristics** entry in the *DDInstall* section. For more information, see DDInstall Section.

An **ExcludeFromSelect** entry prevents an adapter or software component from being listed in the **Select Component for Installation** dialog box. The adapter or component, however, can still be listed in the **Connections** dialog box. The NCF_HIDDEN value prevents the adapter or component from being displayed in any part of the user interface, including the **Connections** dialog box.

Add-registry-sections in a Network INF File

Article • 12/15/2021

An INF file contains one or more *add-registry-sections* for each component that it installs. An *add-registry-section* adds keys and values to the registry. The **DDInstall** section of an INF file contains an **AddReg** directive that references one or more *add-registry-sections*. For more information about the *add-registry-section* and the **AddReg** directive, see **INF AddReg Directive**.

Adding Keys and Values to Instance Keys

One or more *add-registry-sections* can add keys and values to the instance key for a component to accomplish any of the following:

- Set static parameters for a component -- that is, configuration parameters that cannot be modified through a user interface. For more information, see Setting Static Parameters.

- Specify the number of endpoints (also known as channels, circuits or bearer channels) for a WAN adapter. For more information, see Specifying WAN Endpoints for a WAN Adapter.

- Specify keys and values for an ISDN adapter. For more information, see Specifying ISDN Keys and Values for an ISDN Adapter.

- Require the installation of another network component. For more information, see Requiring the Installation of Another Network Component.

- Specify values that support a custom properties sheet for a network adapter. For more information, see Specifying Custom Property Pages for Network Adapters.

Adding Keys and Values to a NetClient Component

An *add-registry-section* in an INF file for a **NetClient** component must add a **NetworkProvider** key to the *service* key for that component. The **NetworkProvider** key has two values: a **Name** that specifies the name of the network provider, and a **ProviderPath** that specifies the full path to the network provider DLL. For more information, see Specifying the Name and Provider Path for a NetClient Component.

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

Creating the Ndi Key

Each network INF file must contain at least one *add-registry-section* that adds an **Ndi** key for the component installed by the file. The **Ndi** key is a network-specific key that is added to the instance key for the component. The keys and values that are added to the **Ndi** key vary according to the type of network component being installed and its capabilities. The **Ndi** key specifies the following:

- **HelpText** value for a **NetTrans**, **NetClient**, or **NetService** component. For more information, see Adding a HelpText Value.

- Values for a notify object. For more information, see Adding Registry Values for a Notify Object.

- Service-related values. For more information, see Adding Service-Related Values to the Ndi Key.

- Binding interfaces. For more information, see Specifying Binding Interfaces.

- Adapter configuration parameters for the **Advanced** page. For more information, see Specifying Configuration Parameters for the Advanced Properties Page.

- Bundle membership. For more information, see Specifying Bundle Membership.

For a list of **Ndi** registry keys and values that are available in Windows 95/98/Me but not used in Windows 2000 and later versions, see Ndi Values and Keys Not Used in Windows 2000 and Later Versions.

Setting Static Parameters

Article • 12/15/2021

An INF file sets a static parameter only once. This parameter cannot be reconfigured through a properties page in the user interface.

An *add-registry-section* adds a static parameter as a REG_SZ value to a component's instance key as shown in the following example:

INF

```
[a1.staticparams.reg]
HKR,, MediaType, 0, "1"
HKR,, InternalId, 0, "232"
```

An *add-registry-section* can add any vendor-defined static parameter to a component's instance key.

Specifying WAN Endpoints for a WAN Adapter

Article • 12/15/2021

A INF file for a WAN adapter must add a **WanEndpoints** value to the instance key for the adapter. **WanEndpoints** is a REG_DWORD value that specifies the number of endpoints (also known as channels, circuits or bearer channels) that are supported by the WAN adapter. For example, the **WanEndpoints** value for a *basic rate interface* (BRI) ISDN adapter is 2, whereas the **WanEndpoints** value for a *primary rate interface* (PRI) ISDN adapter is typically 23.

Note ISDN drivers are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

The following is an example of an *add-registry-section* that adds a **WanEndpoints** value of 2 for a BRI ISDN adapter:

INF

```
[a1.reg]
HKR,, WanEndpoints, 0x00010001, 2
```

Specifying ISDN Keys and Values for an ISDN Adapter

Article • 12/15/2021

In addition to a **WanEndpoints** value, an INF file for an ISDN adapter must add (through an *add-registry-section*) the following keys and values to the instance key for the adapter. For more information, see Specifying WAN Endpoints for a WAN Adapter.

Note ISDN drivers are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

- **IsdnNumDChannels**

  Specifies the number of D-channels that are supported by the ISDN adapter.

- **IsdnAutoSwitchDetect** (Optional)

  Specifies whether the ISDN adapter supports automatic switch detection. A value of 1 indicates that the adapter supports automatic switch detection. A value of zero indicates that the adapter does not support automatic switch detection.

- **IsdnSwitchTypes**

  Specifies the switch types that are supported by the ISDN adapter.

Switch	Description
ISDN_SWITCH_AUTO	Auto Detect (North America only)
ISDN_SWITCH_ATT	ESS5 (AT&T, North America)
ISDN_SWITCH_NI1	National ISDN 1 (NI-1)
ISDN_SWITCH_NI2	National ISDN 2 (NI-2)
ISDN_SWITCH_NT1	Northern Telecom DMS 100 (NT-1)
ISDN_SWITCH_INS64	NTT INS64 (Japan)
ISDN_SWITCH_1TR6	German National (1TR6). This switch type is rarely used.
ISDN_SWITCH_VN3	French National (VN3). This switch type is rarely used.
ISDN_SWITCH_NET3	European ISDN (DSS1)
ISDN_SWITCH_DSS1	European ISDN (DSS1)

Switch	Description
ISDN_SWITCH_AUS	Australian National. This switch type is rarely used.
ISDN_SWITCH_BEL	Belgium National. This switch type is rarely used.
ISDN_SWITCH_VN4	French National (VN4)
ISDN_SWITCH_SWE	Swedish National
ISDN_SWITCH_ITA	Italian National
ISDN_SWITCH_TWN	Taiwanese

To specify multiple switch types, simply add the individual switch type values together.

The ISDN Wizard, which runs automatically during the installation of an ISDN component, allows the user to select one of the switch types specified by **IsdnSwitchTypes**. The selected switch type determines which other ISDN parameters the ISDN Wizard subsequently displays for configuration. These ISDN parameters include the phone number, the SPID (service profile identifier), the subaddress, and the multisubscriber number.

- An **IsdnNumBChannels** value and a *D-channel* key for each D-channel

  The *D-channel* key is an zero-based index from 0 through 9 that identifies the D-channel. **IsdnNumBChannels** is a REG_DWORD value added to the *D-channel* key. **IsdnNumBChannels** specifies the number of B-channels supported by the D-channel.

The following is an example of an *add-registry-section* that adds ISDN keys and values to the instance key of an ISDN adapter. Two D-channels are specified for the adapter, and two B-channels are specified for each D-channel.

INF

```
[ISDNadapter.reg]
HKR,,  WanEndPoints,          0x00010001, 4
HKR,,  IsdnNumDChannels,      0x00010001, 2
HKR,,  IsdnAutoSwitchDetect, 0x00010001, 1
HKR,,  IsdnSwitchTypes,       0x00010001, 0x00000004  ;NI1

HKR, 0, IsdnNumBChannels,     0x00010001, 2

HKR, 1, IsdnNumBChannels,     0x00010001, 2
```

The ISDN Wizard itself also adds ISDN keys and values to the instance key for an ISDN adapter, based on the parameter values specified by the user. The ISDN Wizard adds the following keys and values:

- **IsdnSwitchType**

  A REG_DWORD that indicates the switch type that was selected by the user for the ISDN adapter.

- **IsdnMultiSubscriberNumbers** value for each D-channel

  A REG_MULTI_SZ value that indicates the multisubscriber numbers that were specified by the user for the D-channel.

- A *B-channel* key and an **IsdnSpid**, **IsdnPhoneNumber**, and/or an **IsdnSubaddress** value for each B-channel:

Key or Value	Description
B-channel key	A zero-based index that identifies the B-channel. The maximum value for a *B-channel* key is one less than the **IsdnNumBchannels** value assigned to the D-channel to which the B-channel belongs.
IsdnSpid	A REG_SZ value that indicates the SPID, if any, specified by the user for the B-channel.
IsdnPhoneNumber	The phone number, if any, specified by the user for the B-channel.
IsdnSubaddress	The subaddress, if any, specified by the user for the B-channel.

The following example is an ISDN adapter's registry section layout . Each registry key is enclosed in square brackets, for example: [*KeyName*]. The ISDN keys and values that were added by the INF file for the ISDN adapter are highlighted in boldface text; the ISDN keys and values that were added by the ISDN Wizard appear in normal (nonboldface) text.

INF

```
[...Enum\emumeratorID\device-instance-id]  ;ISDN adapter instance key
WanEndpoints=4
IsdnNumDChannels=2
IsdnAutoSwitchDetect=1
IsdnSwitchType=0x4  ;National ISDN 1
```

```
[...Enum\emumeratorID\device-instance-id\0]  ;D-channel 0
IsdnNumBChannels=2
IsdnMultiSubscriberNumbers=1234567 2345678 3456789

[...Enum\emumeratorID\device-instance-id\0\0]  ;B-channel 0 for D-channel 0
IsdnSpid=00555121200
IsdnPhoneNumber=5551212
IsdnSubaddress=

[...Enum\emumeratorID\device-instance-id\0\1]  ;B-channel 1 key for D-
channel 0
IsdnSpid=00555121300
IsdnPhoneNumber=5551213
IsdnSubaddress=

[...Enum\emumeratorID\device-instance-id\1]  ;D-channel 1 key
IsdnNumBChannels=2
IsdnMultiSubscriberNumbers=8675309 2390125 7658156

[...Enum\emumeratorID\device-instance-id\1\0]  ;B-channel 0 for D-channel 1
IsdnSpid=00555987600
IsdnPhoneNumber=5559876
IsdnSubaddress=

[...Enum\emumeratorID\device-instance-id\1\0]  ;B-channel 1 for D-channel 1
IsdnSpid=00555876500
IsdnPhoneNumber=5558765
IsdnSubaddress=
```

Installing a Multiprotocol WAN NIC

Article • 12/15/2021

A multiprotocol WAN NIC provides more than one WAN protocol. For example, such a NIC might allow the user to select ISDN, Frame Relay, or channelized T1. The user selects the WAN protocol during installation of the NIC or when configuring the NIC.

> ⓘ Note
>
> ISDN capabilities have been deprecated in Windows 10 and later.

A vendor of a multiprotocol WAN NIC must provide a co-installer that installs a wizard page. (For more information about co-installers, see Writing a Co-installer). The wizard page prompts the user to select a WAN protocol:

- If the user selects ISDN, the ISDN Wizard is displayed. The ISDN Wizard prompts the user for the ISDN switch type and, depending on the selected switch type, other ISDN parameter values. For more information, see Specifying ISDN Keys and Values for an ISDN Adapter.

- If the user selects a WAN protocol other than ISDN, the Wizard adds the **ShowIsdnPages** registry value to the WAN NIC's instance key. The Wizard, in this case, sets **ShowIsdnPages** to zero to suppress the display of the ISDN Wizard. As long as **ShowIsdnPages** is zero, the ISDN Wizard is suppressed.

After the WAN NIC has been installed, the user can reconfigure the NIC, using the NIC's property page:

- If the user changes the protocol from ISDN to another WAN protocol, the property page adds the **ShowIsdnPages** registry value to the WAN NIC's instance key, if necessary. The property page sets **ShowIsdnPages** to zero to suppress the display of the ISDN Wizard.

- If the user changes the protocol to ISDN, the property page for the WAN NIC displays a dialog box that prompts the user to apply the change. When the user applies the change, the property page sets **ShowIsdnPages** to 1. When the user again opens the NIC's property page, the ISDN Wizard is displayed.

Note that the **LowerRange** binding interface for a multiprotocol WAN NIC that supports ISDN must be set to **isdn**. For more information, see Specifying Binding Interfaces. If the **ShowIsdnPages** registry value is not present and if the NIC's **LowerRange** is set to **isdn**, the ISDN Wizard is displayed during installation and configuration of the NIC. If

ShowIsdnPages is set to zero, the ISDN Wizard is not displayed. If **ShowIsdnPages** is set to 1, the ISDN Wizard is displayed during configuration of the NIC.

Requiring the Installation of Another Network Component

Article • 12/15/2021

A network component may require the installation of one or more other network components in order to function properly. A network INF file specifies each such dependency with a **RequiredAll** value. The **RequiredAll** value is added (through an *add-registry-section*) to the **Ndi** key of the network component that requires the installation of another network component.

The following example shows a **RequiredAll** entry in an *add-registry-section*:

INF

```
[ndi.reg]
HKR, Ndi, RequiredAll, 0, "component id"
```

The *component ID* is the *hw-id* of the required network component. For more information, see INF Models Section. If a network component requires the installation of more than one other network component, use one **RequiredAll** entry for each network component that must be installed, as shown in the following example:

INF

```
HKR, Ndi, RequiredAll, 0, "component1 id, component2 id"
```

Note The **RequiredAll** value should only be used to install hidden network components that cannot be installed by the user. Such components should not support a user interface. Any network components specified by **RequiredAll** cannot be removed until the network component that required their installation through **RequiredAll** is itself removed.

For example, if the INF file for component A specifies, through **RequiredAll**, a dependency on component B, component B cannot be removed until component A is removed. **RequiredAll** should therefore install only network components that are absolutely required for the operation of another network component. For example, if an INF file for a Net component (an adapter) uses **RequiredAll** to specify that TCP/IP must be installed, the user will not be able to remove TCP/IP until that adapter is removed. Since the adapter does not require TCP/IP to operate, the INF for the adapter should not use **RequiredAll** to specify a dependency on TCP/IP.

The INF file that specifies a **RequiredAll** dependency must ensure that the INF file for the required network component is present in the inf directory. Typically, this is accomplished with a **CopyINF** directive. For more information about the **CopyINF** directive, see **INF CopyINF Directive**. For more information about copying INF files, see Copying INFs.

If the installation of a network component specified by a **RequiredAll** entry fails, the installation of the network component that requires the specified component fails as well.

Specifying the Name and Provider Path for a NetClient Component

Article • 12/15/2021

An INF file that installs a NetClient component must add a **NetworkProvider** key to the *service* key for the component. The INF file adds the **NetworkProvider** key through an *add-registry-section* that is referenced by an **AddReg** directive in the *service-install* section for the component.

The **NetworkProvider** key has two values: a **Name** that specifies the name of the network provider, and a **ProviderPath** that specifies the full path to the network provider DLL.

The following is an example of an *add-registry-section* that adds the **NetworkProvider** key to the instance key for a component:

```INF
[NWCWorkstation.AddReg]
HKR, NetworkProvider, Name, 0, "NetWare or Compatible Network"
HKR, NetworkProvider, ProviderPath, 0x20000, "%11%\nwprovau.dll"
```

Note An INF file that installs a **NetClient** component does not have to update the **ProviderOrder** value under the component's ... **Control\Network\Provider\Order** key. This is done automatically by the network class installer.

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

Adding a HelpText Value

Article • 12/15/2021

The INF file for a **NetTrans**, **NetClient**, or **NetService** network component that is visible in a user interface should add a **HelpText** value (REG_SZ) to the component's **Ndi** key.

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

The **HelpText** value is a localizable string that explains how the component benefits the user. For example, the **HelpText** value for a **NetClient** component should not simply identify the client but indicate what the client allows the user to connect to. The **HelpText** value is displayed at the bottom of the **General** page of the **Connection Properties** dialog box when a component on the page is selected.

Note Net components (adapters) and IrDA components do not support a **HelpText** value.

The following is an example of an *add-registry-section* that adds a **HelpText** value to the **Ndi** key:

INF

```
[MS_Protocol.ndi_reg]
HKR, Ndi, HelpText, 0, %MyTransport_Help%
```

The **HelpText** value is a % *strkey*% token that is defined in the **Strings** section of the INF file. For more information about the **Strings** section, see the INF Strings Section.

Note For Multilingual User Interface (MUI) support, the **HelpText** value can be an indirect string in the form `@filename,resource`. For example: "@%SystemRoot%\System32\drivers\mydriver.sys,-1000". The target string is located in the specified file. The resource value identifies the specific string within the file. If the resource value is zero or greater, the number is used as an index of the string in a binary file. If the resource value is negative, it is used as a resource identifier in a resource file.

Adding Registry Values for a Notify Object

Article • 12/15/2021

A **NetTrans**, **NetClient**, or **NetService** component can have a notify object that performs one or more of the following actions:

- Displays a user interface for the component
- Notifies the component of binding events so that the component can exercise some control over the binding process
- Conditionally installs or removes software components

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

For more information about notify objects, see Notify Objects for Network Components.

Note **Net** components (adapters) do not support notify objects; therefore, these components should use a co-installer.

For more information about co-installers, see Writing a Co-installer.

If a component has a notify object, the INF file for that component must add (through an *add-registry-section*) the following values to the component's **Ndi** key:

ClsID
A REG_SZ value that specifies the GUID (globally unique identifier) for the notify object. Obtain this GUID by running the uuidgen.exe utility. For more information about this utility, see the Microsoft Windows SDK.

ComponentDll
A REG_SZ value that specifies the path to the notify object DLL. The **ComponentDll** must specify the complete path to the DLL if the DLL is not in the Windows\System32 directory.

The following is an example of an *add-registry-section* that adds **ClsID** and **ComponentDll** values to the **Ndi** key:

INF

```
[MS_Protocol.ndi.reg]
HKR, Ndi, ClsID, 0, "GUID"
```

```
HKR, Ndi, ComponentDll, 0, "notifyobject.dll"
```

The *DDInstall* section for a component that has a notify object must also contain a **CopyFiles** directive which references a *file-list-section* that copies the notify object DLL to the destination directory specified by the **DestinationDirs** section. For more information about the **CopyFiles** directive and **DestinationDirs** sections, see INF File Sections and Directives.

Adding Service-Related Values to the Ndi Key

Article • 12/15/2021

If a component has an associated service (device driver), the *add-registry-section* referenced by the *DDInstall* section for that component must add a **Service** value to the Ndi key. The **Service** value is a REG_SZ value that specifies the primary service associated with the component. The **Service** value must match the *ServiceName* parameter of the **AddService** directive that references the *service-install-section* for the primary service. For more information, see INF DDInstall.Services Section.

If a component has one or more associated services, the *add-registry-section* referenced by the *DDInstall* section for that component must add a **CoServices** value to the **Ndi** key. The **CoServices** value is a MULTI_SZ value that specifies all the services that the component installs, including the primary service specified by the **Service** value. The **CoServices** value is required for all **NetTrans**, **NetClient**, and **NetService** components.

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

Note **Net** components (adapters) should not have a **CoServices** value, because only one service can be associated with an adapter.

Except for shutting down services, all service-related actions are performed on the **CoServices** in the order that they are listed. For example, services are started in the order that they are listed. Services are stopped, however, in reverse order. Service-related actions for a component are performed on a service only if that service is listed in **CoServices**.

Specifying Binding Interfaces

Article • 05/16/2022

For each network component that it installs, a network INF file must specify the upper and lower binding interfaces for the component by adding the **Interfaces** key to the **Ndi** key.

The **Interfaces** key has at least two values:

UpperRange
A REG_SZ value that defines the interfaces to which the component can bind at its top edge.

LowerRange
A REG_SZ value that defines the interfaces to which the component can bind at its lower edge. For physical adapters, this interface should always be the network media, such as Ethernet, to which the adapter connects.

> ⓘ Note
>
> The **DefUpper** and **DefLower** values in Windows 95/98/Me network INF files, however, are not supported for INF files that will be used on Windows 2000 and later versions of the operating system.

The following table lists the Microsoft-supplied **UpperRange** values:

Value	Description
netbios	NetBIOS
ipx	IPX
tdi	TDI interface to TCP/IP
ndis5	NDIS 5.x (ndis2, ndis3, and ndis4 should no longer be used). This value should be specified for any non-ATM network component, such as a non-ATM adapter, that interfaces with NDIS at its upper edge.
Ndisatm	NDIS 5.x with ATM support. Specified value for any ATM network component, such as an ATM adapter, whose upper edge interfaces with NDIS

Value	Description
ndiswan	Upper edge for a WAN adapter. When specified, this value causes the operating system to automatically enable the WAN adapter for use with RAS
Ndiscowan	Upper edge for a WAN adapter over which connection-oriented NDIS runs
noupper	Upper edge for any component that does not expose an upper edge for binding; such a component typically has a private interface at its upper edge
winsock	The Windows socket interface
ndis5_atalk	Upper edge for an NDIS 5.x Net component (adapter) that binds only to an AppleTalk interface at its upper edge
ndis5_dlc	Upper edge for an NDIS 5.x Net component (adapter) that binds only to a DLC interface at its upper edge
ndis5_ip	Upper edge for an NDIS 5.x Net component (adapter) that binds only to a TCP/IP interface at its upper edge
ndis5_ipx	Upper edge for an NDIS 5.x Net component (adapter) that binds only to an IPX interface at its upper edge
ndis5_nbf	Upper edge for an NDIS 5.x Net component (adapter) that binds only to a NetBEUI interface at its upper edge
ndis5_streams	Upper edge for an NDIS 5.x Net component (adapter) that binds only to a streams interface at its upper edge. This value is obsolete for Windows XP and later operating systems.
flpp4	A mobile broadband (MB) device that supports IPv4.
flpp6	A mobile broadband (MB) device that supports IPv6.

The following table lists the Microsoft-supplied **LowerRange** values:

Value	Description
ethernet	Lower edge for an Ethernet adapter
atm	Lower edge for an ATM adapter
tokenring	Lower edge for a token ring adapter
serial	Lower edge for a serial adapter
fddi	Lower edge for an FDDI adapter
baseband	Lower edge for a baseband adapter
broadband	Lower edge for a broadband adapter
bluetooth	Lower edge for a Bluetooth adapter
arcnet	Lower edge for an Arcnet adapter
isdn	Lower edge for an ISDN adapter
localtalk	Lower edge for a LocalTalk adapter
wan	Lower edge for a WAN adapter
nolower	Lower edge for any component that does not expose a lower edge for binding
ndis5	NDIS 5.x. (ndis2, ndis3, and ndis4 should no longer be used.) For any network component whose lower edge interfaces through NDIS with non-ATM components
Ndisatm	Ndis 5.x with ATM support. For any network component whose lower edge interfaces through NDIS with ATM components
Wlan	Lower edge for a native 802.11 wireless LAN adapter.
ppip	Lower edge for a mobile broadband (MB) adapter
vwifi	Lower edge for a virtual wifi interface

The **UpperRange** and **LowerRange** values specify the types of interfaces -- not the actual components -- to which a component can bind. The binding engine binds a network component to all components that provide the specified interface at the appropriate (upper or lower) edge. For example, a protocol with a **LowerRange** of ndis5 binds to all components that have an **UpperRange** of ndis5, such as physical or virtual adapters.

> **Note**
>
> NDIS LWF drivers can't attach to adapters that have nolower in their **LowerRange** of their INF file. NDIS LWF drivers aren't allowed to have nolower in their **FilterMediaTypes**.

If an NDIS 5.x Net component (adapter) works only with one or more specific protocols, then its **UpperRange** should be assigned one or more protocol-specific values, such as ndis5_atalk, ndis5_dlc, ndis5_ip, ndis5_ipx, ndis5_nbf, or ndis5_streams. Such a net class component should not be assigned an **UpperRange** value of ndis5, because this would cause that component to bind to all protocols that provide an ndis5 lower edge.

An INF-file-writer can define and use vendor-specific **UpperRange** and **LowerRange** values for private binding interfaces. For example, if a vendor wants to bind its adapter only to its own proprietary protocol driver, the INF-file-writer could specify **XXX** for the **UpperRange** of the adapter and **XXX** for the **LowerRange** of the proprietary protocol. The Windows 2000 binding engine will bind all components that have an **UpperRange** of **XXX** (in this case, the adapter) with all components that have a **LowerRange** of **XXX** (in this case, the proprietary protocol).

The following is an example of an *add-registry-section* that adds **UpperRange** and **LowerRange** values for an ATM adapter:

INF

```
[addreg-section]
HKR, Ndi\Interfaces, UpperRange, 0, "ndisATM"
HKR, Ndi\Interfaces, LowerRange, 0, "atm"
```

Specifying Configuration Parameters for the Advanced Properties Page

Article • 12/15/2021

> ⓘ Note
>
> Prior to Windows 10, version 1703, driver upgrades and Windows updates could result in changes to INF values that the driver had previously defined in the **Advanced** properties page. Starting in Windows 10, version 1703, advanced properties that a driver specifies in its INF file persist through these updates.

An INF file that installs a Net component (adapter) can specify adapter configuration parameters for display in the **Advanced** properties page for the component. Configuration values specified by the user in the **Advanced** properties page are written to the root instance key for the component.

Note that if an adapter supports an **Advanced** properties page, the **Characteristics** entry in the *DDInstall* section for the adapter must include the NCF_HAS_UI value.

A network INF file specifies configuration parameters for display in the Advanced page through an *add-registry-section* that is referenced by the *DDInstall* section for the component. Such an *add-registry-section* adds one or more configuration subkeys to the **Ndi\params** key. The format for a configuration parameter subkey is **Ndi\params\***SubKeyName*, where *SubKeyName* is a REG_SZ value that specifies a vendor-specific parameter name. For example, the key for a parameter that specifies a transceiver type could be named **Ndi\params\TransceiverType**.

The following keywords are reserved and cannot be used as an **Ndi\params\***SubKeyName*: **BundleId**, **BusType**, **Characteristics**, **ComponentId**, **Description**, **DeviceInstanceId**, **DriverDate**, **DriverDesc**, **DriverVersion**, **InfPath**, **InfSection**, **InfSectionExt**,** *IfType** **InstallTimeStamp**, **Manufacturer**,** *MediaType, **NetCfgInstanceId, NetLuidIndex, PhysicalMediaType, **Provider, and **ProviderName*.

For each parameter subkey that is added to **Ndi\params**, the *add-registry-section* must add **ParamDesc**(parameter description) and **Type** values. The *add-registry-section* can also add **Default** and **Optional** values for the parameter and, if the parameter is numeric, **Min**, **Max**, and **Step** values. The following table describes the values that can be added to each **Ndi\params** key.

Name	Value	Description

Name	Value	Description
ParamDesc	*String*	Name displayed for the parameter on the **Advanced** page
Type	**int**, **long**, **Word**, **dword**, **edit**, or **enum**	Type of parameter: **int**, **long**, **Word**, and **dword** specify a numeric parameter; **edit** and **enum** specify a text parameter.
Default	*default value*	Default value for the parameter: for a numeric parameter, must be a numeric value (**int**, **long**, **Word**, or **dword**) that matches the specified parameter type; for a text parameter, must be a string. Default values must be specified for required parameters. Default values can also be specified for optional parameters. When a user selects the option to enter a value for an optional parameter, the default value, if specified, appears in the edit box for that parameter.
Optional	**0** or **1**	**0** required. Specify a value for the parameter or use the default value. **1** optional. Can be marked **Not Present** on the **Advanced** page.
Min	*numeric value*	Minimum value for a numeric parameter.
Max	*numeric value*	Maximum value for a numeric parameter.
Step	*numeric value*	Step (interval) between valid values for a numeric parameter. The minimum value is the starting point.

The range of values for an **enum** parameter are specified with a subkey that has the following format:

Ndi\params\*SubKeyName***\enum**

Each enumerated value must have a subkey. Each **enum** subkey specifies a numeric value (starting with zero for the first enumerated value) and a description for that value.

The following is an example of an *add-registry-section* that adds a configuration parameter named **TransType**.

INF

```
[a1.params.reg]
HKR, Ndi\params\TransType,      ParamDesc, 0, "Transceiver Type"
HKR, Ndi\params\TransType,      Type,      0, "enum"
HKR, Ndi\params\TransType,      Default,   0, "0"
HKR, Ndi\params\TransType,      Optional,  0, "0"
HKR, Ndi\params\TransType\enum, "0",       0, "Auto-Connector"
HKR, Ndi\params\TransType\enum, "1",       0, "Thick Net(AUI/DIX)"
HKR, Ndi\params\TransType\enum, "2",       0, "Thin Net (BNC/COAX)"
HKR, Ndi\params\TransType\enum, "3",       0, "Twisted-Pair (TPE)"
```

Specifying Custom Property Pages for Network Adapters

Article • 12/15/2021

If the **Advanced** property page is not suitable for displaying the configuration choices for a Net component (adapter), you can create one or more custom property pages.

To create a custom property page

1. Create a Microsoft Win32 property page. Then create a property sheet extension DLL that provides *AddPropSheetPageProc* and *ExtensionPropSheetPageProc* callback functions. For more information, see the Windows 2000 Platform SDK.

2. Use the *add-registry-section* that is referenced by the **DDInstall** section for the adapter to add the **EnumPropPages32** key to the instance key for the adapter. The **EnumPropPages32** key has two REG_SZ values: the name of the DLL that exports the *ExtensionPropSheetPageProc* function and the name of the *ExtensionPropSheetPageProc* function. The following is an example of an *add-registry-section* that adds the **EnumPropPages32** key:

   INF

   ```
   HKR, EnumPropPages32, 0, "DLL name, ExtensionPropSheetPageProc function
   name"
   ```

3. In the INF file for the adapter, include a **CopyFiles** section that copies the property sheet extension DLL to the Windows\System32 directory. For more information about the **CopyFiles** section, see INF File Sections and Directives.

4. In the **DDInstall** section for the adapter, specify NCF_HAS_UI as one of the **Characteristics** values to indicate that the adapter supports a user interface. For more information, see DDInstall Section.

5. After the user applies changes to a property page, the property sheet extension DLL must:

   - Call **SetupDiGetDeviceInstallParams**

   - Set the DI_FLAGSEX_PROPCHANGE_PENDING flag in the SP_DEVINSTALL_PARAMS structure supplied by **SetupDiGetDeviceInstallParams**

- Pass the updated SP_DEVINSTALL_PARAMS structure to **SetupDiSetDeviceInstallParams**.

  This reloads the driver so that it can read the changed parameter values.

Specifying Bundle Membership

Article • 12/15/2021

ⓘ **Note**

Bundle membership has been deprecated in Windows Vista and later.

An INF file that installs **Net** components (physical or virtual network adapters) can specify that those network adapters belong to the same bundle of adapters. Note that NDIS intermediate drivers and filter drivers, which export virtual network adapters, are included in the Net class. An NDIS driver can use adapters that it installed to balance its workload by distributing the workload over the bundle of adapters. For more information about load balancing, see Load Balancing and Failover.

To specify that an adapter belongs to a particular bundle of adapters, the INF file for the driver that installs the adapter must contain the **BundleId** keyword and a case-insensitive string value (REG_SZ). This string value identifies the driver's bundle of adapters. The registry is configured using the bundle-identifier information.

The following is an example of an *add-registry-section* in a driver's INF file that adds the **BundleId** subkey to the **Ndi\params** key and gives the **ParamDesc** (parameter description) for **BundleId** a string value of "Bundle1".

INF

```
[a1.params.reg]
HKR, Ndi\params\BundleId, ParamDesc, 0, "Bundle1"
```

Deprecated Ndi Values and Keys

Article • 12/15/2021

Important The following **Ndi** registry keys and values are no longer used in the Windows operating system. If you are migrating network drivers from Windows 95/98/Me to later versions of the operating system, do not use these values.

DeviceVxD

DevLoader

DriverDesc

InfFile

InfSelection

Ndi\CardType

Ndi\Compability

Ndi\DeviceID

Ndi\*filename*\...

Ndi\Install

Ndi\InstallInf

Ndi\Interfaces\DefLower

Ndi\Interfaces\DefUpper

Ndi\Interfaces\ExcludeAny

Ndi\Interfaces\RequireAny

Ndi\NdiInstaller

Ndi\*param-key-name***\resc**

Ndi\Params\*param-key-name***\flag**

Ndi\Params\*param-key-name***\location**

Ndi\Remove

NDIS\...

StaticVxD

Because Windows does not support **Ndi\***param-key-name***\resc** and **Ndi\Params\param-key-name\flag** values, a user cannot specify adapter resources through the **Advanced** properties page.

DDInstall.Services Section in a Network INF File

Article • 12/15/2021

A *DDInstall*.**Services** section in a network INF file is based on the generic INF DDInstall.Services section.

A *DDInstall*.**Services** section contains one or more **AddService** directives, each of which references an INF-writer-defined *service-install- section* that specifies how and when the services of particular component drivers are loaded.

A *DDInstall*.**Services** section is required in an INF file that installs a Net component (adapter); it is optional in an INF file that installs a **NetTrans**, **NetClient**, or **NetService** component.

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

An **AddService** directive in a *DDInstall*.**Services** section can also reference an *error-log-install-section* that installs an error log for a component. An error log is optional for all network components.

For more information, see INF AddService Directive.

The following is an example of a *DDInstall*.**Services** section, a *service-install-section*, an *error-log-install-section*, and an *add-registry-section* that is referenced by an **AddReg** directive in the *error-log-install-section*:

```C++
[a1.ndi.NT.Services]
AddService = a1, 2, a1.AddService, a1.AddEventLog

[a1.AddService]
DisplayName = %Adapter1.DispName%
ServiceType = 1 ;SERVICE_KERNEL_DRIVER
StartType = 2 ;SERVICE_AUTO_START
ErrorControl = 1 ;SERVICE_ERROR_NORMAL
ServiceBinary = %13%\a1.sys
LoadOrderGroup = NDIS

[a1.AddEventLog]
AddReg = a1.AddEventLog.reg

[a1.AddEventLog.reg]
```

```
HKR,,EventMessageFile,0x00020000,"%%SystemRoot%%\System32\netevent.dll"
HKR,,TypesSupported,0x00010001,7
```

The *ServiceName* parameter of the **AddService** directive, which in the above example is **a1**(the first **AddService** parameter), must match the component's **Ndi\Service** value. For more information, see Adding Service-Related Values to the Ndi Key.

NetworkProvider and PrintProvider Sections in a Network INF File

Article • 12/15/2021

NetClient components are considered to be network providers because they provide network services to user applications. The Microsoft Client for Networks and the NetWare Client are examples of **NetClient** components.

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

In addition to being a network provider, a **NetClient** component can also be a print provider. A print provider provides print services to user applications over a network.

A **NetClient** component is always installed as a network provider. An INF file that installs a **NetClient** component does not require a NetworkProvider section for that component unless at least one of the following is true:

- An alternative device name is specified for the component.

- A short name for the component is specified for use with the **net view** command. For more information, see Including a NetworkProvider Section.

An INF that installs a **NetClient** component that is a print provider must contain a **PrintProvider** section for that component. For more information, see Including a PrintProvider Section.

An INF file that installs a **NetClient** component must also contain an *add-registry-section* (referenced by a **AddReg** directive in the *service-install-section* for a component) that adds a **NetworkProvider** key to the component's **service** key. For more information, see Specifying the Name and Provider Path for a NetClient Component.

Including a NetworkProvider Section

Article • 12/15/2021

A **NetworkProvider** section specifies either a substitute device name for a **NetClient** component or a short name for use with the NetWare **net view** command, or both.

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

To create a **NetworkProvider** section, add the **NetworkProvider** extension to the *DDInstall* section for the component, as shown in the following example:

INF

```
[DDInstall] ; Install section
[DDInstall.NetworkProvider] ; NetworkProvider section
```

Specifying a Device Name

The network class installer usually creates the device name for a network provider by copying the **Ndi\Service** value for the component to the NetworkProvider key under the component's **Service** key. For more information, see Adding Service-Related Values to the Ndi Key. To specify a different device name for the component, include a **DeviceName** entry in the **NetworkProvider** section for the component, as shown in the following example:

INF

```
[DDInstall-section.NetworkProvider]
DeviceName = "nwrdr"
```

The **DeviceName** is optional and should be specified only if the **Ndi\Service** value for the component is inadequate as a device name for the network provider.

Specifying a Short Name

To specify a short name for a network provider for use with the NetWare **net view** command, include a **ShortName** entry in the **NetworkProvider** section for the component, as shown in the following example:

INF

```
[DDInstall-section.NetworkProvider]
ShortName = "nw"
```

The following is an example of a short name used with the **net view** command:

INF

```
net view /n:nw
```

The **ShortName** is easier to remember and type than the entire name of the network provider.

The **ShortName** is optional and should only be specified if needed.

Including a PrintProvider Section

Article • 12/15/2021

An INF file that installs a **NetClient** component that is a print provider must contain a **PrintProvider** section for that component.

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

To create a **PrintProvider** section, add the **PrintProvider** extension to the *DDInstall* section for the component, as shown in the following example:

C++

```
[DDInstall-section] ; Install section
[DDInstall-section.PrintProvider] ; PrintProvider section
```

The **PrintProvider** section must include the following entries:

PrintProviderName
A nonlocalized string that specifies the name of the print provider.

PrintProviderDll
The file name of the print provider DLL.

DisplayName
A localizable string that specifies the name of the print provider. The **DisplayName** can differ from the **PrintProviderName**.

The **PrintProviderName** and **PrintProviderDll** entries supply information that is used as input (in a PROVIDOR_INFO_1 structure) to the **AddPrintProvidor** function. The **AddPrintProvidor** function adds the print provider component as a print provider. For more information about the **AddPrintProvidor** function, see the Microsoft Windows SDK.

The following is an example of a **PrintProvider** section:

C++

```
[DDnstall-section.PrintProvider]
PrintProviderName = "NetWare or Compatible Network"
PrintProviderDll  = "nwprovau.dll"
DisplayName       = "%NWC_Network_Display_Name%"
```

Winsock Sections in a Network INF File

Article • 12/06/2022

An INF file for a **NetTrans** component that provides a Winsock interface must specify this Winsock dependency. Such an INF file must contain a *Winsock-install* section. To create a Winsockinstall section, add the .Winsock extension to the *DDInstall* section name for the protocol. For example, if the *DDInstall* section for a protocol is named **Ipx**, the *Winsock-install* section for that protocol must be named Ipx.Winsock.

> **Note**
>
> Winsock dependency has been deprecated in Windows 8 and later.

A *Winsock-install* section must contain an **AddSock** directive. The **AddSock** directive specifies a vendor-named section that contains values to be added to the component's **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\*TransportDriverName*\Params\Winsock** key.

The vendor-named section referenced by the **AddSock** directive must contain the following required values:

Value Name	Description
TransportService	A REG_SZ value that specifies the service name of the protocol. This must be the same as the **Ndi\Service** value for the protocol. For more information, see Adding Service-Related Values to the Ndi Key.
HelperDllName	A REG_EXPAND_SZ value that specifies the path to the Windows Sockets helper (WSH) DLL for the protocol. For more information, see WSH DLL Function Summary.
MaxSockAddrLength	A REG_DWORD value that specifies the largest valid SOCKADDR size, in bytes, for the WSH DLL
MinSockAddrLength	A REG_DWORD value that specifies the smallest valid SOCKADDR size, in bytes, for the WSH DLL

If an optional **ProviderId** for a namespace provider is specified, the following values must also be specified:

Value Name	Description
ProviderId	A REG_SZ value that specifies the Globally Unique Identifier (GUID) that identifies the namespace provider. The GUID is used as a key to all subsequent references to the namespace provider. Obtain the GUID by running the uuidgen.exe utility. For more information about this utility, see the Microsoft Windows SDK.
LibraryPath	A REG_EXPAND_SZ value that specifies the complete path to the namespace provider DLL.
DisplayString	A localizable string that specifies the name displayed for the namespace provider in the user interface.
SupportedNameSpace	A REG_DWORD value which specifies the namespace that is supported by the namespace provider.
Version	An optional REG_DWORD value that specifies the version number of the namespace provider. If this value is not specified, the default value (1) is used for the version number.

The following namespace values can be assigned to SupportedNameSpace and are defined in Winsock2.h:

Namespace	Value
NS_ALL	0
NS_SAP	1
NS_NDS	2
NS_PEER_BROWSE	3
NS_TCPIP_LOCAL	10
NS_TCPIP_HOSTS	11
NS_DNS	12
NS_NETBT	13
NS_WINS	14
NS_NBP	20

Namespace	Value
NS_MS	30
NS_STDA	31
NS_CAIRO	32
NS_X500	40
NS_NIS	41
NS_WRQ	50

For more information about namespace providers, see the Windows SDK documentation.

The following example shows Winsock sections for an IPX protocol:

INF

```
[Ipx.Winsock]
AddSock = Install.IpxWinsock

[Install.IpxWinsock]
TransportService = nwlinkipx
HelperDllName = "%%SystemRoot%%\System32\wshisn.dll"
MaxSockAddrLength = 0x10
MinSockAddrLength = 0xe
ProviderId = "GUID"
LibraryPath = "%SystemRoot%\\System32\\nwprovau.dll"
DisplayString = %NwlnkIpx_Desc%
SupportedNameSpace = 1
Version = 2
```

An INF file can remove a Winsock dependency for a protocol by including a *Winsock-remove* section. To create a *Winsock-remove* section, add the .Winsock extension to the *Remove* section name for the protocol. For example, if the *Remove* section for a protocol is named Ipx.Remove, the *Winsock-remove* section for the protocol must be named Ipx.Remove.Winsock.

The *Winsock-remove* section contains a **DelSock** directive that specifies an INF-writer-named section. The INF-writer-named section must specify the transport service to remove. If a **ProviderId** was previously registered for the protocol, the vendor-named section must also specify the **ProviderId** to remove.

The following example shows two sections that remove the Winsock dependency for an IPX protocol:

INF

```
[Ipx.Remove.Winsock]
DelSock = Remove.IpxWinsock

[Remove.IpxWinsock]

Installation Requirements for Network Adapters

Article • 12/15/2021

This topic summarizes the installation requirements for network adapters.

Note NDIS 6.0 and later drivers support a set of standardized INF keywords for network devices.

General Requirements

INF File Section	Status	Comments
Version Section	Required	**Class**= Net **ClassGuid**= {4D36E972-E325-11CE-BFC1-08002BE10318}
INF SourceDisksNames Section and **INF SourceDisksFiles Section**	Required if ...	Required if the INF file is not distributed with Windows 2000. If the INF file is distributed with Windows 2000, a **LayoutFile** entry must be specified in the **Version** section, and the **SourceDisksNames** and **SourceDisksFiles** sections are not used. No network-specific requirements.
INF DestinationDirs Section	Required	No network-specific requirements.
ControlFlags Section	Required	Must contain an **ExcludeFromSelect** entry for each Plug and Play (PnP) adapter installed by the INF file. Non-PnP adapters, such as non-PnP ISA and EISA adapters, should not be listed. Note that Windows XP and later operating systems do not support non-PnP ISA adapters and EISA adapters.
INF Manufacturer Section	Required	No network-specific requirements.
Models Section	Required	The *hw-id* must match the hardware ID supplied by the adapter to the PnP manager.

INF File Section	Status	Comments
DDInstall Section	Required	**Characteristics** entry Allowable values: NCF_VIRTUAL, NCF_SOFTWARE_ENUMERATED, NCF_PHYSICAL, NCF_MULTIPORT_INSTANCED_ADAPTER, NCF_HAS_UI, NCF_HIDDEN, NCF_NOT_USER_REMOVABLE NCF_VIRTUAL, NCF_SOFTWARE_ENUMERATED, and NCF_PHYSICAL are mutually exclusive. The **BusType** entry is required for a physical adapter. The **EisaCompressedId** entry is required for an EISA adapter. This entry specifies both an EISA Compressed ID and an adapter mask for the adapter. Windows XP and later operating systems do not support EISA adapters. A **Port1DeviceNumber** or **Port1FunctionNumber** entry is required for a multiport network adapter.
DDInstall.Services Section	Required	No network-specific requirements.

INF File Section	Status	Comments
Add-registry-sections	Required	Creating the Ndi Key Specifying service-related values Specifying Bundle Membership(only for LBFO miniport drivers) Specifying Binding Interfaces Allowable binding interfaces: **UpperRange**: ndis5, ndisatm, ndiswan, ndiscowan, noupper, ndis5_atalk, ndis5_dlc, ndis5_ip, ndis5_ipx, ndis5_nbf, ndis5_streams **LowerRange**: ethernet, atm, tokenring, serial, fddi, baseband, broadband, arcnet, isdn, localtalk, wan
	Optional	Setting static parameters for the component Requiring the Installation of Another Network Component Specifying Configuration Parameters for the Advanced Properties Page Specifying Custom Property Pages for Network Adapters
INF Strings Section	Required	No network-specific requirements.

Additional Requirements for WAN Adapters

WAN adapters have additional installation requirements that are described in the following topics:

Specifying WAN Endpoints for a WAN Adapter

Specifying ISDN Keys and Values for an ISDN Adapter

Installing a Multiprotocol WAN NIC

Note The Remove Section and Notify Objects for Network Components are not supported.

Installation Requirements for Network Protocols

Article • 12/15/2021

This topic summarizes the installation requirements for network protocols.

INF File Section	Status	Comments
Version Section	Required	**Class**= NetTrans **ClassGuid**= {4D36E975-E325-11CE-BFC1-08002BE10318}
INF SourceDisksNames Section and **INF SourceDisksFiles Section**	Required if ...	Required if the INF file is not distributed with Windows 2000. If the INF file is distributed with Windows 2000, a **LayoutFile** entry must be specified in the **Version** section, and the **SourceDisksNames** and **SourceDisksFiles** sections are not used. No network-specific requirements.
INF DestinationDirs Section	Required	No network-specific requirements.
ControlFlags Section	Optional	No network-specific requirements.
INF Manufacturer Section	Required	No network-specific requirements.
Models Section	Required	The *hw-id* should consist of a provider name followed by an underscore and a manufacturer name or the product name, for example: MS_DLC.

INF File Section	Status	Comments
DDInstall Section	Required	**Characteristics** entry Allowable values: NCF_HIDDEN NCF_NO_SERVICE NCF_NOT_USER_REMOVABLE NCF_HAS_UI
DDInstall.Services Section	Optional	No network-specific requirements.
Add-registry-sections	Required	Required: Creating the Ndi Key Specifying Binding Interfaces Allowable binding interfaces: **UpperRange**: netbios, ipx, tdi, winsock, noupper **LowerRange**: ndis5, ndisatm, nolower
	Optional	Setting static parameters for the component Requiring the Installation of Another Network Component Specifying service-related values Adding a HelpText Value Adding Registry Values for a Notify Object
Remove Section	Optional	

INF File Section	Status	Comments
Winsock Sections	Optional	For a protocol that provides a Winsock interface, a **Winsock-install** section is required and a **Winsock-remove** section is optional.
INF Strings Section	Required	No network-specific requirements.

Installation Requirements for Network Filter Drivers

Article • 12/15/2021

This topic summarizes the INF file requirements for network filter drivers. Filter drivers are supported in NDIS 6.0 and later versions. For more information about how to install filter drivers, see NDIS Filter Driver Installation.

INF File Section	Status	Comments
Version Section	Required	**Class**= NetService **ClassGuid**= {4D36E974-E325-11CE-BFC1-08002BE10318}
INF SourceDisksNames Section and **INF SourceDisksFiles Section**	Optional	No network-specific requirements.
INF DestinationDirs Section	Required	No network-specific requirements.
ControlFlags Section	Optional	No network-specific requirements.
INF Manufacturer Section	Required	No network-specific requirements.
Models Section	Required	The *hw-id* should consist of a provider name followed by an underscore and a manufacturer name or the product name (for example, MS_DLC).
DDInstall Section	Required	**Characteristics** entry: NCF_LW_FILTER (0x40000) is set. Filter drivers must not set the NCF_FILTER (0x400) flag. The values of the NCF_*Xxx* flags are defined in Netcfgx.h. For more information about NCF_*Xxx* flags, see DDInstall Section in a Network INF File. Set the **NetCfgInstanceId** entry.

INF File Section	Status	Comments
DDInstall.Services Section	Optional	No network-specific requirements.
Add-registry-sections	Required	Creating the Ndi Key The **ServiceBinary** entry in the **service-install** section of the INF file specifies the path to the binary for the filter driver. Set the **FilterType** and **FilterRunType** . See Types of Filter Drivers. Set the **UpperRange**, **LowerRange**, and **FilterMediaTypes** entries. See Specifying Filter Driver Binding Relationships. Specify the primary service name of the filter for the **CoServices** attribute. Specify the **FilterClass** to determine the order in a stack of modifying filters. See Configuring an INF File for a Modifying Filter Driver. See also Configuring an INF File for a Monitoring Filter Driver, Adding Service-Related Values to the Ndi Key, and DDInstall.Services Section in a Network INF File.
	Optional	Setting static parameters for the component Requiring the Installation of Another Network Component Adding a HelpText Value Adding Registry Values for a Notify Object
Remove Section	Optional	

INF File Section	Status	Comments
INF Strings Section	Required	No network-specific requirements.

Installation Requirements for Network MUX Intermediate Drivers

Article • 12/15/2021

This topic summarizes the installation requirements for network MUX intermediate drivers. For more information about installation requirements for MUX intermediate drivers, see Installing an Intermediate Driver.

Two INF files are required to install a network MUX intermediate driver :

- Driver protocol (**Class**= NetTrans)
- Driver device (**Class**= Net)

Protocol INF File for a Network MUX Intermediate Driver

INF File Section	Status	Comments
Version Section	Required	**Class**= NetTrans **ClassGuid**= {4D36E975-E325-11CE-BFC1-08002BE10318}
INF SourceDisksNames Section and **INF SourceDisksFiles Section**	Required if ...	Required if the INF file is not distributed with Windows 2000. If the INF file is distributed with Windows 2000, a **LayoutFile** entry must be specified in the **Version** section, and the **SourceDisksNames** and **SourceDisksFiles** sections are not used. No network-specific requirements.
INF DestinationDirs Section	Required	No network-specific requirements.
ControlFlags Section	Optional	No network-specific requirements.
INF Manufacturer Section	Required	No network-specific requirements.

INF File Section	Status	Comments
Models Section	Required	The *hw-id* should consist of a provider name followed by an underscore and a manufacturer name or the product name--for example: MS_DLC.
DDInstall Section	Required	**Characteristics** entry: NCF_HAS_UI is required. The device INF must be copied to the system INF directory, see Copying INFs.
DDInstall.Services Section	Optional	No network-specific requirements.
Add-registry-sections	Required	Creating the Ndi Key Specifying Binding Interfaces UpperRange: noupper **LowerRange**: ethernet, atm, tokenring, serial, fddi, baseband, broadband, arcnet, isdn, localtalk, wan
	Optional	Setting static parameters for the component Requiring the Installation of Another Network Component Specifying service-related values Adding a HelpText Value Adding Registry Values for a Notify Object
Remove Section	Optional	
INF Strings Section	Required	No network-specific requirements.

Device INF File for a Network MUX Intermediate Driver

INF File Section	Status	Comments
Version Section	Required	**Class**= Net **ClassGuid**= {4D36E972-E325-11CE-BFC1-08002BE10318}
ControlFlags Section	Required	This section must contain an **ExcludeFromSelect** entry for the device.
INF Manufacturer Section	Required	No network-specific requirements.
Models Section	Required	The *hw-id* should consist of a provider name followed by an underscore and a manufacturer name or the product name--for example: MS_DLC.
DDInstall Section	Required	**Characteristics** entry: NCF_VIRTUAL is required. NCF_HIDDEN and NCF_NOT_USER_REMOVABLE are optional.
DDInstall.Services Section	Required	No network-specific requirements.

INF File Section	Status	Comments
Add-registry-sections	Required	Creating the Ndi Key Specifying service-related values Specifying Binding Interfaces Allowable binding interfaces: **UpperRange**: ndis5, ndisatm, ndiswan, ndiscowan, noupper, ndis5_atalk, ndis5_dlc, ndis5_ip, ndis5_ipx, ndis5_nbf, ndis5_streams LowerRange: nolower
	Optional	Setting static parameters for the component Requiring the Installation of Another Network Component
INF Strings Section	Required	No network-specific requirements.

Installation Requirements for Network Filter Intermediate Drivers

Article • 12/15/2021

Note Filter intermediate drivers are not supported in NDIS 6.0 and later. You should use the NDIS filter driver interface instead. For more information about NDIS filter drivers, see NDIS Filter Drivers.

This topic summarizes the INF file requirements for NDIS 5.*x* network filter intermediate drivers.

Two INF files are required to install a network filter intermediate driver:

- Driver service (**Class**= NetService)
- Driver device (**Class**= Net)

Service INF File for a Network Filter Intermediate Driver

INF File Section	Status	Comments
Version Section	Required	**Class**= NetService **ClassGuid**= {4D36E974-E325-11CE-BFC1-08002BE10318}
INF SourceDisksNames Section and **INF SourceDisksFiles Section**	Required if ...	Required if the INF file is not distributed with Windows 2000. If the INF file is distributed with Windows 2000, a **LayoutFile** entry must be specified in the **Version** section, and the **SourceDisksNames** and **SourceDisksFiles** sections are not used. No network-specific requirements.
INF DestinationDirs Section	Required	No network-specific requirements.
ControlFlags Section	Optional	No network-specific requirements.

INF File Section	Status	Comments
INF Manufacturer Section	Required	No network-specific requirements.
Models Section	Required	The *hw-id* should consist of a provider name followed by an underscore and a manufacturer name or the product name--for example: MS_DLC.
DDInstall Section	Required	**Characteristics** entry: NCF_FILTER is required. NCF_HAS_UI and NCF_NO_SERVICE are optional. The device INF must be copied to the system INF directory, see Copying INFs.
DDInstall.Services Section	Optional	No network-specific requirements.
Add-registry-sections	Required	Creating the Ndi Key FilterClass, FilterDeviceInfId, FilterMediaTypes Specifying Binding Interfaces Allowable binding interfaces: UpperRange: noupper LowerRange: nolower
	Optional	Setting static parameters for the component Requiring the Installation of Another Network Component Adding a HelpText Value Adding Registry Values for a Notify Object
Remove Section	Optional	
INF Strings Section	Required	No network-specific requirements.

Device INF File for a Network Filter Intermediate Driver

INF File Section	Status	Comments
Version Section	Required	**Class**= Net **ClassGuid**= {4D36E972-E325-11CE-BFC1-08002BE10318}
ControlFlags Section	Required	This section must contain an **ExcludeFromSelect** entry for the device.
INF Manufacturer Section	Required	No network-specific requirements.
Models Section	Required	The *hw-id* should consist of a provider name followed by an underscore and a manufacturer name or the product name--for example: MS_DLC.
DDInstall Section	Required	**Characteristics** entry: NCF_VIRTUAL is required. NCF_HIDDEN and NCF_NOT_USER_REMOVABLE are optional.
DDInstall.Services Section	Required	The *ServiceName* value of the **AddService** directive must match the filter component's Service value under the **Ndi** key.
Add-registry-sections	Required	Creating the Ndi Key Specifying service-related values
	Optional	Setting static parameters for the component Requiring the Installation of Another Network Component
INF Strings Section	Required	No network-specific requirements.

Installation Requirements for Network Clients

Article • 12/15/2021

This topic summarizes the installation requirements for network clients.

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

INF File Section	Status	Comments
Version Section	Required	**Class**= NetClient **ClassGuid**= {4D36E973-E325-11CE-BFC1-08002BE10318}
INF SourceDisksNames Section and **INF SourceDisksFiles Section**	Required if ...	Required if the INF file is not distributed with Windows 2000. If the INF file is distributed with Windows 2000, a **LayoutFile** entry must be specified in the **Version** section, and the **SourceDisksNames** and **SourceDisksFiles** sections are not used. No network-specific requirements.
INF DestinationDirs Section	Required	No network-specific requirements.
ControlFlags Section	Optional	No network-specific requirements.
INF Manufacturer Section	Required	No network-specific requirements.
Models Section	Required	The *hw-id* should consist of a provider name followed by an underscore and a manufacturer name or the product name--for example: MS_DLC.

INF File Section	Status	Comments
DDInstall Section	Required	**Characteristics** entry Allowable values: NCF_HIDDEN NCF_NO_SERVICE NCF_NOT_USER_REMOVABLE NCF_HAS_UI
DDInstall.Services Section	Optional	No network-specific requirements.
Add-registry-sections	Required	Creating the Ndi Key Specifying Binding Interfaces Allowable binding interfaces: UpperRange: noupper **LowerRange**: ipx, tdi, winsock, netbios, nolower
Add-registry-sections	Optional	Setting static parameters for the component Requiring the Installation of Another Network Component Specifying service-related values Adding a HelpText Value Adding Registry Values for a Notify Object
Remove Section	Optional	
NetworkProvider and PrintProvider Sections	Required if ...	Required if an alternative device name is specified for the network client or a short name for the component is specified for use with the **net view** command.
NetworkProvider and PrintProvider Sections	Required if ...	Required if the network client is a print provider.

INF File Section	Status	Comments
INF Strings Section	Required	No network-specific requirements.

Installation Requirements for Network Services

Article • 12/15/2021

This topic summarizes the installation requirements for network services.

INF File Section	Status	Comments

Version Section	Required	Class = NetService
		ClassGuid = {4D36E974-E324-11CE-BFC1-08002BE10318}

INF SourceDisksNames Section and **INF SourceDisksFiles Section**	Required if ...	Required if the INF file is not distributed with Windows 2000. If the INF file is distributed with Windows 2000, a LayoutFile entry must be specified in the Version section, and the SourceDisksNames and SourceDisksFiles sections are not used. No network-specific requirements.
INF DestinationDirs Section	Required	No network-specific requirements.
ControlFlags Section	Optional	No network-specific requirements.
INF Manufacturer Section	Required	No network-specific requirements.
Models Section	Required	The *hw-id* should consist of a provider name followed by an underscore and a manufacturer name or the product name--for example: MS_DLC.

INF File Section	Status	Comments
DDInstall Section	Required	Characteristics entry--allowable values: NCF_HIDDEN NCF_NO_SERVICE NCF_NOT_USER_REMOVABLE NCF_HAS_UI
DDInstall.Services Section	Optional	No network-specific requirements.
Add-registry-sections	Required	Creating the Ndi Key Specifying Binding Interfaces Allowable binding interfaces: UpperRange: noupper LowerRange: ipx, tdi, winsock, netbios, nolower
	Optional	Setting static parameters for the component Requiring the Installation of Another Network Component Specifying service-related values Adding a HelpText Value Adding Registry Values for a Notify Object
Remove Section	Optional	
INF Strings Section	Required	No network-specific requirements.

Notify Objects for Network Components

Article • 12/15/2021

A *notify object* processes notifications that are sent by the network configuration subsystem to the object on behalf of a specific network component. A notify object is served up by a dynamic-link library (DLL). A notify object is used to display Property pages for a network component and to give that component programmatic control over the network configuration.

Note A network component does not generally require a notify object if both of the following conditions are true:

- A network component can be installed and removed through its information (INF) file
- Reacting to changes in network configuration is not a requirement

The following sections describe notify objects and explain how to develop them:

About Notify Objects

Creating a Notify Object

For reference information for the interface methods that support notify objects, see Notify Objects.

About Notify Objects

Article • 12/15/2021

A notify object processes notifications that the network configuration subsystem sends to the object on behalf of a specific network component. This network component owns the notify object. Network components that can own a notify object are:

- Transports such as a protocol driver
- Services such as an intermediate driver
- Clients such as a Client for Microsoft Networks

Note Network cards do not support and cannot own notify objects. Physical or virtual network cards that participate in either configuring the network or installing and uninstalling must use INF files or the device co-installer mechanism. For more information, see Writing a Co-installer.

A notify object performs the following actions:

- Exposes interface methods to the network configuration subsystem so that the network configuration subsystem can inform the notify object about the occurrence of events on which the notify object requested notification.
- Calls methods of the network configuration subsystem's public interfaces to perform actions that include but are not limited to installing and removing network devices. For more information, see Network Configuration Interfaces.

To request and receive notifications and to communicate with each other, the notify object and the network configuration subsystem implement Component Object Model (COM) interfaces.

Notify objects are COM objects that reside within dynamic-link libraries (DLLs). These DLLs are COM *component servers*. Each type of network component is associated with a *class installer* which installs specific types of network components and registers COM *class objects* that are owned by these network components. After the main install phase for network components is complete, the objects are registered. To register a COM class object, the class installer calls the object's DLL entry-point function.

Whenever the operating system installs, upgrades, or removes networking functionality, or whenever applications configure the network, the operating system or those applications must start the network configuration subsystem. After the network configuration subsystem starts, it creates an instance of a notify object, and the notify object performs particular operations.

The following topics describe the types of notifications that notify objects receive and the operations that notify objects perform:

Notify Object Diagram

Processing Notifications

Installing Network Components

Removing Network Components

Upgrading Network Components

Displaying and Changing Properties

Configuring the Network

Notify Object Diagram

Article • 12/15/2021

The following diagram shows how client applications that install or control networking call the *network configuration subsystem*. This subsystem calls network class installers to install network components and to register notify objects for those components. Notify objects call back to the subsystem to configure the network on behalf of those components that own the objects.

Notify objects for specific network components

Processing Notifications

Article • 12/15/2021

The network configuration subsystem sends notifications to notify objects at the following intervals:

- During networking setup--including operating system installation, installing networking capability on an operating system that did not previously support networking, upgrading the operating system, or uninstalling networking features
- During network configuration--including adding, removing, enabling, and disabling network components, changing network components, and changing how the network configuration subsystem binds network components together
- After an application directs the subsystem to display the properties of network components that own notify objects

To process notifications, a notify object performs the following general sequence of operations:

1. When the notify object is loaded, it reads the system registry to form a model of the current network configuration in its internal data structures.
2. After the network configuration subsystem sends notifications to the notify object about networking changes that the notify object previously requested, the notify object modifies its internal data structures to keep track of those changes.
3. When the network configuration subsystem is done sending notifications to the notify object, the subsystem calls the notify object's **INetCfgComponentControl::ApplyRegistryChanges** method to commit the changes to the system registry.

Note The notifications mentioned in the preceding sequence can also include a call to the notify object's **INetCfgComponentControl::CancelChanges** method in which case the notify object should revert back to the original network configuration. Before modifying the original network configuration, the notify object should make two copies of the configuration. The notify object can modify one copy to include changes and leave the other copy in the original condition. The notify object can use the unmodified copy when reverting back to the original network configuration.

Installing Network Components

Article • 05/30/2023

Network components are installed by the network configuration subsystem.

To create a driver package with a notify object that is executed from the Driver Store, you must have a minimum OS build number of 25341. You can't successfully install a driver package in this scenario on older versions of Windows.

To install a network component

1. The network configuration subsystem calls the class installer for the particular component type. The class installer then calls the Setup API to retrieve information from the component's INF file and to install the component.

   If the component owns a notify object, the class installer retrieves the name of the DLL that houses the notify object. This DLL appears in the component's INF file as follows:

   INF

   ```
   HKR, Ndi, ComponentDll,     0,     "notifyobject.dll"
   ```

   The class installer calls the DLL's entry-point function to register the notify object. The network configuration subsystem creates an instance of the notify object and calls the object's **INetCfgComponentControl::Initialize** method. This method initializes the object and provides access to the component and all aspects of network configuration.

2. To perform operations required to install the component, the network configuration subsystem calls the notify object's **INetCfgComponentSetup::Install** method.

   If installation of the component is unattended, the network configuration subsystem calls the notify object's **INetCfgComponentSetup::ReadAnswerFile** method. This method opens and retrieves the component's parameters from a file for unattended setup that is known as an *answer file*.

3. After the network configuration subsystem creates an instance of and initializes the notify object, the subsystem calls the notify object's **INetCfgComponentNotifyGlobal::GetSupportedNotifications** method to retrieve the types of notifications required by the object. The subsystem uses this information to send required notifications to the object. The object can use these

notifications to control aspects of networking setup and configuration that might affect the component that owns the object. For example, if the subsystem calls the **INetCfgComponentNotifyGlobal::SysNotifyComponent** method to notify the object that the subsystem installed or removed another network component, the object has the opportunity to perform operations related to the change.

After the network configuration subsystem creates an instance of and initializes the notify object, the subsystem also calls any of the methods of the notify object's INetCfgComponentNotifyBinding interface to notify the object about changes to the way the subsystem binds other network components to the component that owns the notify object.

4. When the network configuration subsystem is ready to apply the component's properties to the operating system, it calls the notify object's **INetCfgComponentControl::ApplyRegistryChanges** method to assign the component's parameters under the component's registry key. The notify object calls its component's **INetCfgComponent::OpenParamKey** method to open and retrieve the component's registry key.

5. To configure the component's driver, the network configuration subsystem calls the notify object's **INetCfgComponentControl::ApplyPnpChanges** method and passes the **INetCfgPnpReconfigCallback** interface. The notify object calls the **INetCfgPnpReconfigCallback::SendPnpReconfig** method to send configuration information to its component's driver.

For more information about the Setup API and on files for unattended setup, see the Microsoft Windows SDK.

Removing Network Components

Article • 12/15/2021

Network components are removed by the network configuration subsystem.

To remove a network component

1. The network configuration subsystem creates an instance of the notify object and calls the object's INetCfgComponentControl::Initialize method. This method initializes the object and provides access to the component and all aspects of network configuration.

2. The subsystem calls the notify object's INetCfgComponentSetup::Removing method to perform operations required to remove the component. The **Removing** method performs cleanup operations to prepare for the component's removal.

3. The subsystem calls the notify object's INetCfgComponentControl::ApplyRegistryChanges method to remove information about the network component from the registry.

Upgrading Network Components

Article • 12/15/2021

Network components are upgraded by the network configuration subsystem.

To upgrade a network component

1. The network configuration subsystem creates an instance of the notify object and calls the object's INetCfgComponentControl::Initialize method. This method initializes the object and provides access to the component and all aspects of network configuration.

2. When the operating system is installed or upgraded to a different version, the network configuration subsystem calls the notify object's INetCfgComponentSetup::Upgrade method.

3. The subsystem calls the notify object's INetCfgComponentControl::ApplyRegistryChanges method to modify information about the network component in the registry and then calls the notify object's INetCfgComponentControl::ApplyPnpChanges method and passes the INetCfgPnpReconfigCallback interface to configure the component's driver with the upgraded information.

Displaying and Changing Properties

Article • 12/15/2021

The network configuration subsystem displays Property pages for a network component and changes the component's parameters.

A component's properties can be displayed and modified from Control Panel. When you click the **Network** icon, you start the network configuration subsystem, which creates an instance of the notify object and calls the object's INetCfgComponentControl::Initialize method. This method initializes the object and provides access to the component and all aspects of network configuration.

The application calls the component's INetCfgComponent::RaisePropertyUi method to display the component's properties. The **RaisePropertyUi** method then calls the following notify object methods:

- INetCfgComponentPropertyUi::QueryPropertyUi method to determine if a specific context is appropriate to display properties for the component.

- INetCfgComponentPropertyUi::SetContext method to direct the component's notify object to display the component's properties in the specified context.

- INetCfgComponentPropertyUi::MergePropPages method to create and merge custom pages for the component's property sheet into the default set.

If the user changes one of the component's parameters on one of the custom pages, **RaisePropertyUi** calls the notify object's INetCfgComponentPropertyUi::ApplyProperties method to store the change in memory.

To apply the change, the network configuration subsystem calls the notify object's INetCfgComponentControl::ApplyRegistryChanges method to modify information about the network component in the registry. To configure the component's driver with the modified information, the network configuration subsystem calls the notify object's INetCfgComponentControl::ApplyPnpChanges method and passes the INetCfgPnpReconfigCallback interface.

Configuring the Network

Article • 12/15/2021

A notify object can provide the network component that owns it with programmatic control over network configuration.

A network component's properties can be configured from the Network Control Panel application. When you click the **Network** icon, you start the network configuration subsystem, which creates an instance of the notify object and calls the object's **INetCfgComponentControl::Initialize** method. This method initializes the object and provides access to the component and all aspects of network configuration.

After the network configuration subsystem creates an instance of and initializes the notify object, the subsystem calls the notify object's **INetCfgComponentNotifyGlobal::GetSupportedNotifications** method to retrieve the types of notifications required by the object. Using this information, the subsystem can send required notifications to the object. The object can use these notifications to control aspects of networking setup and configuration that might affect the component that owns the object. For example, if the subsystem calls the notify object's **INetCfgComponentNotifyGlobal::SysQueryBindingPath** method to notify the object that the subsystem is about to add a binding path to which other network components belong, the object has the opportunity to request that the subsystem disable that binding path. In addition, the subsystem calls any of the methods of the notify object's INetCfgComponentNotifyBinding interface. These methods notify the object about changes to the way the subsystem binds other network components to the component that owns the notify object.

Creating a Notify Object

Article • 12/15/2021

A notify object should be created for a network component if the network component requires some control over networking setup and configuration and the ability to display custom property pages that users can use to modify the component's properties.

The following topics describe how to create a notify object:

Loading the Notify Object DLL and Class Object

Defining a Notify Class

Creating and Initializing an Instance of a Notify Object

Installing, Upgrading, and Removing the Component

Creating Property Pages for the Component

Setting Context to Display Properties

Evaluating Changes to Network Configuration

Applying Component Changes to the Registry

Configuring the Component's Driver

Retrieving Network Configuration Interface Pointers

Loading the Notify Object DLL and Class Object

Article • 12/15/2021

Notify objects for network components should be implemented as Component Object Model (COM) objects. These COM objects reside in DLLs that are COM component servers. For more information about developing DLL COM servers, see the Microsoft Windows SDK.

The DLL for a particular notify object should be implemented to export a set of entry-point functions:

- A **DllMain** function to let the network configuration subsystem load the DLL into the virtual address space for the subsystem.

- **DllRegisterServer** and **DllUnregisterServer** functions to put information into the operating system registry for the DLL's class objects. The network configuration subsystem uses this registry information to locate and load a network component's notify object.

- A **DllCanUnloadNow** function to let the network configuration subsystem determine whether the DLL is in use. If the DLL is not in use, the subsystem can safely unload the DLL from memory.

In order for a notify object DLL to be a COM server, it must expose a class factory for the notify object the server supports. This class factory lets the network configuration subsystem create an instance of the notify object. The class factory should inherit from the **IClassFactory** interface. For more information about implementing classes that inherit from **IClassFactory**, see the Windows SDK.

Defining a Notify Class

Article • 12/15/2021

Notify classes must be implemented so that they inherit from the **INetCfgComponentControl** interface. However, if notify objects perform certain operations their notify classes must also be implemented to inherit from the following interfaces:

- If a notify object performs operations related to installing, upgrading, and removing the component that owns the object, the associated notify class must inherit from the **INetCfgComponentSetup** interface.

- If a notify object displays custom property pages for the component that owns the object, the associated notify class must inherit from the **INetCfgComponentPropertyUi** interface.

- If a notify object evaluates changes to the way the network configuration subsystem binds the component that owns the object to other network components, the associated notify class must inherit from the INetCfgComponentNotifyBinding interface.

- If a notify object evaluates changes to network configuration that might affect the component that owns the object, the associated notify class must inherit from the **INetCfgComponentNotifyGlobal** interface.

Certain data members within notify classes should be defined as common to all notify objects. Certain data members should be defined as specific to their component. Data members that all notify objects should define include:

- A pointer to an instance of the network component that owns the object of type **INetCfgComponent** interface. An instance of a notify object uses this pointer to access and control the component that owns the object.

- A pointer to an instance of the network configuration object of type **INetCfg** interface. An instance of a notify object uses this pointer to access all aspects of network configuration.

- Variables to store parameter information for the component that owns the notify object

- A variable that specifies the action that a notify object previously performed. Define constants to indicate the different actions that notify objects might perform. When the network configuration subsystem calls the notify object's

INetCfgComponentControl::ApplyRegistryChanges method to apply configuration changes to the registry, **ApplyRegistryChanges** uses this variable to determine how to make registry changes. For example, if a notify object previously performed operations relating to installing the component that owns the object in its INetCfgComponentSetup::Install method, **Install** should set this variable to indicate the action as install.

- A registry key of type **HKEY**. A notify object calls the INetCfgComponent::OpenParamKey method of the component that owns the object to open and retrieve the registry key that contains parameters for the component. The notify object then sets the **HKEY** member to that key.

Define a constructor and a destructor for your notify class. Also consider defining private methods that only the notify class can use.

All the **IUnknown** interface methods should be implemented for a notify class. If a notify class inherits from any of the optional interfaces noted in the preceding list, all the methods of those interfaces must be implemented. Note that E_NOTIMPL is not a valid return type for any of the methods of the notify object interfaces. If a notify object does not require an implementation for a particular method, simply implement the method to return S_OK.

Creating and Initializing an Instance of a Notify Object

Article • 12/15/2021

The network configuration subsystem must create an instance of the notify object and initialize the object before the subsystem can inform a notify object about changes to network configuration and display custom property pages for the component that owns the object.

The subsystem creates an instance of the notify object from the DLL's class factory. The class factory then calls the constructor for the notify class.

The class constructor should first assign initial values to class data members. Values that the constructor should initially assign include the following:

- The constructor should set the interface pointer to an instance of a network component, **INetCfgComponent**, to a **NULL** value.

- The constructor should set the interface pointer to an instance of the network configuration object, **INetCfg**, to a **NULL** value.

- The constructor should set the variable that specifies the action that the notify object previously performed to a constant that identifies an unknown action. For more information about this variable, see Defining a Notify Class.

After the network configuration subsystem creates an instance of the notify object, the subsystem calls the object's **INetCfgComponentControl::Initialize** method to initialize the object instance. In this call, the subsystem passes an **INetCfgComponent** interface pointer. This **INetCfgComponent** provides the notify object with an instance of the object's component that the object can use to access and control the component. In this call, the subsystem also passes an **INetCfg** interface pointer to provide the notify object with an instance of the network configuration object that the notify object uses to access all aspects of network configuration.

The **Initialize** method should assign the **INetCfgComponent** and **INetCfg** interface pointers provided by the network configuration subsystem to data members of the notify class. **Initialize** should then call:

- the **INetCfg::AddRef** method to increment the reference count of the network configuration object

- the **INetCfgComponent::AddRef** method to increment the reference count of the component that owns the notify object

No other notify object interface methods are called until **Initialize** returns.

Installing, Upgrading, and Removing the Component

Article • 12/15/2021

When the network configuration subsystem installs, upgrades, or removes a network component, the subsystem also calls the component's notify object to complete the installation, upgrade, and removal. The component's notify object can be implemented to perform operations that the component might require. For example:

- A notify object for a multiplexer for a virtual LAN can be implemented so that when the subsystem installs the multiplexer, the notify object will install virtual adapters that the multiplexer protocol binds to.

  To install a virtual adapter, the notify object calls the network configuration's INetCfgClassSetup::Install method. In this call, the notify object passes the identifier of the virtual adapter to install. The notify object can call **INetCfgClassSetup::Install**, for example, from its INetCfgComponentNotifyBinding::NotifyBindingPath or INetCfgComponentPropertyUi::ApplyProperties method.

  To complete the installation of the virtual adapter, the operating system requires the INF file for the virtual adapter. To ensure that this INF file can be located, it must be copied to the operating system when the multipexer is installed. For more information, see Copying INFs. This topic indicates that the **CopyINF** directive or a call to the **SetupCopyOEMInf** function by a co-installer or setup application can be used to copy INF files to the target system's INF directory. However, if the INF file for the multiplexer (original INF) is copied using **SetupCopyOEMInf**, then the INF file for the virtual adapter must also be copied using **SetupCopyOEMInf** because the operating system only handles a **CopyINF** directive if the original INF is not yet in the INF directory.

- The multiplexer's notify object can be implemented so that when the subsystem removes the multiplexer, the notify object will remove all virtual adapters. To remove a virtual adapter, the notify object calls the network configuration's INetCfgClassSetup::DeInstall method. In this call, the notify object passes the pointer to the **INetCfgComponent** interface of the virtual adapter. The notify object can call **INetCfgClassSetup::DeInstall**, for example, from its **INetCfgComponentNotifyBinding::NotifyBindingPath** or **INetCfgComponentPropertyUi::ApplyProperties** method.

- The component's notify object can be implemented so that when the subsystem upgrades the component, the notify object will change the order of the component's binding path. To change this order, a notify object's INetCfgComponentSetup::Upgrade method calls either the INetCfgComponentBindings::MoveBefore or the INetCfgComponentBindings::MoveAfter methods.

Creating Property Pages for the Component

Article • 12/06/2022

A notify object creates custom property pages after the network configuration subsystem calls the notify object's INetCfgComponentPropertyUi::MergePropPages method. Custom property pages can be merged into the default set of pages on the component's property sheet using the **MergePropPages** method. **MergePropPages** will return the appropriate number of default pages into which the custom pages can be merged.

To create custom property pages, **MergePropPages** calls the COM **CoTaskMemAlloc** function to allocate memory for handles to PROPSHEETPAGE structures. Each of these handles represents a property page to create. If **CoTaskMemAlloc** successfully allocates the memory for the handles, **MergePropPages** will declare and fill **PROPSHEETPAGE** structures for each property page. After **MergePropPages** fills these structures, it calls the Win32 **CreatePropertySheetPage** function for each property page. In this call, **MergePropPages** passes the address of the PROPSHEETPAGE structure to create.

A dialog-box callback function should also be implemented for each property page that **MergePropPages** creates. A dialog-box callback function processes messages that the operating system sends to the property page that is associated with that dialog-box function. To associate a property page with a dialog-box function, **MergePropPages** should point the **pfnDlgProc** member of each PROPSHEETPAGE structure for each page to the dialog-box function for the page.

A dialog-box function processes the following messages:

- The WM_INITDIALOG message, which is sent to the dialog-box function immediately before the operating system displays its associated property page. Dialog-box functions typically use this message to initialize the property page and to perform tasks that affect the appearance of the property page.

- The WM_NOTIFY message, which is sent to the dialog-box function after an event occurs in the property page. Other information sent with this message identifies what event has occurred. This event information is contained in a pointer to a NMHDR structure. Information that NMHDR can contain for a property sheet includes, for example:

  - The PSN_APPLY event, which indicates that a user clicks OK, Close, or Apply on the property page. If the user clicks OK, Close, or Apply, the dialog-box function can call the **PropSheet_Changed** macro to inform the property sheet that information in the page has changed. In this call, the dialog-box function passes handles to the property sheet and the page. The dialog-box function can call the Win32 **GetParent** function and pass the handle to the page to retrieve the handle to the property sheet.

    After the dialog-box function notifies the property sheet about the change, the network configuration subsystem calls the INetCfgComponentPropertyUi::ValidateProperties method to check the validity of all changes. If all changes are valid, the subsystem calls the notify object's INetCfgComponentPropertyUi::ApplyProperties method to cause all changes to take effect. The network configuration subsystem calls **ApplyProperties** before the operating system closes the dialog box.

    The **ApplyProperties** method can be implemented to retrieve information that the user enters and to set the information to the notify object's data members.

  - The PSN_RESET event, which indicates that the operating system is about to destroy a property page. A user might click Cancel on the property page to initiate this action. If the user clicks Cancel, the network configuration subsystem calls the INetCfgComponentPropertyUi::CancelProperties method to cause all changes to be disregarded. The network configuration subsystem calls **CancelProperties** before the dialog box is closed.

  - The PSN_KILLACTIVE event, which indicates that a property page is about to become inactive. This event occurs when a user activates another page or clicks OK.

Property-page callback functions can also be implemented for each property page that **MergePropPages** creates. A property-page callback function performs initialization and cleanup operations for the page. To associate a property page with a property-page callback function, **MergePropPages** should point the **pfnCallback** member of each PROPSHEETPAGE structure for each page to the property-page callback function for that page.

See the Microsoft Windows SDK documentation for more information about:

- creating property pages and structures, functions, and notifications for property pages

- dialog-box callback procedures, messages, and structures

Setting Context to Display Properties

Article • 12/15/2021

A notify object can set the context in which to display properties for the network component that owns the object. The notify object sets the display context after the network configuration subsystem calls the object's INetCfgComponentPropertyUi::SetContext method but before the subsystem calls the object's INetCfgComponentPropertyUi::MergePropPages method.

When the network configuration subsystem calls **SetContext**, it passes an **IUnknown** interface. **SetContext** calls the **QueryInterface** method on this **IUnknown** interface to determine the interface of the specific object that the subsystem supplied.

For example, the network configuration subsystem can supply the INetLanConnectionUiInfo interface when it calls **SetContext**. **SetContext** can use the GetDeviceGuid method of **INetLanConnectionUiInfo** to retrieve the GUID of a LAN device. The notify object can subsequently display properties for its network component in the context of this LAN device. For example, the notify object for the TCP/IP protocol can display an IP address that is associated with a particular LAN adapter in the context of that adapter. Doing so enables users to specify an IP address for that adapter.

Evaluating Changes to Network Configuration

Article • 12/15/2021

After the network configuration subsystem calls the methods of a notify object's **INetCfgComponentNotifyGlobal** and INetCfgComponentNotifyBinding interfaces, the notify object should evaluate the proposed change in network configuration that the subsystem sends and should perform operations related to the change. The methods of a notify object's **INetCfgComponentNotifyGlobal** and **INetCfgComponentNotifyBinding** interfaces should be implemented to process only the changes that affect the component that owns the object.

The following topics describe examples of how a notify object processes changes to network configuration:

Adding a Component

Changing Bindings for a Component

Adding a Component

Article • 12/15/2021

The network configuration subsystem can inform a notify object when the subsystem adds network components. After initializing a notify object, the subsystem calls the notify object's INetCfgComponentNotifyGlobal::GetSupportedNotifications method to retrieve the types of notifications required by the object. If the notify object specified that it required notification when network components are added, the subsystem calls the notify object's INetCfgComponentNotifyGlobal::SysNotifyComponent method and passes NCN_ADD to inform the notify object that the subsystem installed a network component. If the component that owns the notify object should bind to the specified component, the notify object should perform operations to facilitate the binding. For example, the following code shows how the notify object can bind its component to the specified component if the specified component is a required physical network card.

```C++
HRESULT CSample::SysNotifyComponent(DWORD dwChangeFlag,
        INetCfgComponent* pnccItem)
{
    HRESULT hr = S_OK;
    INetCfgComponentBindings *pncfgcompbind;
    // Retrieve bindings for the notify object's component (m_pncc)
    hr = m_pncc->QueryInterface(IID_INetCfgComponentBindings,
                                (LPVOID*)&pncfgcompbind);
    // Determine if notification is about adding a component
    if (SUCCEEDED(hr) && (NCN_ADD & dwChangeFlag)) {
        // Retrieve the characteristics of the added component
        DWORD dwcc;
        hr = pnccItem->GetCharacteristics(&dwcc);
        // Determine if the added component is a physical adapter
        if (SUCCEEDED(hr) && (dwcc & NCF_PHYSICAL)) {
            // Determine the component's ID
            LPWSTR pszwInfId;
            hr = pnccItem->GetId(&pszwInfId);
            if (SUCCEEDED(hr)) {
                // Compare the component's ID to the required ID
                // and if they are the same perform the binding.
                static const TCHAR c_szCompId[] = TEXT("BINDTO_NIC");
                if (!_tcsicmp(pszwInfId, c_szCompId)) {
                    hr = pncfgcompbind->BindTo(pnccItem);
                }
            }
        }
    }
    return hr;
}
```

Changing Bindings for a Component

Article • 12/15/2021

The network configuration subsystem always informs a notify object about changes in binding that affect the notify object's network component. The subsystem calls the notify object's INetCfgComponentNotifyBinding::NotifyBindingPath method and passes a value that specifies the change along with a pointer to the **INetCfgBindingPath** interface of the binding path involved in the change. If the subsystem passes NCN_DISABLE to disable the binding path that the notify object's network component shares with a specific network card, the notify object can activate the binding with another network card as shown in the following code.

C++

```
HRESULT CSample::NotifyBindingPath(DWORD dwChangeFlag,
        INetCfgBindingPath* pncbp1)
{
    INetCfgComponent *pnccLow;
    INetCfgComponentBindings *pncbind;
    IEnumNetCfgBindingPath *penumncbp;
    INetCfgBindingPath *pncbp2;
    IEnumNetCfgBindingInterface *penumncbi;
    INetCfgBindingInterface *pncbi;
    DWORD dwFlags = EBP_BELOW;
    ULONG celt = 1; // Request one enumeration element.
    HRESULT hr = S_OK;
    // Retrieve bindings for the notify object's component (m_pncc)
    hr = m_pncc->QueryInterface(IID_INetCfgComponentBindings,
                                (LPVOID*)&pncbind);
    // Determine if notification is about disabling a binding path.
    if (SUCCEEDED(hr) && (NCN_DISABLE & dwChangeFlag)) {
        // Retrieve enumerator for binding paths for the component.
        hr = pncbind->EnumBindingPaths(dwFlags, &penumncbp);
        // Reset the sequence and retrieve a binding path.
        hr = penumncbp->Reset();
        hr = penumncbp->Next(celt, &pncbp2, NULL);
        // Ensure the binding path is different.
        do {
            if (pncbp1 != pncbp2) break;
   hr = penumncbp->Skip(celt); // skip one element
            hr = penumncbp->Next(celt, &pncbp2, NULL);
        } while (SUCCEEDED(hr));
        if (SUCCEEDED(hr)) {
            // Retrieve enumerator for interfaces of the binding path.
            hr = pncbp2->EnumBindingInterfaces(&penumncbi);
            // Retrieve a binding interface for the binding path.
            hr = penumncbi->Next(celt, &pncbi, NULL);
            // Retrieve the lower network component.
            hr = pncbi->GetLowerComponent(&pnccLow);
            // If the component is a physical network card and binding
            // is currently disabled, enable binding.
            DWORD dwcc;
            hr = pnccLow->GetCharacteristics(&dwcc);
            if (SUCCEEDED(hr) && (dwcc & NCF_PHYSICAL)) {
                hr = pncbp2->IsEnabled(); // S_FALSE for disabled
                if (hr == S_FALSE)  hr = pncbp2->Enable(TRUE);
            }
        }
        else return hr;
    }
    return hr;
}
```

Applying Component Changes to the Registry

Article • 12/15/2021

After the network configuration subsystem calls a notify object's INetCfgComponentControl::ApplyRegistryChanges method, the notify object should set, modify, or delete information from the registry depending on the action previously performed by the notify object. After the notify object performs specific actions related to installing, removing, or modifying parameters of the component that owns the object, the notify object should set a data member that indicates the action performed. After the subsystem calls **ApplyRegistryChanges** to apply configuration changes to the registry, **ApplyRegistryChanges** should use this data member to determine how to make registry changes. For example:

- If a notify object previously performed operations related to installing the component that owns the object, the notify object should have set the data member that indicates the action as "install". After the subsystem calls **ApplyRegistryChanges** to apply configuration changes to the registry, **ApplyRegistryChanges** should set information about the component in the registry.

- If a notify object previously performed operations related to removing the component that owns the object, the notify object should have set the data member that indicates the action as "remove". After the subsystem calls **ApplyRegistryChanges** to apply configuration changes to the registry, **ApplyRegistryChanges** should remove information about the component from the registry.

- If a user displays one of a component's custom property pages and modifies one of the component's parameters, the component's notify object should have set the data member that indicates the action as "modify parameter". After the subsystem calls **ApplyRegistryChanges** to apply configuration changes to the registry, **ApplyRegistryChanges** should change information about the component's parameter in the registry.

To open and retrieve a component's registry key to modify information about the component, the **ApplyRegistryChanges** method should be implemented to call the component's INetCfgComponent::OpenParamKey method. To set values in the registry under the component's registry key, implement **ApplyRegistryChanges** to write registry data using Win32 functions. For example, **ApplyRegistryChanges** can call the

RegCreateKeyEx function to create a subkey to hold values, and the **RegSetValueEx** function to create and set those values.

For more information about the registry, writing data to it, and retrieving data from it, see the Microsoft Windows SDK.

Configuring the Component's Driver

Article • 12/15/2021

After the network configuration subsystem calls a notify object's INetCfgComponentControl::ApplyPnpChanges method, the notify object should send configuration information to the driver of the network component that owns the notify object. The network configuration subsystem calls **ApplyPnpChanges** after it calls the INetCfgComponentControl::ApplyRegistryChanges method and after drivers and services for the particular network component have started. In the **ApplyPnpChanges** call, the network configuration subsystem passes the INetCfgPnpReconfigCallback interface. The component's notify object can use the **INetCfgPnpReconfigCallback** interface to send configuration information to the component's driver. This driver must be either a TDI provider or an NDIS miniport driver.

The notify object can call INetCfgPnpReconfigCallback::SendPnpReconfig within its **ApplyPnpChanges** implementation to send configuration information to its component's driver. **SendPnpReconfig** passes configuration information to the driver.

Alternatively, the notify object can call the Win32 CreateFile function to open a connection to its component's driver. The notify object can call the Win32 DeviceIoControl function to send a control code along with input data directly to its component's driver.

The notify object is not required to use **INetCfgPnpReconfigCallback**. But, if the notify object uses **INetCfgPnpReconfigCallback**, a user will not be required to reboot the operating system to cause configuration changes to take effect in the driver.

Retrieving Network Configuration Interface Pointers

Article • 12/15/2021

When the network configuration subsystem initializes an instance of the notify object as described in Creating and Initializing an Instance of a Notify Object, the object receives INetCfgComponent and INetCfg interface pointers. **INetCfgComponent** points to the notify object's component interface that the object can use to access and control the component. **INetCfg** points to the root network configuration interface that the notify object can use to access all aspects of network configuration. The following code uses these **INetCfgComponent** and **INetCfg** interface pointers to retrieve other network configuration interfaces that the notify object might require.

C++

```cpp
// Using the notify object's component interface that the notify
// object received:
INetCfgComponent *pncfgcompThis, *pncfgcompUp, *pncfgcompLow;
INetCfgComponentBindings *pncfgcompbind;
IEnumNetCfgBindingPath *penumncfgbindpath;
INetCfgBindingPath *pncfgbindpath;
IEnumNetCfgBindingInterface *penumncfgbindintrfc;
INetCfgBindingInterface *pncfgbindintrfc;
HRESULT hr;
DWORD dwFlags;  // EBP_ABOVE or EBP_BELOW
ULONG celt, celtFetched; // Number of requested and returned elements

// Retrieve a pointer to INetCfgComponentBindings to control and
// retrieve information about bindings for the component.
hr = pncfgcompThis->QueryInterface(IID_INetCfgComponentBindings,
                                   (LPVOID*)&pncfgcompbind);
// Retrieve a pointer to IEnumNetCfgBindingPath to enumerate binding
// paths for the component.
hr = pncfgcompbind->EnumBindingPaths(dwFlags, &penumncfgbindpath);
// Retrieve a pointer to INetCfgBindingPath that points to one or more
// binding paths for the component.
hr = penumncfgbindpath->Next(celt, &pncfgbindpath, &celtFetched);
// Retrieve a pointer to IEnumNetCfgBindingInterface to enumerate
// the collection of binding interfaces for the binding path.
hr = pncfgbindpath->EnumBindingInterfaces(&penumncfgbindintrfc);
// Retrieve a pointer to INetCfgBindingInterface that points to one or
// more binding interfaces for the binding path.
hr = penumncfgbindintrfc->Next(celt, &pncfgbindintrfc, &celtFetched);
// Retrieve pointers to INetCfgComponent for network components
// above and below the binding interface.
hr = pcfgbindintrfc->GetUpperComponent(&pncfgcompUp);
hr = pcfgbindintrfc->GetLowerComponent(&pncfgcompLow);
```

```
// Using the root network configuration interface that the notify
// object received:
INetCfg *pnetcfg;
INetCfgLock *pncfglock;
INetCfgClass *pncfgclass;
INetCfgComponent *pncfgcompOther, *pncfgcompInstall;
INetCfgClassSetup *pncfgclsSetup
GUID *pguidClass; // For example, set to GUID_DEVCLASS_NETTRANS
IEnumNetCfgComponent *penumncfgcomp;
HWND hwndParent; // Handle to Window for selecting.
OBO_TOKEN *pOboToken; // Another component or the user installs.
DWORD dwSetupFlags, dwUpgradeFromBuildNo;

// Retrieve a pointer to INetCfgLock to obtain a lock on network
// configuration.
hr = pnetcfg->QueryInterface(IID_INetCfgLock, (LPVOID*)&pncfglock);
// Retrieve a pointer to INetCfgComponent for a specific component.
hr = pnetcfg->FindComponent(TEXT("MS_TCPIP"), &pncfgcompOther);
// Retrieve a pointer to IEnumNetCfgComponent to enumerate
// the collection of a particular type of component.
hr = pnetcfg->EnumComponents(pguidClass, &penumncfgcomp);
// Retrieve a pointer to INetCfgClass for a specific class of
// component.
hr = pnetcfg->QueryNetCfgClass(pguidClass, IID_INetCfgClass,
                              (LPVOID*)&pncfgclass);
// Retrieve a pointer to INetCfgComponent for a specific component.
hr = pncfgclass->FindComponent(TEXT("MS_TCPIP"), &pncfgcompOther);
// Retrieve a pointer to IEnumNetCfgComponent to enumerate
// the collection of a particular type of component.
hr = pncfgclass->EnumComponents(&penumncfgcomp);
// Retrieve a pointer to INetCfgComponent that points to one or
// more components for the particular type of component.
hr = penumncfgcomp->Next(celt, &pncfgcompOther, &celtFetched);
// Retrieve a pointer to INetCfgClassSetup that enables installation
// or removal of a particular type of component.
hr = pncfgclass->QueryInterface(IID_INetCfgClassSetup,
                               (LPVOID*)&pncfgclsSetup);
// Retrieve a pointer to INetCfgComponent for an installed component.
hr = pncfgclsSetup->SelectAndInstall(hwndParent, pOboToken,
                                     &pncfgcompInstall);
// Retrieve a pointer to INetCfgComponent for an installed component.
hr = pncfgclsSetup->Install(TEXT("MS_TCPIP"), pOboToken, dwSetupFlags,
                           dwUpgradeFromBuildNo, TEXT("AnswerFile"),
                    TEXT("AnswerFileSections"), &pncfgcompInstall);
```

Process for upgrading network components

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (Service Pack 1 [SP1] and later), Microsoft Windows Server 2003, and later operating systems.

The network upgrade process migrates parameter values for network components during an operating system upgrade. The network upgrade process thus eliminates the need to reconfigure upgraded network components after the new operating system is installed.

The network upgrade process upgrades network components from Microsoft Windows NT 3.51 or Windows NT 4.0 to Microsoft Windows 2000 or later versions of the operating system. The network upgrade process does not upgrade network components from Windows 2000 to later versions of the operating system.

Vendors whose network components are not released as part of Windows 2000 or later should provide upgrade support for these components by supplying the following:

- A network migration DLL that migrates the preupgrade parameter values for one or more network components.
- A netmap.inf file that maps the preupgrade device, hardware, or compatible ID of one or more network components, to the corresponding ID in the new operating system.
- Optional custom Help message files that provide information about upgrading network components.

The network upgrade process is described in the following topics:

Customizing the Network Upgrade Process

The Network Upgrade Process

Writing a Network Migration DLL

Creating a Netmap.inf File

There are two major steps involved in testing the upgrade of network components. These are described in the following topics:

Setting Up the Test System

Running the Upgrade Test and Examining the Results

Network components whose drivers are released as part of Windows 2000 or later operating systems are automatically upgraded when the operating system is installed. No additional upgrade support is required for such components.

Customizing the Network Upgrade Process

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

System administrators can customize the network upgrade process.

To customize the network upgrade process

1. Create a directory on the system for each network component to be upgraded.
2. Copy the vendor-supplied upgrade files for each network component to the appropriate directory that you created in Step 1. These files must include a netmap.inf file. NetSetup uses the netmap.inf file to identify which network components to upgrade.
3. Create a netupg.inf file that contains an **OemNetUpgradeDirs** section and place it a directory of your choice. Each line in the **OemNetUpgradeDirs** section of the netupg.inf file specifies a path to a directory created in Step 1. Each directory specified in the netupg.inf file must contain the vendor-supplied upgrade files for the network component, including a netmap.inf file.
4. Set the NET_UPGRD_INIT_FILE_DIR environment variable to the directory that contains the netupg.inf file.

During the Winnt32 phase of the network upgrade, NetSetup locates the netupg.inf file in the directory specified by the NETUPGRD_INIT_FILE_DIR environment variable. In each directory specified in the netupg.inf file, NetSetup then locates the netmap.inf file and other vendor files for the network component to be upgraded. NetSetup processes these files to upgrade the component. For more information, see The Network Upgrade Process.

Creating a Netupg.inf File

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

The netupg.inf file contains a single section called **OemNetUpgradeDirs**. Each entry in this section specifies the complete path to a directory that contains the vendor-supplied upgrade files for a non-Microsoft-supported network component. Every network component being upgraded must have a corresponding entry in the **OemNetUpgradeDirs** section.

The following is an example of a netupg.inf file:

INF

```
[OemNetUpgradeDirs]
c:\temp\adapter1
c:\temp\adapter2
c:\temp\protocol1
c:\temp\netclient1
c:\temp\netservice1
```

Each directory specified in the **OemNetUpgradeDirs** section must contain a netmap.inf file. This file, which is provided by the vendor of the network component, maps the preupgrade device, hardware or compatible ID of a network component to the corresponding ID in the upgraded operating system.

The Network Upgrade Process

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

The network upgrade process is divided into three distinct phases, which can be briefly summarized as follows:

- **Winnt32 phase**

  Winnt32.exe calls NetSetup. NetSetup writes network component-specific information to the AnswerFile and calls any vendor-supplied network migration DLLs. The DLLs write component-specific information to the AnswerFile. Winnt32.exe copies the Microsoft Windows 2000 or later files to the system being upgraded and prepares the boot sector on the system. The system then boots into text mode.

- **Text mode phase**

  Installation messages are displayed on a blue, text-based screen. Setup performs the basic Windows 2000 or later installation. The system then boots into GUI mode.

- **GUI mode phase**

  NetSetup processes the winnt.sif file, which is also known as the AnswerFile, and installs the network components. Network migration DLLs can display a user interface in which a user or system administrator can specify parameter values for network components. Either NetSetup or a network migration DLL writes a network component's preupgrade parameter values to the Windows 2000 or later registry.

The phases of the network upgrade process are described in more detail in the following topics:

Winnt32 Phase of the Network Upgrade Process

Text Mode Phase of the Network Upgrade Process

GUI Mode Phase of the Network Upgrade Process

Winnt32 Phase of the Network Upgrade Process

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

The user or system administrator starts the upgrade process by taking either of the following actions:

- Selecting the component upgrade in the user interface that is displayed after the Windows 2000 or later CD-ROM spins up
- Selecting and running \i386\winnt32.exe on the CD-ROM

If the user or system administrator has set the NETUPGRD_INIT_FILE_DIR environment variable on the system being upgraded, NetSetup searches for a netupg.inf file in the directory specified by that variable. The netupg.inf file contains only one section: **OemNetUpgradeDirs**. Each entry in this section specifies the complete path to a directory that contains the vendor-supplied upgrade files, including a netmap.inf file, for a network component. If the NETUPGRD_INIT_FILE_DIR environment variable is not set, NetSetup (netupgrd.dll) looks for netmap.inf files in its own directory.

NetSetup reads the netmap.inf files to identify the network components that do not have built-in upgrade support. If NetSetup is running in unattended mode, it displays a wizard; however, the user or system administrator cannot use the wizard. If NetSetup is not running in unattended mode, the wizard displays a list of the network components that do not have built-in upgrade support.

Using the wizard, a user or system administrator can:

- Click **Cancel** to abort the installation of the operating system.
- Click **Next** to install the operating system without upgrading the listed network components.
- Specify the drive and directory location of vendor-supplied upgrade files for listed network components.

  NetSetup reads the netmap.inf file at the specified location and copies the vendor-supplied upgrade files at that location to a temporary directory on the system's hard disk. This temporary directory becomes the working directory for the vendor-supplied network migration DLL. NetSetup also removes any component that has a netmap.inf file from the component list in the wizard.

NetSetup generates the winnt.sif file (also known as the AnswerFile) in the Win_nt.~bt directory, which is usually located on the C: drive.

NetSetup generates the AnswerFile as follows:

1. NetSetup reads the registry of the preupgraded system to enumerate each network component. For each network component that has built-in upgrade support, NetSetup writes the information that is read from the registry to the AnswerFile.

2. For each network component that does not have built-in upgrade support, NetSetup reads the component's netmap.inf file. The netmap.inf file maps the preupgrade device, hardware, or compatible ID of a network component to the corresponding ID in the upgraded operating system. If NetSetup matches the preupgrade ID of the network component that it read from the registry with a preupgrade ID in the **OemNetAdapters**, **OemNetProtocols**, **OemNetServices**, or **OemAsyncAdapters** section of the netmap.inf file, NetSetup writes vendor-provided information for the component to the AnswerFile.

3. Using the component's operating system device, hardware, or compatible ID, NetSetup reads the **OemUpgradeSupport** section of the netmap.inf file to determine which network migration DLL to load. NetSetup then loads the network migration DLL, and calls the DLL's PreUpgradeInitialize function. The **PreUpgradeInitialize** function supplies information that the DLL uses to initialize itself.

4. NetSetup calls the DLL's DoPreUpgradeProcessing function once for each network component supported by the network migration DLL. **DoPreUpgradeProcessing** reads a network component's preupgrade parameter values from the registry and calls the NetUpgradeAddSection and NetUpgradeAddLineToSection functions to write these parameters, along with other component-specific information, to the AnswerFile. **DoPreUpgradeProcessing** can also migrate binary data associated with the preupgraded component by making appropriate entries in the AnswerFile.

5. After the AnswerFile is completely generated, NetSetup copies the vendor-supplied upgrade files to the appropriate directories and then boots into the text mode phase of the upgrade process.

Text Mode Phase of the Network Upgrade Process

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

Setup strips all comments from the AnswerFile and writes the AnswerFile to the System32 directory under the name $Winnt$.inf. Then the system boots into GUI mode setup. No network-specific processing occurs during the text mode phase.

GUI Mode Phase of the Network Upgrade Process

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

Before the Windows 2000 or later operating system is installed on the system, NetSetup reads the network-specific information that was written to the AnswerFile during the Winnt32 phase.

If a network migration DLL wrote the **InfToRunBeforeInstall** key to a component's *OEM section* in the AnswerFile, NetSetup finds the INF file and section specified by the key and processes the INF directives in this section. This section usually contains the **AddReg**, **DelReg**, **AddService**, or **DelService** directives.

After the Windows 2000 or later operating system is installed, NetSetup installs each network component detected in the system, using the default parameter values specified for the component in the component's Windows 2000 or later INF file. NetSetup then installs network components listed in the AnswerFile.

If a network component's *OEM section* in the AnswerFile contains an OemDllToLoad key, NetSetup loads the network migration DLL if the DLL is not already loaded and then calls the DLL's **PostUpgradeInitialize** function. The **PostUpgradeInitialize** function supplies the DLL with information that the DLL uses to initialize itself. NetSetup then calls the DLL's **DoPostUpgradeProcessing** function once for each network component to be upgraded by the DLL. **DoPostUpgradeProcessing** can display a user interface that allows a user to specify parameter values for a component. **DoPostUpgradeProcessing** writes any user-specified parameter values to the registry.

If the miniport driver for a network adapter required the adapter's instance ID before the upgrade, it will probably require the adapter's instance ID after the upgrade. A network migration DLL can call **HrGetInstanceGuidOfPreNT5NetCardInstance** from its **DoPostUpgradeProcessing** function to obtain the Windows 2000 or later instance GUID for a network adapter.

NetSetup starts the installed network protocols, clients, and services.

NetSetup processes the entries in the **Identification** section of the AnswerFile and tries to connect the system to the workgroup or domain specified in that section.

If the system being upgraded contains any Async adapters, Setup calls the Async class installer, which upgrades each Async adapter as follows:

- The Async class installer locates the OEM section for the Async adapter in the AnswerFile.
- From the Async adapter's OEM section, the Async class installer reads the preupgrade parameter values for the adapter. These parameter values were written by the network migration DLL for the adapter during the Winnt32 phase of the upgrade.
- The Async class installer writes the adapter's preupgrade parameter values to the Windows 2000 or later registry.

Writing a Network Migration DLL

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

A network migration DLL migrates the parameter values for one or more network components from Microsoft Windows NT 3.51 or Windows NT 4.0 to Windows 2000 or later.

A network migration DLL must:

- **Load under the preupgrade operating system (Windows NT 3.51 or Windows 4.0)**

  The DLL cannot call any functions specific to Windows 2000 or later or use any features specific to Windows 2000 or later. If the DLL runs in the postupgrade (GUI mode) phase, it must also load under Windows 2000 and later operating systems.

- **Export the PreUpgradeInitializeandDoPreUpgradeProcessingfunctions**

  If the DLL runs in the GUI mode phase, it must export the PostUpgradeInitialize and DoPostUpgradeProcessing functions, as well.

- **Make no irreversible changes during the Winnt32 phase**

  The DLL must not make any irreversible changes, such as deleting files or modifying registry keys, during this phase because a user can cancel the upgrade of a network component or the operating system. The DLL can, however, modify files in its temporary working directory, which is specified by NetSetup in the call to **PreUpgradeInitialize**.

Creating a Netmap.inf File

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

The netmap.inf file is a vendor-supplied file that resides either in a directory specified by an entry in the **OemNetUpgradeDirs** section of a netupg.inf file or in the directory that contains netupgrd.dll. The netmap.inf file:

- Maps a network component's preupgrade device ID to the component's Microsoft Windows 2000 or later device ID

- Specifies the network migration DLL that NetSetup loads

- Optionally specifies an alternative Help message file

A network component that has built-in upgrade support in Windows 2000 or later operating systems does not require a vendor-supplied netmap.inf file because these components are automatically upgraded during the installation of Windows 2000 and later operating systems.

This section includes the following topics:

Mapping IDs in a Netmap.inf File

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

A netmap.inf file contains one or more of the following top-level sections. Each section contains ID mappings for the components listed in the **Map** column.

Section	Map
OemNetAdapters	Network adapters, excluding Async adapters
OemAsyncAdapters	Async network adapters
OemNetProtocols	Network protocol drivers
OemNetServices	Network services
OemNetClients	Network clients

Each entry in a section maps a network component's preupgrade device, hardware, or compatible ID to its corresponding Windows 2000 or later ID. Each entry specifies either *one-to-one* ID mapping or *one-to-many* ID mapping. These mapping strategies are described following.

Network clients are not defined as such in Windows NT 3.51 and Windows NT 4.0; therefore, if an earlier network service becomes a network client under Windows 2000 or later, its device ID mapping must be listed in the **OemNetClients** section, not in the **OemNetServices** section.

One-to-One ID Mapping

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

An entry in an **Oem*Xxx*** section of a netmap.inf file that specifies one-to-one ID mapping has the following format:

preupgrade-ID = postupgrade-ID

For example:

C++

```
netservice=netservice_2000
```

A one-to-one ID mapping must be used for network protocols, services, and clients. Either one-to-one ID mapping or one-to-many ID mapping can be used for network adapters.

One-to-Many ID Mapping

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

A one-to-many ID mapping maps a single preupgrade ID that represents more than one network adapter. The only way to differentiate the adapters associated with a single preupgrade ID is to inspect the values under the registry key that contains the parameter values for the network adapter instance.

An entry in an **OemAdapters** or **OemAsyncAdapters** section that specifies a one-to-many ID mapping has the following format:

preupgrade-ID = *mapping-method-number*, *section-name*

where:

mapping-method-number must be 0

section-name specifies a section in the netmap.inf file that contains the mapping information

The netmap.inf file section specified by *section-name* contains the following entries:

ValueName = "*Name*"

Specifies the value that NetSetup reads under the registry key that contains the parameter values for the network adapter instance. *Name* identifies a particular network adapter.

ValueType = *Type*

Specifies the registry value type for *ValueName*. *Type* is an integer that corresponds to a specific registry type.

ValueName= *postupgrade-ID*

ValueName is the value that NetSetup reads under the registry key that contains the parameter values for the network adapter instance. *postupgrade-ID* is the Windows 2000 or later device ID for the adapter. One *ValueName* entry should be provided for each adapter type that will be upgraded. If *ValueName* is set to the keyword **ValueNotPresent** and if NetSetup finds no parameters values for the adapter instance, NetSetup uses the *postuprgrade-ID* associated with **ValueNotPresent** for the adapter.

The following example shows a one-to-many device ID mapping:

C++

```
[OemAdapters]
DATAFIREU=0, DATAFIREU

[DATAFIREU]
ValueName  = "BoardType"
ValueType  = 1
DataFireIsaU = "DATAFIRE - ISA1U"
DataFireIsa1ST= "DATAFIRE - ISA1ST"
DataFireIsa4ST= "DATAFIRE - ISA4ST"
DataFireIsaGeneric = "ValueNotPresent"
```

The **OemAdapters** section in the above example contains a single entry that identifies the preupgrade device ID of the network adapter as DATAFIREU and specifies that the **DATAFIREU** section of the netmap.inf file contains the mapping information for this adapter.

The DATAFIREU section contains the following information:

- The **ValueName** entry directs NetSetup to look for the **BoardType** value under the **Parameters** key of the network adapter instance.

- The **ValueType** entry, which is set to 1, specifies that the **BoardType** value is a DWORD.

- Each remaining value specifies a preupgrade device ID and a corresponding Windows 2000 or later ID. For example, the ID for the DataFireIsaU board type is DATAFIRE - ISA1U. The **ValueNotPresent** keyword can be specified instead of a preupgrade ID.

NetSetup performs a one-to-many ID mapping as follows:

1. NetSetup reads the specified ValueName under the registry key that contains the parameter values for the network adapter instance.

2. NetSetup attempts to match the ValueName with one of the ValueNames listed in the specified section of the netmap.inf file. If no ValueName is listed under the registry key, NetSetup attempts to find the ValueNotPresent keyword in the specified section of the netmap.inf file.

3. If NetSetup finds a match, it installs the network adapter, using the INF file that has the same name as the mapped Windows 2000 or later ID.

If the registry keys or values for an adapter instance are identical for different adapter types, it is not possible to map a single preupgrade device ID to more than one Windows 2000 or later device ID without first modifying these registry keys or values.

The most effective way of handling this situation is as follows:

1. The network migration DLL's **PreUpgradeInitialize** function modifies the registry so that the registry contains unique values for each instance of the network adapter. These unique values should indicate the adapter type.

2. The **PreUpgradeInitialize** function sets the NUA_REQUEST_ABORT_UPGRADE flag, which causes NetSetup to display a message that prompts the user to restart winnt32.exe and abort the upgrade.

3. The user aborts the upgrade and then restarts winnt32.exe. The network migration DLL can now use the unique values to map the single preupgrade device ID to more than one Windows 2000 or later device ID.

Specifying the Upgrade DLL in a Netmap.inf File

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

A netmap.inf file must have an **OemUpgradeSupport** section. For each network component to be upgraded, the **OemUpgradeSupport** section must contain an entry that has the following format:

postupgrade-ID = *network-migration-DLL*[, *Inf-file-name*]

where:

postupgrade-ID is the network component's Windows 2000 or later device ID, which was obtained by NetSetup, as described in Winnt32 Phase of the Network Upgrade Process.

network-migration-DLL is the name of the network migration DLL that NetSetup must load to upgrade the network component. Only one migration DLL can be specified in a netmap.inf file. If the netmap.inf file contains device ID mappings for more than one component, then all such components must be upgraded by the same migration DLL.

Inf-file-name is the name of the INF file that installs the network component.

Specifying Alternative Help Message Files in a Netmap.inf File

Article • 05/05/2023

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

If NetSetup fails to find the device ID mapping for a network component in any of the netmap.inf files, it lists this component on the Compatibility Report page in the wizard. Associated with each such component is a Help message file.

By default, NetSetup displays a Help message contained in the \winntupg\unsupmsg.txt file or, if an HTML browser is installed on the system, in the \winntupg\unsupmsg.htm file. You can optionally supply a custom message file that overrides the unsupmsg.txt and unsupmsg.txt message files. For example, if a vendor provides upgrade support for only some of its network components, the vendor could supply a custom Help message file that indicates that upgrade support is not provided for certain components.

An optional **OemUpgradeHelpFiles** section in a netmap.inf file specifies one or more custom Help message files. Each entry in this section has the following format:

postupgrade-ID = *text-name*, *htm-file*

where:

postupgrade-ID is the Windows 2000 or later device ID of network component

text-name is the path and name of the text version of the custom Help message file

htm-file is the path and name of the HTML version of the custom Help message file.

If a full path name is not specified in *text-name* or *htm-file*, the specified path is appended to the i386 directory--for example: \i386\mydirectory\myfile.txt.

The following example of a netmap.inf file contains an **OemUpgradeHelpFiles** section.

INF

```
[Version]
signature="$Windows NT$

[OemNetProtocols]
Protocol1=Protoco1_2000
Protocol2=Protocol2_2000
```

```
[OemUpgradeSupport]
Protocol1=NotSupported
Protocol2=abc_upgrade.dll, abc.inf

[OemUpgradeHelpFiles]
Protoco11=helpmsg.txt, helpmsg.htm
```

Even though this sample netmap.inf file does not provide upgrade support for Protocol1, it provides a device ID mapping for Protocol1 in the **OemNetProtocols** section. This mapping specifies a Windows 2000 device ID for Protocol1. The Windows 2000 device ID is required to associate custom Help message files with a network component.

Notice that the keyword **NotSupported** is assigned to Protocol1 in the **OemUpgradeHelpFiles** section. This keyword indicates that there is no need to load a migration DLL to upgrade Protocol1.

In the **OemUpgradeHelpFiles** section of the previous example, the Protoco11=helpmsg.txt, helpmsg.htm entry specifies two custom Help message files for Protocol1. The custom Help message contained in these files could indicate, for example, that the vendor does not support the upgrade of Protocol1 and that the user must separately upgrade Protocol1 to Protocol2 before attempting to upgrade the system to Windows 2000 or later.

Setting Up the Test System

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

Before you upgrade network components, make sure that the network components to be upgraded are correctly installed and configured.

To set up the test system

1. Create one partition for the preupgrade operating system and another partition for the Microsoft Windows 2000 or later operating system. **Note** Do not install the preupgrade operating system and the upgrade operating system in the same partition. If the preupgrade operating system and Windows 2000 or later are installed in the same partition, they will share the same Program Files directory.

2. On the test system, boot an operating system build other than the one to be upgraded. Then copy the entire partition to be upgraded, except for the pagefile.sys file, into a back-up directory. There is no need to copy the pagefile.sys file, since it is created on the start-up of Windows 2000 or later.

   This method of creating a back-up installation is preferable to creating a disk-image program, because it allows you to use **xcopy**, which takes less time to copy files than a disk-image program. You can repeat an upgrade test by simply copying the contents of the back-up partition into a new partition to be upgraded; it is not necessary to reinstall the preupgrade operating system.

3. Create a test directory for storing the network migration DLL and the netmap.inf file, and then copy these files to the test directory.

4. Create another directory for storing the Windows 2000 or later files required for the Winnt32 upgrade phase.

5. Insert the Windows 2000 or later Driver Development Kit (DDK) CD-ROM that contains the checked build of Windows 2000 or later. From the \i386 directory on the CD-ROM, copy the following files to the back-up directory (Step 2):

   - winnt32.exe
   - winnt32u.dll
   - pidgen.dll
   - wetuplog.*

6. Create an upgrade directory named winntupg. Copy the files in the \i386\winntupg directory on the CD-ROM to the winntupg directory on the test system.

7. Enable the debugger on the text system or start debugmon.exe, which is included with the Resource Kit for Windows 2000 or later operating systems. Then copy a netcfg.ini file to %windir%. The netcfg.ini file enables debug tracing.

   The following is a sample netcfg.ini file:

   INI

   ```ini
   [DebugFlags]
   BreakOnAddLegacy=0
   BreakOnAlloc=0
   BreakonDoUnattend=0
   BreakonDwrefProblem=0
   BreakOnError=0
   BreakOnHr=0
   BreakOnHrInteraction=0
   BreakOnIteration=0
   BreakOnNetInstall=0
   BreakOnWizard=0
   DisableTray=0
   DumpLeaks=0
   DumpNetCfgTree=0
   NetShellBreakOnInit=0
   ShowIngnoreErrors=0
   ShowProcessAndThreadIds=0
   SkipLanEnum=0
   TracingTimeStamps=0

   [Default]
   OutputToDebug=1

   [EsLocks]
   OutputToDebug=0

   [ShellViewMsgs]
   OutputToDebug=0

   [OptErrors]
   OutputToDebug=0
   ```

Running the Upgrade Test and Examining the Results

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

Before you upgrade the system to Windows 2000 or later, note the parameter values in the registry for each network component to be upgraded.

To run the upgrade test

1. Make sure that the CD-ROM that contains the checked build of Windows 2000 or later is in the CD-ROM drive.

2. Run winnt32.exe on the test system. For example, use the following command to run winnt32.exe on an Intel-based system with the CD-ROM in drive O:

   CMD

   ```
   winnt32.exe /s:o\i386
   ```

3. After Windows 2000 or later is installed, verify that the upgraded network component's parameters have been correctly migrated to the new operating system.

Examining the AnswerFile

Article • 12/15/2021

Note Vendor-supplied network upgrades are not supported in Microsoft Windows XP (SP1 and later), Microsoft Windows Server 2003, and later operating systems.

Immediately before the "Setup is Copying Files" progress bar is displayed on a system being upgraded, the AnswerFile is created. NetSetup and vendor-supplied network migration DLLs create sections in the AnswerFile and then write entries to these sections during the Winnt32 upgrade phase.

You can examine the AnswerFile by copying c:\win_nt.~bt\winnt.sif to %TEMP%. After the AnswerFile has been copied, you can click **Cancel** to cancel file copying. You do not have to wait until file copying is finished.

The following table lists the top-level sections in the AnswerFile and the corresponding entries that each section contains that pertain to network components:

Section	Entries Contained
NetAdapters	Network adapters, including ISDN adapters
AsyncAdapters	Async adapters
NetProtocols	Network protocols
NetServices	Network services
NetClients	Network clients

Note **NetClient** components are deprecated in Windows 8.1, Windows Server 2012 R2, and later.

For each network component that it finds during the Winnt32 phase, NetSetup writes an entry to the appropriate top-level section of the AnswerFile. Each entry has the following format:

params.*postupgrade-ID*

The *postupgrade-ID* entry is the Windows 2000 or later device ID that NetSetup obtained from the netmap.inf file for the component.

Each entry specifies the name of the parameters section for that component in the AnswerFile. For example, if a component's Windows 2000 or later device ID is netadapter2, its entry in the **NetAdapters** section is **params.netadapter2**. The top-level sections and the parameter sections in an AnswerFile are not visible to a network migration DLL.

To the parameters section name for a component, NetSetup adds the extension **OemSection** to create the *OEM-section* name for the component. For example, if the parameters section for a component is params.netadapter2, the *OEM-section* name for the component is params.netadapter2.OemSection. NetSetup passes the *OEM-section* name as the *szSectionName* parameter to the DoPreUpgradeProcessing function supplied by the network migration DLL for the component. The **DoPreUpgradeProcessing** function calls the NetUpgradeAddSection function to create the *OEM-section* for a component in the AnswerFile. The **DoPreUpgradeProcessing** function then calls the NetUpgradeAddLineToSection to add component-specific information to the *OEM-section*.

The following portion of an AnswerFile shows the sections and entries for a network adapter whose Windows 2000 or later device ID is **adapter2**:

```
INF
```

```
[NetAdapter]              ;top-level adapters section
adapter2=params.adapter2      ;entry for adapter2
[params.adapter2]          ;parameters section for adapter2
InfID=adapter2            ;Windows 2000 or later device ID
OemSection=params.adapter2.OemSection  ;Identifies the OemSection

[params.adapter2.OemSection]  ;OemSection created by migration DLL
InfToRunAfterInstall="", adapter2.SectionToRun ;Written by DLL

[adapter2.SectionToRun]      ;Section created by migration DLL
AddReg=adapter2.SectionToRun.AddReg ;AddReg directive

[adapter2.SectionToRun.AddReg] ;AddReg section created by DLL
HKR,0\0,IsdnPhoneNumber,0,"111-1111" ;AddReg entries written by DLL
HKR,0\1,IsdnPhoneNumber,0,"222-2222"
HKR,0\0,IsdnSpid,0,"111"
HKR,0\1,IsdnSpid,0,"222"
HKR,0,IsdnSwitchType,0x00010001,1
```

During the GUI mode phase, NetSetup detects the InfToRunAfterInstall key written by the migration DLL to the **params.adapter2.OemSection** of the example AnswerFile. As directed by this key, NetSetup processes the **adapter2.SectionToRun.AddReg** section. The **adapter2.SectionToRun.AddReg** section directs NetSetup to add parameter values to adapater2's instance key in the Windows 2000 or later registry. These parameter values should match the preupgrade parameter values that the migration DLL read from adapter2's the registry during the Winnt32 phase of the upgrade.

If a network migration DLL is to be loaded during the GUI mode phase, its DoPreUpgradeProcessing function sets the NUA_LOAD_POST_UPGRADE flag. This flag causes NetSetup to write the **OemDllToLoad** entry to the component's parameters section in the AnswerFile. The **OemDllToLoad** entry causes NetSetup to load the migration DLL for the component during the GUI mode phase.

The following example shows the AnswerFile sections and entries for a component whose network migration DLL is loaded during the GUI mode phase:

INF

```
[NetAdapter]              ;top-level adapters section
adapter2=params.adapter2      ;entry for adapter2
[params.adapter2]          ;parameters section for adapter2
InfID=adapter2            ;postupgrade device ID
OemSection=params.adapter2.OemSection;Identifies the OemSection
OemDllToLoad=c:\temp\oem0001\migration.dll
```

Note the **OemDllToLoad** entry in the **params.adapter2** section. Also note that the migration DLL did not create a **params.adapter2.OemSection**. When the migration DLL is to be loaded during the GUI mode phase, it typically does not write an **InfToRunAfterInstall** key to the AnswerFile. The DLL performs the postinstallation upgrade; therefore, it does not need to create an *Oem-Section* name that contains directives for NetSetup to perform during the GUI mode phase.

NDIS general statistics OIDs

Article • 02/06/2024

A driver should respond to a query of a statistics OID with complete information so that the driver can supply the operating system and applications with information that they need to monitor network status, respond to security issues, and diagnose problems. If statistics counters are in hardware, the driver should read the appropriate statistics value from hardware each time that a statistics OID is queried.

Note: General statistics OIDs count all traffic through the network adapter including Network Direct Kernel (NDK) traffic. NDK statistics may be counted separately with OID_NDK_STATISTICS.

Miniport driver support for 64-bit counters

All one-Gbps and faster miniport drivers must support 64-bit counters for the following statistics OIDs. In addition, Microsoft recommends that all 100Mbps and faster miniport drivers support 64-bit counters for the following statistics OIDs:

- OID_GEN_STATISTICS
- OID_GEN_BYTES_RCV
- OID_GEN_BYTES_XMIT
- OID_GEN_RCV_DISCARDS
- OID_GEN_XMIT_DISCARDS
- OID_GEN_XMIT_OK
- OID_GEN_RCV_OK
- OID_GEN_XMIT_ERROR
- OID_GEN_RCV_ERROR
- OID_GEN_RCV_NO_BUFFER
- OID_GEN_DIRECTED_BYTES_XMIT
- OID_GEN_DIRECTED_FRAMES_XMIT
- OID_GEN_MULTICAST_BYTES_XMIT
- OID_GEN_MULTICAST_FRAMES_XMIT
- OID_GEN_BROADCAST_BYTES_XMIT
- OID_GEN_BROADCAST_FRAMES_XMIT
- OID_GEN_DIRECTED_BYTES_RCV
- OID_GEN_DIRECTED_FRAMES_RCV
- OID_GEN_MULTICAST_BYTES_RCV
- OID_GEN_MULTICAST_FRAMES_RCV
- OID_GEN_BROADCAST_BYTES_RCV

- OID_GEN_BROADCAST_FRAMES_RCV
- OID_GEN_RCV_CRC_ERROR
- OID_GEN_TRANSMIT_QUEUE_LENGTH
- OID_GEN_INIT_TIME_MS
- OID_GEN_RESET_COUNTS
- OID_GEN_MEDIA_SENSE_COUNTS

Miniport drivers can also support 64-bit counters for other statistics OIDs, such as OIDs that indicate transmit or receive errors.

System support for 64-bit counters is available in Windows XP and later operating systems.

Note: If an NDIS MUX driver exposes multiple miniport instances, querying the following general statistics OIDs should return data specific to that miniport instance. For example, if a MUX driver implements virtual local area network (VLAN) filtering and exposes one miniport per VLAN, the statistics values returned from the following OIDs are expected to be per VLAN.

- OID_GEN_STATISTICS
- OID_GEN_RCV_OK
- OID_GEN_XMIT_OK

NDIS network interface OIDs

Article • 03/14/2023

NDIS network interface object identifiers (OIDs) provide information about network interfaces to support the MIB (RFC 2863).

NDIS interface providers must support these OIDs. Drivers that are not registered interface providers should not support the OIDs in this section.

NDIS calls the ProviderQueryObject function to make a query request for information from the interface provider. The *ObjectId* parameter of this function contains the object identifier. The interface provider registered *ProviderQueryObject* when it called the NdisIfRegisterProvider function to register as an interface provider.

The handle at the *ProviderIfContext* parameter of the *ProviderQueryObject* function identifies the network interface. This handle was provided to NDIS when the interface provider called the NdisIfRegisterInterface function to register the interface. The *pOutputBuffer* parameter of the *ProviderQueryObject* function contains the result of the OID request.

For more information about NDIS network interface OIDs, see NDIS 6.0 Network Interfaces.

This section describes the following NDIS network interface OIDs:

- OID_GEN_ALIAS
- OID_GEN_ADMIN_STATUS
- OID_GEN_OPERATIONAL_STATUS
- OID_GEN_PROMISCUOUS_MODE
- OID_GEN_XMIT_LINK_SPEED
- OID_GEN_RCV_LINK_SPEED
- OID_GEN_UNKNOWN_PROTOS
- OID_GEN_DISCONTINUITY_TIME
- OID_GEN_LAST_CHANGE
- OID_GEN_INTERFACE_INFO
- OID_GEN_MEDIA_CONNECT_STATUS_EX
- OID_GEN_LINK_SPEED_EX
- OID_GEN_MEDIA_DUPLEX_STATE
- OID_TUNNEL_INTERFACE_RELEASE_OID
- OID_TUNNEL_INTERFACE_SET_OID

Mandatory OIDs for miniport drivers

Article • 12/15/2021

The following table lists the OIDs that are mandatory for all miniport drivers. Your miniport driver will be required to support additional OIDs, depending on its NDIS version and the services that it supports, such as:

- Connection-Oriented Objects
- CoNDIS
- Ethernet statistics OIDs
- Header-Data Split OIDs
- Hyper-V Extensible Switch OIDs
- IPsec Offload Version 2 OIDs
- MB OIDs
- Native 802.11 Wireless LAN OIDs
- NDIS TCP/IP Offload OIDs
- NDKPI OIDs
- Operational Power Management OIDs
- Overview of Receive Filter OIDs
- Receive Filter OIDs
- Receive Side Scaling OIDs
- Remote NDIS OIDs
- Required and Optional OIDs for Power Management
- SR-IOV OIDs
- Statistical Power Management OIDs
- Task Offload Objects
- VMQ OIDs

In the "O/M" columns in the table:

- "M" means "mandatory" and "O" means "optional."
- "N/A" in the "O/M for Query" column means that NDIS handles the OID query request and does not send it to the miniport driver, so the miniport driver only needs to support the OID set request.
- If there is no entry in the "O/M for Query" column, this OID is a set-only OID.
- If there is no entry in the "O/M for Set" column, this OID is a query-only OID.

OID	O/M for Query	O/M for Set	Comments

OID	O/M for Query	O/M for Set	Comments
OID_GEN_CURRENT_LOOKAHEAD	N/A	M	NDIS handles query and unsuccessful Set requests for the miniport driver. NDIS sends valid Set requests to the miniport driver. You can obtain the same information with OID_GEN_RECEIVE_BLOCK_SIZE.
OID_GEN_CURRENT_PACKET_FILTER	N/A	M	Query is not mandatory. Set is mandatory.
OID_GEN_INTERRUPT_MODERATION	M	M	
OID_GEN_LINK_PARAMETERS		M	
OID_GEN_MAXIMUM_TOTAL_SIZE	M		There is no other way to get this information.
OID_GEN_RCV_OK	M		NDIS does not handle this OID for miniport drivers and OID_GEN_STATISTICS does not include this information. **Note**: Statistics OIDs are mandatory unless NDIS handles them.
OID_GEN_RECEIVE_BLOCK_SIZE	M		NDIS does not handle this OID for miniport drivers.
OID_GEN_RECEIVE_BUFFER_SPACE	M		There is no other way to get this information.
OID_GEN_STATISTICS	M		
OID_GEN_TRANSMIT_BLOCK_SIZE	M		There is no other way to get this information.
OID_GEN_TRANSMIT_BUFFER_SPACE	M		There is no other way to get this information.
OID_GEN_VENDOR_DESCRIPTION	M		There is no other way to get this information.
OID_GEN_VENDOR_DRIVER_VERSION	M		There is no other way to get this information.
OID_GEN_VENDOR_ID	M		There is no other way to get this information. Independent hardware vendor's filter drivers or intermediate drivers might query this OID.

OID	O/M for Query	O/M for Set	Comments
OID_GEN_XMIT_OK	M		NDIS does not handle this OID and OID_GEN_STATISTICS does not include this information. **Note**: Statistics OIDs are mandatory unless NDIS handles them.

Ethernet statistics OIDs

Article • 12/15/2021

The following table summarizes the OIDs used to get Ethernet statistics for Network Interface Controllers (NICs).

Length	Query	Set	Name
4	O		OID_802_3_RCV_OVERRUN
4	O		OID_802_3_XMIT_DEFERRED
4	O		OID_802_3_XMIT_HEARTBEAT_FAILURE
4	O		OID_802_3_XMIT_LATE_COLLISIONS
4	O		OID_802_3_XMIT_MAX_COLLISIONS
4	O		OID_802_3_XMIT_TIMES_CRS_LOST
4	O		OID_802_3_XMIT_UNDERRUN

ⓘ Note

The following OIDs are obsolete in NDIS 6.0 and later:

- OID_802_3_RCV_ERROR_ALIGNMENT
- OID_802_3_XMIT_MORE_COLLISIONS
- OID_802_3_XMIT_ONE_COLLISION

General operational OIDs for connection-oriented miniport drivers

Article • 12/15/2021

The following table summarizes the OIDs used to get or set the general operational characteristics of connection-oriented miniport drivers and/or their NICs.

Tip

A connection-oriented miniport driver handles such requests in its **MiniportCoOidRequest** callback function.

In this table, M indicates an OID is mandatory, while O indicates it is optional.

Length	Query	Set	Name
2	M		OID_GEN_CO_DRIVER_VERSION
8	O		OID_GEN_CO_GET_NETCARD_TIME
8	O		OID_GEN_CO_GET_TIME_CAPS
4	M		OID_GEN_CO_HARDWARE_STATUS
4	M		OID_GEN_CO_LINK_SPEED
4	M		OID_GEN_CO_MAC_OPTIONS
4	M		OID_GEN_CO_MEDIA_CONNECT_STATUS
Arr(4)	M		OID_GEN_CO_MEDIA_IN_USE
Arr(4)	M		OID_GEN_CO_MEDIA_SUPPORTED
4	M		OID_GEN_CO_MINIMUM_LINK_SPEED
4		M	OID_GEN_CO_PROTOCOL_OPTIONS
Arr	O		OID_GEN_CO_SUPPORTED_GUIDS
Arr(4)	M		OID_GEN_CO_SUPPORTED_LIST
Var.	M		OID_GEN_CO_VENDOR_DESCRIPTION
4	M		OID_GEN_CO_VENDOR_DRIVER_VERSION
4	M		OID_GEN_CO_VENDOR_ID

General statistics OIDs for connection-oriented miniport drivers

Article • 05/20/2024

The following table summarizes the OIDs used to get or set the general statistics characteristics of connection-oriented miniport drivers and/or their NICs.

💡 Tip

A connection-oriented miniport driver handles such requests in its MiniportCoOidRequest callback function.

In this table, M indicates an OID is mandatory, while O indicates it is optional.

Expand table

Length	Query	Set	Name
4 or 8	O		OID_GEN_CO_BYTES_RCV
4 or 8	O		OID_GEN_CO_BYTES_XMIT
4 or 8	O		OID_GEN_CO_BYTES_XMIT_OUTSTANDING
4 or 8	O		OID_GEN_CO_NETCARD_LOAD
4 or 8	O		OID_GEN_CO_RCV_CRC_ERROR
4 or 8	M		OID_GEN_CO_RCV_PDUS_ERROR
4 or 8	M		OID_GEN_CO_RCV_PDUS_NO_BUFFER
4 or 8	M		OID_GEN_CO_RCV_PDUS_OK
4 or 8	O		OID_GEN_CO_TRANSMIT_QUEUE_LENGTH
4 or 8	M		OID_GEN_CO_XMIT_PDUS_ERROR
4 or 8	M		OID_GEN_CO_XMIT_PDUS_OK

Miniport driver support for 64-bit counters

All one-Gbps and faster connection-oriented miniport drivers must support 64-bit counters for the following statistics OIDs. In addition, Microsoft recommends that all

100Mbps and faster connection-oriented miniport drivers support 64-bit counters for the following statistics OIDs:

OID_GEN_CO_XMIT_PDUS_OK

OID_GEN_CO_RCV_PDUS_OK

OID_GEN_CO_BYTES_XMIT

OID_GEN_CO_BYTES_RCV

Such miniport drivers can also support 64-bit counters for other statistics OIDs, such as OIDs that indicate transmit or receive errors.

System support for 64-bit counters is available in Windows XP and later versions.

OIDs for connection-oriented call managers and clients

Article • 12/15/2021

The following table summarizes the OIDs that connection-oriented clients can send to call managers or MCM drivers and that call managers or MCM drivers can send to connection-oriented clients.

In this table, M indicates an OID is mandatory, while O indicates it is optional.

Length	Query	Set	Name
Varies		O	OID_CO_ADD_ADDRESS
Varies		O	OID_CO_ADD_PVC
0		O	OID_CO_ADDRESS_CHANGE
0		M	OID_CO_AF_CLOSE
Varies		O	OID_CO_DELETE_ADDRESS
Varies		O	OID_CO_DELETE_PVC
Varies	O		OID_CO_GET_ADDRESSES
			OID_CO_GET_CALL_INFORMATION
0		O	OID_CO_SIGNALING_DISABLED
0		O	OID_CO_SIGNALING_ENABLED

TAPI extension OIDs for connection-oriented NDIS

Article • 03/14/2023

The following table summarizes OIDs that allow TAPI calls to be made over connection-oriented media. Connection-oriented clients send these OIDs to call managers or integrated miniport call manager (MCM) drivers.

In this table, M indicates an OID is mandatory, while O indicates it is optional.

Length	Query	Set	Name
Varies	O		OID_CO_TAPI_ADDRESS_CAPS
Sizeof(CO_TAPI_CM_CAPS)	O		OID_CO_TAPI_CM_CAPS
Varies	O		OID_CO_TAPI_GET_CALL_DIAGNOSTICS
Varies	O		OID_CO_TAPI_LINE_CAPS
Varies	O		OID_CO_TAPI_TRANSLATE_NDIS_CALLPARAMS
Varies	O		OID_CO_TAPI_TRANSLATE_TAPI_CALLPARAMS
Varies	O		OID_CO_TAPI_TRANSLATE_TAPI_SAP

In its call to NdisCoRequest, the client that queries any of the TAPI extension OIDs must specify an *NdisAfHandle* that identifies the address family to which the request applies. The client can specify an *NdisVcHandle* that identifies the virtual connection (VC) to which the request applies. From this VC handle, the call manager or MCM driver may be able to derive the particular line and perhaps the address to which the request applies.

NDIS_STATUS_MEDIA_CONNECT

Article • 03/14/2023

The NDIS_STATUS_MEDIA_CONNECT status indicates that the status of a device's network connection has changed from disconnected to connected. For example, a device connects when it comes within range of an access point (for a wireless device) or when the user connects the device's network cable.

Remarks

NDIS translates NDIS_STATUS_MEDIA_CONNECT status indications to **NDIS_STATUS_LINK_STATE** status indications for overlying NDIS 6.0 drivers.

NDIS 5.*x* and earlier miniport drivers indicate an **NDIS_STATUS_MEDIA_DISCONNECT** status when a miniport driver determines that the network connection has been lost. When the connection is restored, the driver indicates an NDIS_STATUS_MEDIA_CONNECT status.

For more information about NDIS_STATUS_MEDIA_CONNECT, see Indicating Connection Status (NDIS 5.1) and Media Status Indications for 802.11 Networks.

Requirements

Version	Not supported in NDIS 6.0 and later (use **NDIS_STATUS_LINK_STATE** instead). Supported only for NDIS 5.1 drivers in Windows Vista and Windows XP.
Header	Ndis.h (include Ndis.h)

See also

NDIS_STATUS_LINK_STATE

NDIS_STATUS_MEDIA_DISCONNECT

NDIS_STATUS_MEDIA_DISCONNECT

Article • 03/14/2023

The NDIS_STATUS_MEDIA_DISCONNECT status indicates that the status of a network connection has changed from connected to disconnected. For example, the network device loses the connection because it is out of range (for a wireless device), or the user unplugs the device's network cable.

Remarks

NDIS translates NDIS_STATUS_MEDIA_DISCONNECT status indications to **NDIS_STATUS_LINK_STATE** status indications for overlying NDIS 6.0 drivers.

NDIS 5.*x* and earlier miniport drivers indicate an **NDIS_STATUS_MEDIA_CONNECT** status when the connection is restored.

For more information about NDIS_STATUS_MEDIA_DISCONNECT, see Indicating Connection Status (NDIS 5.1) and Media Status Indications for 802.11 Networks.

Requirements

Version	Not supported in NDIS 6.0 and later (use **NDIS_STATUS_LINK_STATE** instead). Supported only for NDIS 5.1 drivers in Windows Vista and Windows XP.
Header	Ndis.h (include Ndis.h)

See also

NDIS_STATUS_LINK_STATE

NDIS_STATUS_MEDIA_CONNECT

NDIS_STATUS_RESET_START

Article • 03/14/2023

The NDIS_STATUS_RESET_START status indicates that a miniport adapter is being reset.

Remarks

Miniport drivers should not call the **NdisMIndicateStatusEx** function to signal the start and finish of each reset operation because NDIS notifies overlying drivers when a reset operation begins and ends.

A miniport driver resets a miniport adapter when NDIS calls the miniport driver's *MiniportResetEx* function. NDIS calls the *ProtocolStatusEx* function of each bound protocol and intermediate driver and the *FilterStatus* function of the overlying filter modules with a status of NDIS_STATUS_RESET_START. When the miniport driver completes the reset, NDIS notifies the overlying drivers with a status of **NDIS_STATUS_RESET_END**.

When a protocol driver receives an NDIS_STATUS_RESET_START status indication, it should:

- Hold any data that is ready to transmit until its *ProtocolStatusEx* function receives an NDIS_STATUS_RESET_END status indication.

- Not make any NDIS calls that are directed to the underlying miniport driver, except calls to return resources such as received data buffers with the **NdisReturnNetBufferLists** function.

Requirements

Version	Supported for NDIS 6.0 and NDIS 5.1 drivers in Windows Vista. Supported for NDIS 5.1 drivers in Windows XP.
Header	Ndis.h (include Ndis.h)

See also

FilterStatus

MiniportResetEx

NDIS_STATUS_RESET_END

NdisMIndicateStatusEx

NdisReturnNetBufferLists

ProtocolStatusEx

NDIS_STATUS_RESET_END

Article • 03/14/2023

The NDIS_STATUS_RESET_END status indicates that a miniport adapter reset operation is complete.

Remarks

Miniport drivers should not call the NdisMIndicateStatusEx function to signal the start and finish of each reset operation because NDIS notifies overlying drivers when a reset operation begins and ends.

When a miniport driver starts a reset operation, NDIS notifies the overlying drivers with an NDIS_STATUS_RESET_START status indication.

After a bound protocol driver receives an NDIS_STATUS_RESET_END status indication, the protocol driver can resume sending data and making OID requests.

After an overlying filter or intermediate driver receives an NDIS_STATUS_RESET_END status indication, the driver can resume sending data and making OID requests to overlying drivers.

Requirements

Version	Supported for NDIS 6.0 and NDIS 5.1 drivers in Windows Vista. Supported for NDIS 5.1 drivers in Windows XP.
Header	Ndis.h (include Ndis.h)

See also

NDIS_STATUS_RESET_START

NdisMIndicateStatusEx

NDIS_STATUS_MEDIA_BUSY

Article • 03/14/2023

The NDIS_STATUS_MEDIA_BUSY status indicates that the IRDA media is busy.

Remarks

For more information about NDIS_STATUS_MEDIA_BUSY, see OID_IRDA_MEDIA_BUSY.

Requirements

Version	Not supported in NDIS 6.0 and later. Supported only for NDIS 5.1 drivers in Windows Vista and Windows XP.
Header	Ndis.h (include Ndis.h)

See also

OID_IRDA_MEDIA_BUSY

NDIS_STATUS_MEDIA_SPECIFIC_INDICATION

Article • 03/14/2023

The NDIS_STATUS_MEDIA_SPECIFIC_INDICATION status indicates a media-specific status.

Remarks

Miniport drivers make media-specific status indications by calling the NdisMIndicateStatusEx function with the **StatusCode** member of the NDIS_STATUS_INDICATION structure set to NDIS_STATUS_MEDIA_SPECIFIC_INDICATION. The **StatusBuffer** member of this structure points to a driver-allocated buffer. The buffer contains data in a format that is specific to the status indication that is identified in the **StatusCode** member.

Requirements

Version	Supported for NDIS 6.0 and NDIS 5.1 drivers in Windows Vista. Supported for NDIS 5.1 drivers in Windows XP.
Header	Ndis.h (include Ndis.h)

See also

NDIS_STATUS_INDICATION

NdisMIndicateStatusEx

NDIS_STATUS_LINK_SPEED_CHANGE

Article • 03/14/2023

The NDIS_STATUS_LINK_SPEED_CHANGE status indicates a link speed change.

Remarks

NDIS translates NDIS_STATUS_LINK_SPEED_CHANGE status indications to **NDIS_STATUS_LINK_STATE** status indications for overlying NDIS 6.0 drivers. When NDIS receives an NDIS_STATUS_LINK_SPEED_CHANGE status, NDIS issues an OID query request of OID_GEN_LINK_SPEED. NDIS uses the results of the OID_GEN_LINK_SPEED query to issue an NDIS_STATUS_LINK_STATE status to overlying NDIS 6.0 drivers.

The NDIS 5.*x* or earlier miniport driver supplies a DWORD-type value at the *StatusBuffer* parameter of the **NdisMIndicateStatus** function. For more information about NDIS_STATUS_LINK_SPEED_CHANGE, see OID_IRDA_RATE_SNIFF.

Requirements

Version	Not supported in NDIS 6.0 and later (use **NDIS_STATUS_LINK_STATE** instead). Supported only for NDIS 5.1 drivers in Windows Vista and Windows XP.
Header	Ndis.h (include Ndis.h)

See also

NDIS_STATUS_LINK_STATE

NdisMIndicateStatus

OID_GEN_LINK_SPEED

OID_IRDA_RATE_SNIFF

NDIS_STATUS_LINK_STATE

Article • 03/14/2023

Miniport drivers use the NDIS_STATUS_LINK_STATE status indication to notify NDIS and overlying drivers that there has been a change in the physical characteristics of a medium.

Remarks

Overlying drivers should not use the OID_GEN_LINK_STATE OID to determine the link state. Instead, use the NDIS_STATUS_LINK_STATE status indication for link state updates.

The **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure contains the **NDIS_LINK_STATE** structure. This structure specifies the physical state of the medium.

Miniport drivers should avoid sending the NDIS_STATUS_LINK_STATE status indication if there have been no changes in the physical state of the medium. However, avoiding this status indication is not a requirement.

If a miniport adapter transitions to a low power state, NDIS 6.0 and later miniport drivers should indicate a connection status of **MediaConnectStateUnknown**. When the miniport adapter transitions back to the working power state, the miniport driver should indicate a status of **MediaConnectStateConnected** after the link has been re-established. NDIS 6.30 miniport drivers should indicate **MediaConnectStateUnknown** during a low power transition only when a wake on link change and selective suspend are disabled. In other words, a miniport driver must indicate a connection state of **MediaConnectStateUnknown** during a low power transition, if it is impossible to detect and wake on a connection state change from a low power state.

NDIS might not pass a status indication to overlying drivers if there are no changes in the link state as specified in the previously indicated link state. However, this behavior is not guaranteed. Overlying drivers that receive this status indication must determine which characteristics of the medium, if any, have changed.

If an overlying driver is an NDIS 5.*x* or earlier protocol driver, NDIS translates the NDIS_STATUS_LINK_STATE status indication to appropriate NDIS 5.1 status indications. NDIS indicates link speed changes with the **NDIS_STATUS_LINK_SPEED_CHANGE** status indication. NDIS indicates changes in the connection state with **NDIS_STATUS_MEDIA_CONNECT** and **NDIS_STATUS_MEDIA_DISCONNECT** status indications.

NDIS also translates the NDIS 5.*x* miniport driver status for overlying NDIS 6.0 and later drivers. NDIS uses status indications or media state changes that NDIS identified in an NDIS 5.*x* OID query to create NDIS_STATUS_LINK_STATE status indications. NDIS performs the following translations:

- The **NDIS_STATUS_MEDIA_CONNECT** status indication is translated to **MediaConnectStateConnected** in the **NDIS_LINK_STATE** structure.

- The **NDIS_STATUS_MEDIA_DISCONNECT** status indication is translated to **MediaConnectStateDisconnected** in the **NDIS_LINK_STATE** structure.

- The **NDIS_STATUS_LINK_SPEED_CHANGE** status indication and the OID_GEN_LINK_SPEED OID are used to generate the link speed status.

For more information about link status, see OID_GEN_LINK_STATE.

Requirements

Version	Supported in NDIS 6.0 and later.
Header	Ndis.h (include Ndis.h)

NDIS_STATUS_PORT_STATE

Article • 03/14/2023

Miniport drivers that support NDIS ports use the NDIS_STATUS_PORT_STATE status indication to indicate changes in the state of an NDIS port.

Remarks

Miniport drivers must set the port number in the **PortNumber** member of the NDIS_STATUS_INDICATION structure. The **StatusBuffer** member of this structure contains a pointer to an NDIS_PORT_STATE structure.

Requirements

Version	Supported in NDIS 6.0 and later.
Header	Ndis.h (include Ndis.h)

See also

NDIS_PORT_STATE

NDIS_STATUS_INDICATION

NDIS_STATUS_OPER_STATUS

Article • 03/14/2023

The NDIS_STATUS_OPER_STATUS status indicates the current operational state of an NDIS network interface to overlying drivers.

Remarks

NDIS generates this status indication; NDIS miniport drivers should not generate this status indication.

NDIS supplies an NDIS_OPER_STATE structure in the **StatusBuffer** member of the NDIS_STATUS_INDICATION structure.

The **StatusBufferSize** member of the NDIS_STATUS_INDICATION structure is set to sizeof(NDIS_OPER_STATE).

Requirements

Version	Supported in NDIS 6.0 and later.
Header	Ndis.h (include Ndis.h)

See also

NDIS_OPER_STATE

NDIS_STATUS_INDICATION

NDIS_STATUS_NETWORK_CHANGE

Article • 03/14/2023

The NDIS_STATUS_NETWORK_CHANGE status indicates a network change to allow overlying drivers to initiate renegotiation of network addresses.

Remarks

NDIS miniport drivers can generate this status indication to request the overlying protocol drivers to renegotiate layer three addresses.

NDIS generates NDIS_STATUS_NETWORK_CHANGE status indications for the older 802.1X wireless miniport drivers that emulate 802.3. These miniport drivers report a media type of **NdisMedium802_3** and a physical media type of **NdisPhysicalMediumWirelessLan**. When such a miniport driver generates an NDIS_STATUS_MEDIA_CONNECT status indication and the associated miniport adapter is in a connected state, NDIS generates an NDIS_STATUS_NETWORK_CHANGE status indication for the miniport adapter.

NDIS 6.0 and later miniport drivers should generate the NDIS_STATUS_NETWORK_CHANGE status indication only after they are ready to handle network data. For example, in native 802.11, this status indication is generated after authentication is completed successfully and full layer two connectivity is achieved.

Note Although the media-connected state is not precisely defined, this state can be loosely defined as - the state in which the miniport adapter is able to transmit and receive network data. Media-connected is not directly related to link authentication status. The native WiFi 802.3 interface is unable to send or receive packets until after the link is authenticated. In this case, the media-connected state is coincident with the link-authenticated state in native 802.11.

NDIS supplies one of the following NDIS_NETWORK_CHANGE_TYPE values in the **StatusBuffer** member of the NDIS_STATUS_INDICATION structure:

NdisPossibleNetworkChange
The miniport driver detected that there might be a network change. In this case, the overlying protocols must detect the network change, if any, and renegotiate the addresses if necessary.

NDIS also uses this value when it generates NDIS_STATUS_NETWORK_CHANGE status indications for older 802.1X wireless miniport drivers that emulate 802.3. However, NDIS uses **NdisNetworkChangeFromMediaConnect** instead of **NdisPossibleNetworkChange** when it translates the same event for Windows Management Instrumentation (WMI).

NdisDefinitelyNetworkChange
The miniport driver detected that there is a network change, so the overlying protocols must renegotiate the addresses.

NdisNetworkChangeFromMediaConnect
An older 802.1X wireless miniport driver that emulates 802.3 generated an NDIS_STATUS_MEDIA_CONNECT status indication when it was in a connected state. This value is used in the WMI event notification for GUID_NDIS_STATUS_NETWORK_CHANGE. **NdisNetworkChangeFromMediaConnect** is not used in the NDIS_STATUS_NETWORK_CHANGE status indication.

The **StatusBufferSize** member of the NDIS_STATUS_INDICATION structure is set to sizeof(NDIS_NETWORK_CHANGE_TYPE).

Requirements

Version	Supported in NDIS 6.0 and later.
Header	Ndis.h (include Ndis.h)

NDIS_STATUS_INDICATION

NDIS_STATUS_MEDIA_CONNECT

NDIS_STATUS_PACKET_FILTER

Article • 03/14/2023

The NDIS_STATUS_PACKET_FILTER status indicates a packet filter change to overlying drivers. NDIS generates this status indications for a miniport adapter to notify overlying drivers that there might be a change in the miniport adapter's packet filter setting.

Remarks

NDIS does not guarantee that the packet filter has changed when NDIS generates the NDIS_STATUS_PACKET_FILTER status indication.

NDIS filter drivers can also generate the NDIS_STATUS_PACKET_FILTER status indication.

NDIS supplies a bitwise OR of the filter type flags in the **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure. For a list of the filter type flags, see the OID_GEN_CURRENT_PACKET_FILTER OID. For additional information about packet filters, see OID_GEN_SUPPORTED_PACKET_FILTERS.

The **StatusBufferSize** member of the **NDIS_STATUS_INDICATION** structure is set to sizeof(ULONG).

Requirements

Version	Supported in NDIS 6.0 and later.
Header	Ndis.h (include Ndis.h)

NDIS_STATUS_INDICATION

OID_GEN_CURRENT_PACKET_FILTER

OID_GEN_SUPPORTED_PACKET_FILTERS

NDIS_STATUS_RECEIVE_FILTER_CURRENT_CAPABILITIES

Article • 03/14/2023

The miniport driver issues an **NDIS_STATUS_RECEIVE_FILTER_CURRENT_CAPABILITIES** status indication when its currently enabled receive filtering capabilities change.

Note This status indication should only be made by miniport drivers that support NDIS receive filters.

When the miniport driver makes this status indication, it sets the **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure to a pointer to an **NDIS_RECEIVE_FILTER_CAPABILITIES** structure. The driver initializes this structure with its currently enabled receive filter capabilities.

Remarks

NDIS receive filters are used in the following NDIS interfaces:

- NDIS Packet Coalescing. For more information about how to use receive filters in this interface, see Managing Packet Coalescing Receive Filters.

- Single Root I/O Virtualization (SR-IOV). For more information about how to use receive filters in this interface, see Setting a Receive Filter on a Virtual Port.

- Virtual Machine Queue (VMQ). For more information about how to use receive filters in this interface, see Setting and Clearing VMQ Filters.

The miniport driver issues the **NDIS_STATUS_RECEIVE_FILTER_CURRENT_CAPABILITIES** status indication when one of the following conditions is true:

- The currently enabled receive filter capabilities change on a single network adapter. For example, receive filters can be enabled or disabled through a management application developed by the independent hardware vendor (IHV).

- The currently enabled receive filter capabilities change for one or more network adapters that belong to a load balancing failover (LBFO) team managed by a MUX intermediate driver. For more information, see NDIS MUX Intermediate Drivers.

The miniport driver follows these steps when it issues the **NDIS_STATUS_RECEIVE_FILTER_CURRENT_CAPABILITIES** status indication:

1. The miniport initializes the NDIS_RECEIVE_FILTER_CAPABILITIES structure with the receive filter capabilities that are currently enabled on the network adapter.

   When the miniport driver initializes the **Header** member, it sets the **Type** member of **Header** to NDIS_OBJECT_TYPE_DEFAULT. The miniport driver sets the **Revision** member of **Header** to NDIS_RECEIVE_FILTER_CAPABILITIES_REVISION_2 and the **Size** member to NDIS_SIZEOF_RECEIVE_FILTER_CAPABILITIES_REVISION_2.

2. The miniport driver initializes an NDIS_STATUS_INDICATION structure for the status indication in the following way:

   - The **StatusCode** member must be set to **NDIS_STATUS_RECEIVE_FILTER_CURRENT_CAPABILITIES**.

   - The **StatusBuffer** member must be set to the address of the NDIS_RECEIVE_FILTER_CAPABILITIES structure.

   - The **StatusBufferSize** member must be set to `sizeof(NDIS_RECEIVE_FILTER_CAPABILITIES)`.

3. The miniport driver issues the status indication by calling NdisMIndicateStatusEx. The driver must pass a pointer to the NDIS_STATUS_INDICATION structure to the *StatusIndication* parameter.

Note Overlying drivers can use the **NDIS_STATUS_RECEIVE_FILTER_CURRENT_CAPABILITIES** status indication to determine the currently enabled receive filter capabilities of the network adapter. Alternatively, these drivers can also issue OID query requests of OID_RECEIVE_FILTER_CURRENT_CAPABILITIES to obtain the currently enabled receive filter capabilities at any time.

Requirements

Version	Supported in NDIS 6.30 and later.
Header	Ndis.h (include Ndis.h)

NDIS_STATUS_INDICATION

NDIS_RECEIVE_FILTER_CAPABILITIES

OID_RECEIVE_FILTER_CURRENT_CAPABILITIES

NDIS_STATUS_RECEIVE_FILTER_HARDWARE_CAPABILITIES

Article • 03/14/2023

The miniport driver issues an **NDIS_STATUS_RECEIVE_FILTER_HARDWARE_CAPABILITIES** status indication when its hardware receive filtering capabilities change. These capabilities include the hardware capabilities that are currently disabled by INF file settings or through the **Advanced** properties page.

Note This status indication should only be made by miniport drivers that support NDIS receive filters.

When the miniport driver makes this status indication, it sets the **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure to a pointer to an **NDIS_RECEIVE_FILTER_CAPABILITIES** structure. The driver initializes this structure with its currently enabled receive filter capabilities.

Remarks

NDIS receive filters are used in the following NDIS interfaces:

- NDIS Packet Coalescing. For more information about how to use receive filters in this interface, see Managing Packet Coalescing Receive Filters.
- Single Root I/O Virtualization (SR-IOV). For more information about how to use receive filters in this interface, see Setting a Receive Filter on a Virtual Port.
- Virtual Machine Queue (VMQ). For more information about how to use receive filters in this interface, see Setting and Clearing VMQ Filters.

The miniport driver issues the **NDIS_STATUS_RECEIVE_FILTER_HARDWARE_CAPABILITIES** status indication when one of the following conditions is true:

- The hardware receive filter capabilities change on a single network adapter. For example, receive filters can be enabled or disabled through a management application developed by the independent hardware vendor (IHV).
- The hardware receive filter capabilities change for the load balancing failover (LBFO) team of network adapters that are managed by a MUX intermediate driver.

For example, the hardware receive filter capabilities could change when an adapter is added to or removed from the team.

For more information, see NDIS MUX Intermediate Drivers.

The miniport driver follows these steps when it issues the **NDIS_STATUS_RECEIVE_FILTER_HARDWARE_CAPABILITIES** status indication:

1. The miniport initializes the **NDIS_RECEIVE_FILTER_CAPABILITIES** structure with the receive filter capabilities that are currently enabled on the network adapter.

   When the miniport driver initializes the **Header** member, it sets the **Type** member of **Header** to NDIS_OBJECT_TYPE_DEFAULT. The miniport driver sets the **Revision** member of **Header** to NDIS_RECEIVE_FILTER_CAPABILITIES_REVISION_2 and the **Size** member to NDIS_SIZEOF_RECEIVE_FILTER_CAPABILITIES_REVISION_2.

2. The miniport driver initializes an **NDIS_STATUS_INDICATION** structure for the status indication in the following way:

   - The **StatusCode** member must be set to **NDIS_STATUS_RECEIVE_FILTER_CURRENT_CAPABILITIES**.

   - The **StatusBuffer** member must be set to the address of the **NDIS_RECEIVE_FILTER_CAPABILITIES** structure.

   - The **StatusBufferSize** member must be set to `sizeof(NDIS_RECEIVE_FILTER_CAPABILITIES)`.

3. The miniport driver issues the status indication by calling **NdisMIndicateStatusEx**. The driver must pass a pointer to the **NDIS_STATUS_INDICATION** structure to the *StatusIndication* parameter.

Note Overlying drivers can use the **NDIS_STATUS_RECEIVE_FILTER_HARDWARE_CAPABILITIES** status indication to determine the currently enabled receive filter capabilities of the network adapter. Alternatively, these drivers can also issue OID query requests of OID_RECEIVE_FILTER_HARDWARE_CAPABILITIES to obtain the hardware receive filter capabilities at any time.

Requirements

Version	Supported in NDIS 6.30 and later.

NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE

Article • 03/14/2023

The miniport driver that supports NDIS Quality of Service (QoS) issues an **NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE** status indication when its operational NDIS QoS parameters are either resolved for the first time or changed later. The miniport driver configures the network adapter with these operational parameters to perform QoS packet transmission.

When the miniport driver makes this status indication, it sets the **StatusBuffer** member of the NDIS_STATUS_INDICATION structure to a pointer to an NDIS_QOS_PARAMETERS structure. The driver initializes this structure with its operational NDIS QoS parameters.

Note This NDIS status indication is valid only for miniport drivers that support the IEEE 802.1 Data Center Bridging (DCB) interface.

Remarks

The miniport driver issues an **NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE** status indication under the following conditions:

- The miniport driver must issue an **NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE** status indication after it has initially resolved its operational NDIS QoS parameters and configured the network adapter with them.

- After this initial status indication, the miniport driver must issue an **NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE** status indication when its operational NDIS QoS parameters are changed. This can happen when either the local or remote NDIS QoS parameters are changed.

- Miniport drivers obtain the local NDIS QoS parameters from the Windows operating system when the Data Center Bridging (DCB) component (Msdcb.sys) issues an object identifier (OID) method request of OID_QOS_PARAMETERS. This OID request contains an **NDIS_QOS_PARAMETERS** structure that specifies the local NDIS QoS parameters.

  There may be situations when the miniport driver has to override the local NDIS QoS parameters when it resolves its operational NDIS QoS parameters. This is especially true if the local QoS parameters compromise the operational QoS parameters that are being used by any underlying protocols or technologies that are currently enabled on the network adapter. For example, the driver can override the local QoS parameters if the network adapter is enabled for remote boot through the Fibre Channel over Ethernet (FCoE) protocol.

The miniport driver notifies NDIS and overlying drivers of its intention to override the local NDIS QoS parameters by issuing an **NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE** status indication.

For more information, see Managing NDIS QoS Parameters.

Note Overlying drivers can use the **NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE** status indication to determine the operational NDIS QoS parameters. Alternatively, these drivers can also issue OID query requests of OID_QOS_OPERATIONAL_PARAMETERS to obtain the operational NDIS QoS parameters at any time.

For information on how the miniport driver issues an **NDIS_STATUS_QOS_OPERATIONAL_PARAMETERS_CHANGE** status indication, see Indicating Changes to the Operational NDIS QoS Parameters.

For more information about the various types of NDIS QoS parameters, see Overview of NDIS QoS Parameters.

Requirements

Version	Supported in NDIS 6.30 and later.

NDIS_QOS_PARAMETERS

OID_QOS_OPERATIONAL_PARAMETERS

NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE

Article • 03/14/2023

The miniport driver that supports NDIS Quality of Service (QoS) issues an **NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE** status indication when its remote NDIS QoS parameters are either received from a peer for the first time or change later. The miniport driver receives these QoS parameters from a remote peer through the IEEE 802.1Qaz Data Center Bridging Exchange (DCBX) protocol.

When the miniport driver makes this status indication, it sets the **StatusBuffer** member of the NDIS_STATUS_INDICATION structure to a pointer to an NDIS_QOS_PARAMETERS structure. The driver initializes this structure with its remote NDIS QoS parameters.

Note This NDIS status indication is valid only for miniport drivers that support the IEEE 802.1 Data Center Bridging (DCB) interface.

Remarks

The miniport driver uses the DCBX protocol to receive the QoS parameters for a remote peer. The miniport driver resolves its operational NDIS QoS parameters based on its local and remote QoS settings. Once the operational parameters are resolved, the miniport driver configures the network adapter with these parameters for QoS packet transmission.

For more information about how the driver resolves its operational NDIS QoS parameter settings, see Resolving Operational NDIS QoS Parameters.

The miniport driver must follow these guidelines for issuing an **NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE** status indication:

- If the miniport driver has not received a DCBX frame from a remote peer, it must not issue an **NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE** status indication.

- The miniport driver must issue an **NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE** status indication after it has first received the QoS settings from a remote peer.

  Note The miniport driver must issue this status indication if the network adapter receives remote QoS parameter settings from a peer before the driver's local QoS parameters are set. For more information, see Setting Local NDIS QoS Parameters.

- After this initial status indication, the miniport driver must only issue an **NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE** status indication when it determines a change in the QoS settings on the remote peer.

  Note Miniport drivers must not issue an **NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE** status indication if there have been no changes to the remote NDIS QoS parameters. If the driver does make this type of status indication, NDIS may not pass the indication to overlying drivers.

Note Overlying drivers can use the **NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE** status indication to determine the remote NDIS QoS parameters. Alternatively, these drivers can also issue OID query requests of OID_QOS_REMOTE_PARAMETERS to obtain the remote NDIS QoS parameters at any time.

For more information on how the miniport driver issues an **NDIS_STATUS_QOS_REMOTE_PARAMETERS_CHANGE** status indication, see Indicating Changes to the Remote NDIS QoS Parameters.

For more information about the remote NDIS QoS parameters, see Overview of NDIS QoS Parameters.

NDIS_STATUS_PM_WAKE_REASON

Article • 03/14/2023

The **NDIS_STATUS_PM_WAKE_REASON** status indication provides information about the wake-up event that was generated by a network adapter.

Remarks

Starting with NDIS 6.30, the miniport driver issues an NDIS status indication of **NDIS_STATUS_PM_WAKE_REASON**. This status indication notifies NDIS and overlying drivers about the reason for a wake-up event generated by the network adapter.

If the miniport driver supports this type of status indication, the miniport driver must issue an **NDIS_STATUS_PM_WAKE_REASON** status indication if the network adapter generated a wake-up signal. The driver does this while it is handling the OID set request of OID_PNP_SET_POWER for the transition of the adapter to a full-power state.

When the miniport driver makes this status indication, it sets the **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure to a pointer to an **NDIS_PM_WAKE_REASON** structure.

For more information about how to issue an **NDIS_STATUS_PM_WAKE_REASON** indication, see Issuing NDIS Wake Reason Status Indications.

Requirements

NDIS_STATUS_WAN_LINE_UP

Article • 03/14/2023

The NDIS_STATUS_WAN_LINE_UP status indicates that a WAN-capable miniport driver has established a connection with a remote node.

Remarks

NDIS 4.*x* and earlier NDIS WAN miniport drivers use this status indication. NDIS 5.0 and later WAN miniport drivers must use the CoNDIS WAN interface. For more information about the CoNDIS WAN interface, see Implementing CoNDIS WAN Miniport Drivers (NDIS 5.1).

The *StatusBuffer* parameter of the **NdisMIndicateStatus** function contains a pointer to an **NDIS_MAC_LINE_UP** structure.

For more information about NDIS_STATUS_WAN_LINE_UP, see Line-Up Indication (NDIS 5.1) and Indicating NDIS WAN Miniport Driver Status (NDIS 5.1).

Requirements

Version	Not supported for NDIS 6.0 drivers or NDIS 5.1 drivers in Windows Vista or Windows XP. Supported for NDIS 4.x drivers.

NDIS_STATUS_RING_STATUS

Article • 03/14/2023

The NDIS_STATUS_RING_STATUS status indicates the ring status of a line. A WAN-capable miniport driver can use this status to report a ring failure.

Remarks

NDIS 4.*x* and earlier NDIS WAN miniport drivers use this status indication. NDIS 5.0 and later WAN miniport drivers must use the CoNDIS WAN interface. For more information about the CoNDIS WAN interface, see Implementing CoNDIS WAN Miniport Drivers (NDIS 5.1).

The *StatusBuffer* parameter of the **NdisMIndicateStatus** function contains a ULONG value with one of the following status values:

NDIS_RING_LOBE_WIRE_FAULT

NDIS_RING_HARD_ERROR

NDIS_RING_SIGNAL_LOSS

These values specify ring conditions that are the reason for the status indication. For more information about NDIS_STATUS_RING_STATUS, see Reporting Hardware Status (NDIS 5.1).

Introduction to Header-Data Split

Article • 12/15/2021

This section describes header-data split services that are available in NDIS 6.1 and later versions. *Header-data split* improves network performance by splitting the header and data in received Ethernet frames into separate buffers. Separating the headers and the data enables the headers to be collected together into smaller regions of memory. As a result, more headers will fit into a single memory page and more headers will fit into the system caches, so the overhead for memory accesses in the driver stack is reduced.

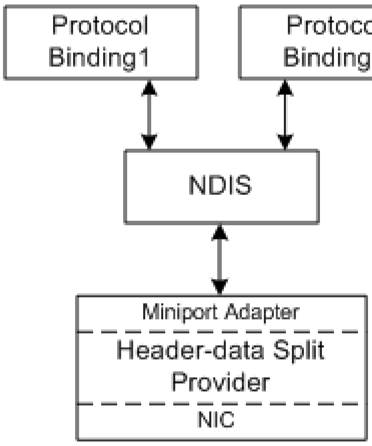
This section includes:

Header-Data Split Architecture

Article • 12/15/2021

A header-data split provider improves network performance by splitting the headers and data in received Ethernet frames into separate buffers. A header-data split provider includes a network interface card (NIC) and an NDIS 6.1 or later miniport driver that services the NIC.

The following figure shows the header-data split architecture.



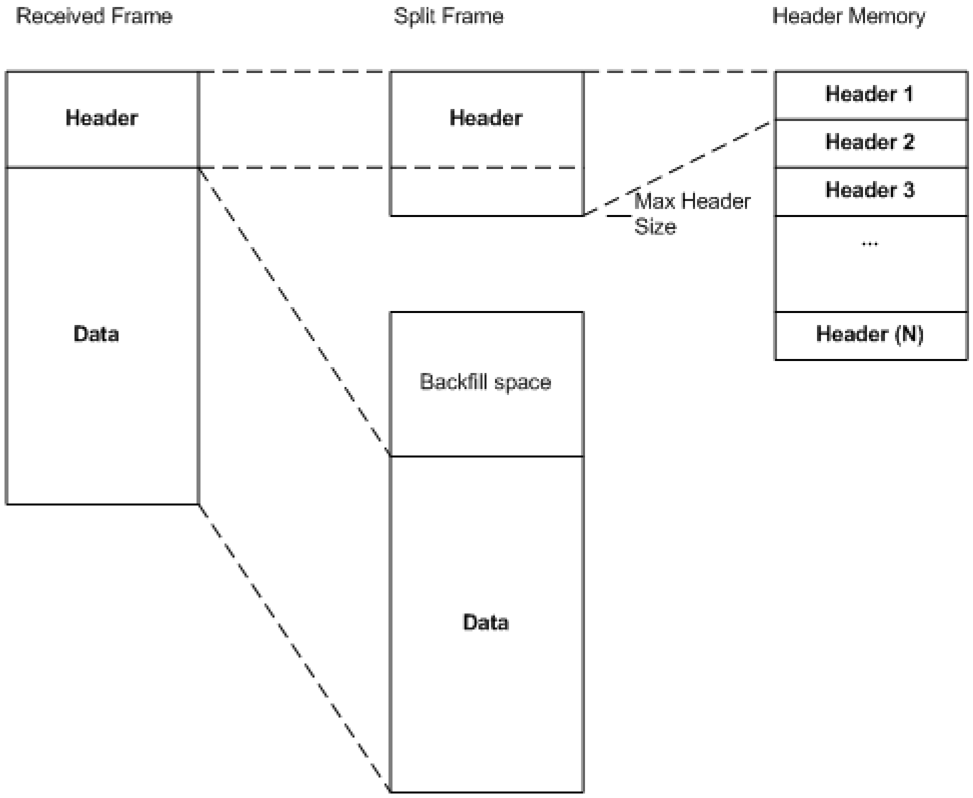
The miniport driver receives configuration information from NDIS to set up the NIC for header-data split receive operations. Also, the miniport driver exposes the NIC's services to NDIS for run-time operations such as send and receive operations.

A NIC that is capable of header-data split operations receives Ethernet frames and splits the headers and data into separate receive buffers.

The miniport driver uses the normal NDIS receive functions to indicate the received data to NDIS. Also, the driver must assign exactly one **NET_BUFFER** structure to a **NET_BUFFER_LIST** structure when indicating received data. For more information, see Indicating Received Ethernet Frames.

For header-data split, the **NET_BUFFER** structures in the receive indications split the received Ethernet frame by using separate memory descriptor lists (MDLs) for the header and the data. Also, the **NET_BUFFER_LIST** structure contains header-data split information in the NET_BUFFER_LIST information.

The following figure shows the received frame, the split buffers, and the memory layout of the header buffers.



The header buffers should all be in a contiguous block of storage.

An *upper-layer protocol* is an IP transport protocol such as TCP, UDP, or ICMP.

Note IPsec is not considered an upper-layer protocol for the purposes of defining header-data split requirements. For more information about splitting IPsec frames, see Splitting IPsec Frames.

Where to Split Header and Data

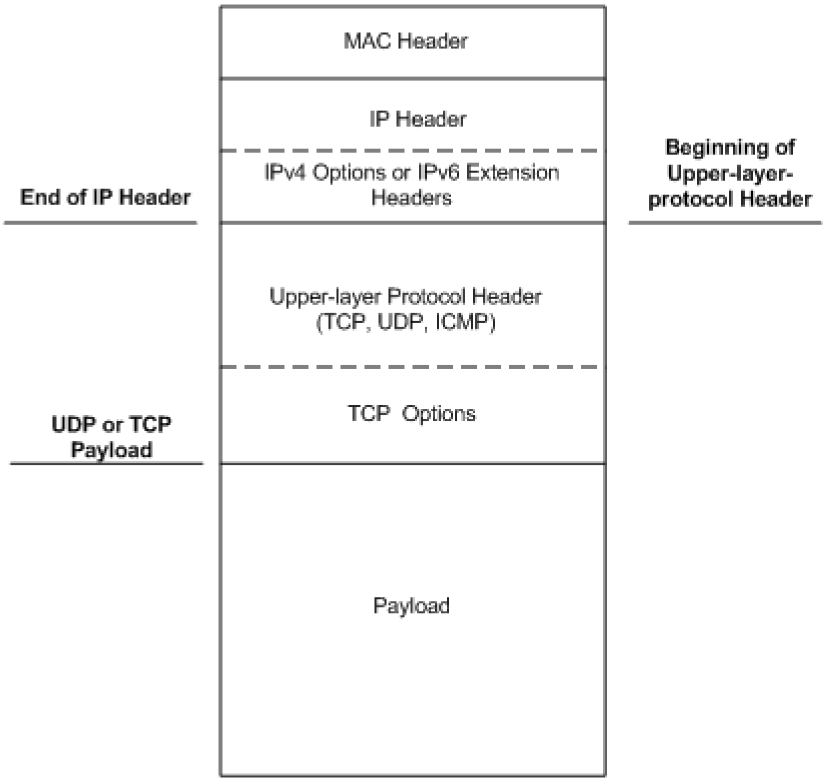
Article • 12/15/2021

The following are the only valid places where a header-data split provider can split an Ethernet frame:

- Beginning of upper-layer-protocol header.
- Beginning of UDP payload.
- Beginning of TCP payload.

Note These requirements apply only to header-data split providers. For more information about splitting frames in cases where header-data split is not used, see Cases Where Header-Data Split Is Not Used.

The following figure shows the major parts of the Ethernet frame and the valid split locations.



MAC Header
IP Header
IPv4 Options or IPv6 Extension Headers
End of IP Header
Beginning of Upper-layer-protocol Header
Upper-layer Protocol Header (TCP, UDP, ICMP)
TCP Options
UDP or TCP Payload
Payload

Cases Where Header-Data Split Is Not Used

Article • 12/15/2021

This topic provides an overview of the cases where a header-data split provider must not split Ethernet frames. For a listing of the minimum requirements that a provider must meet to support header-data split, see Minimum Requirements for Supporting Header-Data Split.

Note There are cases where a received frame can be split outside of the header-data split provider requirements. That is, the header-data split requirements only apply to header-data split providers. In these cases, never split Ethernet frames in the middle of the IP header, IPv4 options, IPsec headers, IPv6 extension headers, or upper-layer-protocol headers, unless the first MDL contains at least as many bytes as NDIS specified for lookahead size.

All Ethernet frames that are not split must follow the general NDIS rules and requirements. For example, the first MDL in the chain of MDLs in a received **NET_BUFFER** structure must contain either the lookahead part of the frame or the entire Ethernet frame (whichever is smaller) in a virtually contiguous buffer. NDIS sets the size of lookahead with the OID_GEN_CURRENT_LOOKAHEAD OID.

Header-data split providers:

- Do not split non-IP frames.

- Do not split frames if they cannot be split in one of these locations: at the beginning of the upper-layer-protocol header, the beginning of the TCP payload, or the beginning of the UDP payload.

- Do not split frames that would exceed the maximum configured header size unless the header can be split at the beginning of the upper-layer-protocol header. For more information about the maximum header size, see Allocating the Header Buffer.

- Do not split frames that contain IPv4 options that the NIC does not recognize.

- Do not split frames that contain IPv6 extension headers that the NIC does not recognize.

- Do not split frames that contain TCP options that the NIC does not recognize unless they can be split at the beginning of the TCP header.

Minimum Requirements for Supporting Header-Data Split

Article • 12/15/2021

This topic summarizes the minimum requirements that a provider must meet to support header-data split. For a complete listing of the rules that apply to splitting Ethernet frames, see Splitting Ethernet Frames.

The following list contains the minimum requirements for header-data split support:

- Providers must not split frames that the Cases Where Header-Data Split Is Not Used topic describes.

- Providers must move virtual LAN (VLAN) tags to the **NET_BUFFER_LIST** structure OOB data. For more information about VLAN requirements, see Receive Indications with Header-Data Split.

- Providers must support splitting IPv4 frames without options. For more information about splitting IPv4 frames, see Splitting IPv4 Frames.

- Providers must support splitting IPv6 frames without extension headers. For more information about splitting IPv6 frames, see Splitting IPv6 Frames.

- Providers must support splitting TCP frames at the TCP payload with no TCP options and with only the timestamp option. For more information about splitting TCP frames, see Splitting Frames at the TCP Payload.

- Providers must support splitting UDP frames at the UDP payload. For more information about splitting UDP frames, see Splitting Frames at the UDP Payload.

- Providers must support the header-data split initialization attributes. For more information about these attributes, see Initializing a Header-Data Split Provider.

- Providers must support the header-data split receive indication requirements, including setting the header-data split flags in the **NblFlags** member of the **NET_BUFFER_LIST** structures, header size requirements, and data backfill requirements. For more information about receive requirements, see Receive Indications with Header-Data Split.

- Providers must support the OID_GEN_HD_SPLIT_PARAMETERS OID, the OID_GEN_HD_SPLIT_CURRENT_CONFIG OID, the **NDIS_STATUS_HD_SPLIT_CURRENT_CONFIG** status indication, and registry settings. For more information about header-data split parameters and settings, see Header-Data Split Administration and Configuration.

For more information about header-data split requirements for protocol drivers and filter drivers, see Supporting Header-Data Split in Protocol Driver and Filter Drivers.

NDIS_STATUS_HD_SPLIT_CURRENT_CONFIG

Article • 03/14/2023

Miniport drivers use the NDIS_STATUS_HD_SPLIT_CURRENT_CONFIG status indication to notify NDIS and overlying drivers that there has been a change in the header-data split configuration of a miniport adapter.

Remarks

When a miniport driver receives an OID_GEN_HD_SPLIT_PARAMETERS set request, the driver must use the contents of the **NDIS_HD_SPLIT_PARAMETERS** structure to update the current configuration of the miniport adapter. After the update, the miniport driver must report the changes with the NDIS_STATUS_HD_SPLIT_CURRENT_CONFIG status indication. The status indication ensures that all of the overlying drivers are updated with the new information.

The **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure contains an **NDIS_HD_SPLIT_CURRENT_CONFIG** structure. This structure specifies the current header-data split configuration of a miniport adapter.

Requirements

Version	Supported in NDIS 6.1 and later.
Header	Ndis.h (include Ndis.h)

Initializing a Header-Data Split Provider

Article • 12/15/2021

To support header-data split, a miniport driver must register as an NDIS 6.1 or later driver. The sources file for the miniport driver must specify DNDIS61_MINIPORT=1 instead of DNDIS60_MINIPORT=1. The miniport driver must also specify NDIS 6.1 or a later version in the NDIS_MINIPORT_DRIVER_CHARACTERISTICS structure.

To register its header-data split attributes, an NDIS 6.1 miniport driver calls the NdisMSetMiniportAttributes function from its *MiniportInitializeEx* function and passes **NdisMSetMiniportAttributes** an initialized NDIS_MINIPORT_ADAPTER_HARDWARE_ASSIST_ATTRIBUTES structure.

The NDIS_MINIPORT_ADAPTER_HARDWARE_ASSIST_ATTRIBUTES structure contains the following information:

- The **HDSplitAttributes** member of NDIS_MINIPORT_ADAPTER_HARDWARE_ASSIST_ATTRIBUTES contains a pointer to an NDIS_HD_SPLIT_ATTRIBUTES structure that specifies the header-data split capabilities that a miniport adapter provides.

- The **HardwareCapabilities** member of NDIS_HD_SPLIT_ATTRIBUTES contains the header-data split capabilities that the miniport adapter supports. These capabilities can include capabilities that are currently disabled by INF file settings or through the **Advanced** properties page.

- The **CurrentCapabilities** member of NDIS_HD_SPLIT_ATTRIBUTES contains the current header-data split capabilities that the miniport adapter supports. If header-data split is enabled through the ***HeaderDataSplit** standardized INF keyword, the miniport driver uses the same flags as the **HardwareCapabilities** member to indicate the current header-data split configuration. For more information about ***HeaderDataSplit**, see Standardized INF Keywords for Header-Data Split.

- The **HDSplitFlags** member of NDIS_HD_SPLIT_ATTRIBUTES contains header-data split configuration flags. The miniport driver should set this member to zero before calling NdisMSetMiniportAttributes. NDIS sets this member with a bitwise OR of the configuration flags. After **NdisMSetMiniportAttributes** successfully returns, the miniport driver must check the flag settings in **HDSplitFlags** and configure the hardware accordingly.

NDIS uses the NDIS_HD_SPLIT_ENABLE_HEADER_DATA_SPLIT flag to enable header-data split for the miniport adapter. NDIS will not set

NDIS_HD_SPLIT_ENABLE_HEADER_DATA_SPLIT if the miniport driver did not set the NDIS_HD_SPLIT_CAPS_SUPPORTS_HEADER_DATA_SPLIT flag in the **CurrentCapabilities** member of the **NDIS_HD_SPLIT_ATTRIBUTES** structure. The miniport driver should enable header-data split in the NIC if NDIS sets the NDIS_HD_SPLIT_ENABLE_HEADER_DATA_SPLIT flag.

The miniport driver should set the **BackfillSize** member of the NDIS_HD_SPLIT_ATTRIBUTES structure to zero before calling **NdisMSetMiniportAttributes**. NDIS sets the **BackfillSize** member if the miniport driver must pre-allocate backfill storage in the data buffer of the split frames. After **NdisMSetMiniportAttributes** successfully returns, the miniport driver must use the **BackfillSize** value that NDIS specified and pre-allocate the data buffers. For more information about the data buffer backfill size, see Allocating Backfill for the Data Buffer.

The miniport driver should set the **MaxHeaderSize** member of the **NDIS_HD_SPLIT_ATTRIBUTES** structure to zero before calling **NdisMSetMiniportAttributes**. NDIS sets this member to the maximum size that is allowed for the header buffer of the split frames. After **NdisMSetMiniportAttributes** successfully returns, the miniport driver must use the **MaxHeaderSize** value that NDIS specified. For more information about the maximum header size, see Allocating the Header Buffer.

Splitting Ethernet Frames Overview

Article • 12/15/2021

This section describes the specific header-data split requirements that apply to header-data split providers, depending on the type of Ethernet frame that the provider is splitting.

Note After you read the general requirements in this topic, you can use the subsequent topics to understand the specific requirements for each type of Ethernet frame. The later topics build on the requirements in the earlier topics. For example, if a frame contains IPv4 and UDP information, you should read the Splitting IPv4 Frames and Splitting Frames at the UDP Payload topics.

If the header-data split provider splits a frame in compliance with the header-data split requirements, the indicated **NET_BUFFER_LIST** structures must have the NDIS_NBL_FLAGS_HD_SPLIT flag set in the **NblFlags** member. If the header-data split provider does not split a frame, the frame must be indicated with the following flags cleared in **NblFlags** :

- NDIS_NBL_FLAGS_HD_SPLIT
- NDIS_NBL_FLAGS_SPLIT_AT_UPPER_LAYER_PROTOCOL_HEADER
- NDIS_NBL_FLAGS_SPLIT_AT_UPPER_LAYER_PROTOCOL_PAYLOAD

For more information about setting header-data split NET_BUFFER_LIST flags and other receive indication requirements, see Receive Indications with Header-Data Split.

There are cases where a header-data split provider can split a received frame outside of the header-data split provider requirements. In these cases, the provider should never split Ethernet frames in the middle of the IP header, IPv4 options, IPsec headers, IPv6 extension headers, or upper-layer-protocol headers, unless the first MDL contains at least as many bytes as NDIS specified for the lookahead size. For more information about the lookahead size, see OID_GEN_CURRENT_LOOKAHEAD.

Splitting Frames at the Beginning of the Upper-Layer-Protocol Headers

Splitting Frames at the TCP Payload

Splitting Frames at the UDP Payload

Splitting Frames Other Than TCP and UDP

Splitting IPv4 Frames

Article • 12/15/2021

To support header-data split, a NIC must support splitting IPv4 Ethernet frames that have no IPv4 options. The NIC must be able to split such frames at the beginning of upper-layer-protocol header.

Support for IPv4 Ethernet frames with IPv4 options is optional. The NIC can support some IPv4 options and not the others. The NIC must not split IPv4 frames that contain IPv4 options that it does not recognize. The header portion of a split frame must contain the entire IPv4 header and all of the IPv4 options that are present.

The NIC can also support header-data split for fragmented IPv4 frames. For more information about fragmented IPv4 frames, see Splitting Fragmented IP Frames.

Note Supporting an IPv4 option, an IPv6 extension header or a TCP option, for the purposes of header-data requirements, implies the ability of the NIC to recognize the element, determine its length, include it in the header MDL and locate its end and the beginning of the next element in the frame.

If the header-data split provider splits an IPv4 frame, the indicated **NET_BUFFER_LIST** structures must have the NDIS_NBL_FLAGS_IS_IPV4 flag set in the **NblFlags** member. For complete information about setting header-data split flags in the NET_BUFFER_LIST structure, see Setting NET_BUFFER_LIST Information.

Additional Ethernet frame characteristics determine how to split IPv4 frames. If the IP frame is fragmented, see Splitting Fragmented IP Frames. If the frame contains TCP information, see Splitting Frames at the TCP Payload. If the frame contains UDP information, see Splitting Frames at the UDP Payload. For all other cases, see Splitting Frames Other Than TCP and UDP.

Splitting IPv6 Frames

Article • 12/15/2021

To support header-data split, a NIC must support splitting IPv6 Ethernet frames without any IPv6 extension headers. The NIC must be able to split such frames at the beginning of upper-layer-protocol header.

Support for IPv6 Ethernet frames with IPv6 extension headers is optional. A NIC can support some IPv6 options and not support others. The NIC must not split IPv6 frames that contain IPv6 extension headers that is does not support. The header portion of a split frame must contain the entire IPv6 header and all of the IPv6 extension headers that are present.

The NIC can also support header-data split for fragmented IPv6 frames. For more information about fragmented IPv4 frames, see Splitting Fragmented IP Frames.

Note Supporting an IPv4 option, an IPv6 extension header or a TCP option, for the purposes of header-data requirements, implies the ability of the NIC to recognize the element, determine its length, include it in the header MDL and locate its end and the beginning of the next element in the frame.

If the header-data split provider splits an IPv6 frame, the indicated **NET_BUFFER_LIST** structures must have the NDIS_NBL_FLAGS_IS_IPV6 flag set in the **NblFlags** member. For complete information about setting header-data split flags in the NET_BUFFER_LIST structure, see Setting NET_BUFFER_LIST Information.

Additional Ethernet frame characteristics determine how to split IPv6 frames. If the frame is fragmented, see Splitting Fragmented IP Frames. If the frame contains TCP information, see Splitting Frames at the TCP Payload. If the frame contains UDP information, see Splitting Frames at the UDP Payload. For all other cases, see Splitting Frames Other Than TCP and UDP.

Splitting Fragmented IP Frames

Article • 12/15/2021

If a fragmented IP frame contains the upper-layer-protocol header, a NIC must split the frame at the beginning of upper-layer-protocol header or must not split the frame. That is, the NIC must not split fragmented IP frames at the beginning of the TCP or UDP payload.

If a fragmented IPv4 frame does not contain the upper-layer-protocol header, the NIC must split the frame at the beginning of the UDP or TCP payload or must not split the frame.

If a fragmented IPv6 frame does not contain the upper-layer-protocol header, the NIC must not split the frame.

For more information about splitting frames at the beginning of the upper-layer-protocol header, see Splitting Frames at the Beginning of the Upper-Layer-Protocol Headers.

Splitting Frames at the Beginning of the Upper Layer-Protocol Headers

Article • 12/15/2021

An *upper-layer protocol* is an IP transport protocol such as TCP, UDP, or ICMP.

Note IPsec is not considered an upper-layer-protocol in the header-data split requirements. For more information about splitting IPsec frames, see Splitting IPsec Frames.

If a NIC splits an Ethernet frame at the beginning of the upper-layer-protocol header, the indicated **NET_BUFFER** must contain exactly two MDLs. The buffer that the first MDL describes must begin with the first byte of the Ethernet frame (MAC header) and the buffer that the second MDL describes must start with the first byte of the upper-layer-protocol header.

Note The NIC can split TCP and UDP frames at the TCP or UDP payload. For more information, see Splitting Frames at the TCP Payload and Splitting Frames at the UDP Payload.

If the header-data split provider splits the frame at the beginning of the upper-layer-protocol header, the indicated **NET_BUFFER_LIST** structures must have the NDIS_NBL_FLAGS_SPLIT_AT_UPPER_LAYER_PROTOCOL_HEADER flag set in the **NblFlags** member. For more information about setting header-data split NET_BUFFER_LIST flags, see Setting NET_BUFFER_LIST Information.

The NIC must not split a frame if the resulting header buffer has a greater length than the maximum header size. For more information about splitting frames when the maximum header size is exceeded, see Allocating the Header Buffer.

Splitting Frames at the TCP Payload

Article • 12/15/2021

NDIS miniport adapters that support header-data split must support splitting frames at the upper-layer-protocol header for TCP frames. However, if the TCP header does not contain any TCP options, the NIC should split the frame at the beginning of the TCP payload.

The NIC might not be able to split a TCP frame if the resulting header buffer has a greater length than the maximum header size. For more information about splitting frames when the maximum header size is exceeded, see Allocating the Header Buffer.

NICs must also support splitting TCP headers with only the timestamp option. That is, the timestamp option is the only TCP option that is mandatory. Otherwise, support for TCP headers with TCP options is optional. If the TCP header of a frame contains an unrecognized TCP option, the NIC must either split the frame at the beginning of TCP header (that is, at the upper-layer-protocol header) or not split the frame.

Note Supporting an IPv4 option, an IPv6 extension header or a TCP option, for the purposes of header-data requirements, implies the ability of the NIC to recognize the element, determine its length, include it in the header MDL and locate its end and the beginning of the next element in the frame.

For more information about splitting frames at the beginning of the upper-layer-protocol header, see Splitting Frames at the Beginning of the Upper-Layer-Protocol Headers.

If the header-data split provider splits the frame at the TCP payload, the indicated **NET_BUFFER_LIST** structures must have the NDIS_NBL_FLAGS_IS_TCP and NDIS_NBL_FLAGS_SPLIT_AT_UPPER_LAYER_PROTOCOL_PAYLOAD flags set in the **NblFlags** member. For more information about setting header-data split NET_BUFFER_LIST flags, see Setting NET_BUFFER_LIST Information.

Splitting Frames at the UDP Payload

Article • 12/15/2021

NDIS miniport adapters that support header-data split must support splitting frames at the upper-layer-protocol header for UDP frames. However, the NIC must first try to split the frame at the beginning of UDP payload.

The NIC might not be able to split a UDP frame if the resulting header buffer has a greater length than the maximum header size. For more information about splitting frames when the maximum header size is exceeded, see Allocating the Header Buffer.

If the NIC cannot split the frame at the UDP payload, the NIC should split the frame at the beginning of the upper-layer-protocol header or should not split the frame. For more information about splitting frames at the beginning of the upper-layer-protocol header, see Splitting Frames at the Beginning of the Upper-Layer-Protocol Headers.

If the header-data split provider splits the frame at the UDP payload, the indicated **NET_BUFFER_LIST** structures must have the NDIS_NBL_FLAGS_IS_UDP and NDIS_NBL_FLAGS_SPLIT_AT_UPPER_LAYER_PROTOCOL_PAYLOAD flags set in the **NblFlags** member. For more information about setting header-data split NET_BUFFER_LIST flags, see Setting NET_BUFFER_LIST Information.

Splitting ICMP Frames and Other Upper-Layer-Protocol Frames

Article • 12/15/2021

A NIC must split IP frames with upper-layer-protocols other than TCP or UDP (for example, ICMP frames) at the beginning of upper-layer-protocol header or must not split such frames.

For more information about splitting at the upper-layer-protocol header, see Splitting Frames at the Beginning of the Upper-Layer-Protocol Headers.

Splitting IPsec Frames

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

A NIC can split IPsec frames at the beginning of the upper-layer-protocol header, the beginning of the TCP payload, or the beginning of the UDP payload. The NIC should treat the IPsec information the same as an IPv4 option or IPv6 extension header.

The NIC might not be able to split the frame if the resulting header buffer has a greater length than the maximum header size. For more information about the maximum header size, see Allocating the Header Buffer.

Receive Indications with Header-Data Split

Article • 12/15/2021

A miniport driver that supports header-data split must indicate received data in the format that header-data split requires. For example, the header buffers should all be in a contiguous block of storage and the data buffers must include backfill space.

The header information in split frames must never include virtual LAN (VLAN) tags. Header-data split requires support for VLAN in hardware and requires removing VLAN tags from the incoming frames and placing them in the **Ieee8021QNetBufferListInfo** OOB information in the **NET_BUFFER_LIST** structure. The miniport driver must specify support for VLAN in the **MacOptions** member of the **NDIS_MINIPORT_ADAPTER_GENERAL_ATTRIBUTES** structure and in response to the OID_GEN_MAC_OPTIONS OID query.

NDIS and overlying drivers or user-mode applications use the OID_GEN_HD_SPLIT_PARAMETERS OID to set the current header-data split settings of a miniport adapter. If the NDIS_HD_SPLIT_COMBINE_ALL_HEADERS flag in the **HDSplitCombineFlags** member of the **NDIS_HD_SPLIT_PARAMETERS** structure is set, the miniport adapter must combine all split frames. If header-data split is enabled in the hardware, the miniport driver must combine the header and data before indicating the frame to NDIS. For more information about OID_GEN_HD_SPLIT_PARAMETERS and other administrative and configuration issues, see Header-Data Split Administration and Configuration.

This section includes:

Allocating the Header Buffer

Allocating Backfill for the Data Buffer

Setting NET_BUFFER_LIST Information

Allocating the Header Buffer

Article • 12/15/2021

NDIS specifies the maximum header size that a miniport driver should allocate in the **MaxHeaderSize** member of the **NDIS_HD_SPLIT_ATTRIBUTES** structure. For more information about setting header-data split attributes, see Initializing a Header-Data Split Provider.

When a NIC splits the header and data in a received Ethernet frame, the size of the header portion of the indicated Ethernet frame must not exceed the **MaxHeaderSize** value.

If an IP header contains IPv4 options, IPsec headers, or IPv6 extension headers, and if the header exceeds the **MaxHeaderSize** value, the NIC must not split the frame.

If a header that includes the UDP header, TCP header, or TCP options exceeds the **MaxHeaderSize** value, the NIC must either split the frame at the beginning of the upper-layer-protocol header or must not split the frame.

Allocating Backfill for the Data Buffer

Article • 12/15/2021

NDIS specifies the amount of data backfill space that the miniport driver should allocate in the **BackfillSize** member of the **NDIS_HD_SPLIT_ATTRIBUTES** structure. For more information about setting header-data split attributes, see Initializing a Header-Data Split Provider.

When a NIC splits the header and data in a received Ethernet frame, the miniport driver must pre-allocate backfill storage of at least the number of bytes that **BackfillSize** specifies before the starting address of data portion of the frame. The backfill storage must not cross a page boundary.

The driver stack can use the pre-allocated backfill storage to copy the header portion of the frame and create a virtually contiguous frame for network drivers that cannot handle split Ethernet frames.

Setting NET_BUFFER_LIST Information

Article • 12/15/2021

A header-data split provider must set the header-data split flags in the **NblFlags** member of the NET_BUFFER_LIST structures for receive indications. For split frames, a NIC must also provide the physical address of the data portion of the received frame in the **DataPhysicalAddress** member of each NET_BUFFER structure.

Note A miniport driver can set the **DataPhysicalAddress** member of the NET_BUFFER structure, even if the NET_BUFFER is not associated with a split frame. In this case, **DataPhysicalAddress** contains the physical address of the header MDL.

The header-data split provider combines the flags in the **NblFlags** member with a bitwise OR operation.

The header-data split provider can set the following flags even if it does not split a frame:

NDIS_NBL_FLAGS_IS_IPV4
All of the frames in the NET_BUFFER_LIST are IPv4 frames. If this flag is set, the NDIS_NBL_FLAGS_IS_IPV6 flag must not be set.

NDIS_NBL_FLAGS_IS_IPV6
All of the frames in the NET_BUFFER_LIST are IPv6 frames. If this flag is set, the NDIS_NBL_FLAGS_IS_IPV4 flag must not be set.

NDIS_NBL_FLAGS_IS_TCP
All of the frames in the NET_BUFFER_LIST are TCP frames. If this flag is set, NDIS_NBL_FLAGS_IS_UDP must not be set. And either NDIS_NBL_FLAGS_IS_IPV4 or NDIS_NBL_FLAGS_IS_IPV6 must be set.

NDIS_NBL_FLAGS_IS_UDP
All of the frames in the NET_BUFFER_LIST are UDP frames. If this flag is set, NDIS_NBL_FLAGS_IS_TCP must not be set. And either NDIS_NBL_FLAGS_IS_IPV4 or NDIS_NBL_FLAGS_IS_IPV6 must be set.

Any NDIS driver can set the preceding flags for debugging, testing, or other purposes. If a driver sets these flags, the values must accurately describe the contents of the received frame. Setting these flags is recommended.

The header-data split provider can set the following header-data split flags:

NDIS_NBL_FLAGS_HD_SPLIT
The header and data are split in all of the Ethernet frames that are associated with the **NET_BUFFER_LIST** structure.

NDIS_NBL_FLAGS_SPLIT_AT_UPPER_LAYER_PROTOCOL_HEADER
All of the frames in the NET_BUFFER_LIST structure are split at the beginning of the upper-layer-protocol header. If this flag is set, either NDIS_NBL_FLAGS_IS_IPV4 or NDIS_NBL_FLAGS_IS_IPV6 must be set. Also, either NDIS_NBL_FLAGS_IS_TCP or NDIS_NBL_FLAGS_IS_UDP can be set. And NDIS_NBL_FLAGS_SPLIT_AT_UPPER_LAYER_PROTOCOL_PAYLOAD must not be set.

NDIS_NBL_FLAGS_SPLIT_AT_UPPER_LAYER_PROTOCOL_PAYLOAD
All of the frames in a NET_BUFFER_LIST structure are split at the beginning of the TCP payload or beginning of the UDP payload. If this flag is set, either NDIS_NBL_FLAGS_IS_IPV4 or NDIS_NBL_FLAGS_IS_IPV6 must be set. Either NDIS_NBL_FLAGS_IS_TCP or NDIS_NBL_FLAGS_IS_UDP must be set. Also, NDIS_NBL_FLAGS_SPLIT_AT_UPPER_LAYER_PROTOCOL_HEADER must not be set.

If the header-data split provider does not split a frame, the frame must be indicated with the following flags cleared in **NblFlags** :

- NDIS_NBL_FLAGS_HD_SPLIT
- NDIS_NBL_FLAGS_SPLIT_AT_UPPER_LAYER_PROTOCOL_HEADER
- NDIS_NBL_FLAGS_SPLIT_AT_UPPER_LAYER_PROTOCOL_PAYLOAD

Setting the Current Header-Data Split Configuration

Article • 12/15/2021

NDIS and overlying drivers or user-mode applications use the OID_GEN_HD_SPLIT_PARAMETERS OID to set the current header-data split settings of a miniport adapter. NDIS 6.1 and later miniport drivers that provide header-data split services must support this OID. Otherwise, this OID is optional.

A system administrator can use the GUID that is associated with this OID through the WMI interface. For more information about header-data split WMI GUIDs, see WMI Support for Header-Data Split.

The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains an **NDIS_HD_SPLIT_PARAMETERS** structure.

If the NDIS_HD_SPLIT_COMBINE_ALL_HEADERS flag in the **HDSplitCombineFlags** member of NDIS_HD_SPLIT_PARAMETERS is set, the miniport adapter must combine all split frames. If header-data split is enabled in the hardware, the miniport driver must combine the header and data before the driver indicates the frame to NDIS.

For example, NDIS might use the OID_GEN_HD_SPLIT_PARAMETERS OID to set the NDIS_HD_SPLIT_COMBINE_ALL_HEADERS flag when an NDIS 5.*x* protocol driver binds to an NDIS 6.1 miniport adapter. NDIS processes this OID before it passes the OID to the miniport driver and updates the miniport adapter's ***HeaderDataSplit** standardized keyword, if required. If header-data split is disabled, NDIS does not send this OID to the miniport adapter.

Getting the Current Header-Data Split Configuration

Article • 12/15/2021

To get the current header-data split settings of a miniport adapter, overlying drivers or user-mode applications can query the OID_GEN_HD_SPLIT_CURRENT_CONFIG OID. However, overlying drivers should use the information that NDIS provides to them during initialization and with status indications.

A system administrator can use the GUID that is associated with the OID_GEN_HD_SPLIT_CURRENT_CONFIG OID through the WMI interface. For more information about header-data split WMI GUIDs, see WMI Support for Header-Data Split.

NDIS handles OID_GEN_HD_SPLIT_CURRENT_CONFIG on behalf of the miniport driver. NDIS maintains the current header-data split configuration information based on the miniport driver initialization attributes and the **NDIS_STATUS_HD_SPLIT_CURRENT_CONFIG** status indication.

The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains an **NDIS_HD_SPLIT_CURRENT_CONFIG** structure. NDIS also provides the NDIS_HD_SPLIT_CURRENT_CONFIG structure to overlying drivers during initialization and with the status indication.

When a miniport driver receives an OID_GEN_HD_SPLIT_PARAMETERS set request, the driver must use the contents of the **NDIS_HD_SPLIT_PARAMETERS** structure to update the current configuration of the miniport adapter. After the update, the miniport driver must report the changes with the **NDIS_STATUS_HD_SPLIT_CURRENT_CONFIG** status indication. The status indication ensures that all of the overlying drivers are updated with the new information.

When NDIS calls the *ProtocolBindAdapterEx* function of NDIS 6.1 or later protocol drivers, NDIS provides an **NDIS_BIND_PARAMETERS** structure with a pointer to an **NDIS_HD_SPLIT_CURRENT_CONFIG** structure.

When NDIS calls the *FilterAttach* function of NDIS 6.1 or later filter drivers, NDIS provides an **NDIS_FILTER_ATTACH_PARAMETERS** structure with a pointer to an NDIS_HD_SPLIT_CURRENT_CONFIG structure.

Standardized INF Keywords for Header-Data Split

Article • 12/15/2021

A *standardized keyword* is defined to enable or disable support for header-data split for a miniport adapters.

The following table describes the possible INF entries for the header-data split keyword.

SubkeyName	ParamDesc	Value	EnumDesc
***HeaderDataSplit**	Header Data Split	0 (Default)	Disabled
		1	Enabled

For more information about standardized INF keywords, see Standardized INF Keywords for Network Devices.

WMI Support for Header-Data Split

Article • 12/15/2021

NDIS 6.1 and later supports header-data split GUIDs for WMI applications to query and set the header-data split configuration and to provide notification of changes.

The following GUIDs support header-data split:

- GUID_NDIS_HD_SPLIT_CURRENT_CONFIG
- GUID_NDIS_HD_SPLIT_PARAMETERS
- GUID_NDIS_STATUS_HD_SPLIT_CURRENT_CONFIG

Supporting Header-Data Split in Protocol Drivers and Filter Drivers

Article • 12/15/2021

NDIS 6.0 and later protocol drivers and filter drivers must support receive indications with the header and data in non-contiguous buffers.

You must not assume that there is only a single MDL in a NET_BUFFER structure. Protocol drivers and filter drivers are not required to do anything specific to support header-data split registration. But, the driver receive handling code must handle more than one MDL in the MDL chain and must use the following NDIS MDL macros to access the MDL chain:

- NET_BUFFER_FIRST_MDL
- NET_BUFFER_CURRENT_MDL
- NET_BUFFER_CURRENT_MDL_OFFSET

With split buffers, the data length that is associated with the NET_BUFFER structure (in the **DataLength** member of the NET_BUFFER_DATA structure) is split across multiple MDLs. For example, if a protocol driver tried to access the entire data buffer in the first MDL, the driver could access invalid data.

Note After the receive indication call returns to a miniport driver, the miniport driver can reclaim the header MDLs. The overlying drivers or their clients must not access the header MDLs after the receive indication call returns to the miniport driver. This restriction also applies even when the miniport driver is not indicating the received data with a status of NDIS_RECEIVE_FLAGS_RESOURCES.

Overview of Network Direct Kernel Provider Interface (NDKPI)

Article • 12/15/2021

The Network Direct Kernel Provider Interface (NDKPI) is an extension to NDIS that allows IHVs to provide kernel-mode Remote Direct Memory Access (RDMA) support in a network adapter (also called an RNIC). To expose the adapter's RDMA functionality, the IHV must implement the NDKPI interface as defined in the NDKPI Reference.

- NDKPI and RDMA
- The NDK provider
- The NDK consumer

NDKPI and RDMA

A NIC vendor implements RDMA as a combination of software, firmware, and hardware. The hardware and firmware portion is a network adapter that provides NDK/RDMA functionality. This type of adapter is also called an RDMA-enabled NIC (RNIC). The software portion is an NDK-capable miniport driver, which implements the NDKPI interface.

The Windows implementation of RDMA is called Network Direct (ND). The kernel portion is called Network Direct Kernel (NDK).

NDK providers must support Network Direct connectivity via both IPv4 and IPv6 addresses assigned to NDK-capable miniport adapters.

For more information about RDMA, see Background Reading on RDMA.

The NDK provider

An NDK provider is a miniport driver that implements the NDKPI interface.

The NDK provider is loaded and initialized by the PnP Manager. For more information, see Initializing an NDK-Capable Miniport Driver and Initializing an NDK Miniport Adapter.

Once the NDK provider is loaded and initialized, it is ready to handle requests from the NDK consumer. These requests arrive as calls to provider functions.

When handling requests from an NDK consumer, the provider can call the consumer's NDK callback functions. These are documented in NDKPI Consumer Callback Functions.

NDK providers must implement all elements of the NDKPI interface that are documented in the NDKPI Reference, except for the NDKPI Consumer Callback Functions.

The NDK consumer

NDK consumers are kernel-mode Windows components, such as SMB server and client.

Note This documentation does not discuss how to implement an NDK consumer. The NDKPI consumer device driver interface (DDI) is a proprietary Windows-internal interface.

An NDK consumer calls the provider's *NdkOpenAdapter* (*OPEN_NDK_ADAPTER_HANDLER*) callback function to create an adapter object and *NdkCloseAdapter* (*NDK_FN_CLOSE_OBJECT*) to close it. Once the provider has created the adapter object, the consumer calls other provider callback functions to create additional NDK objects.

NDK consumers implement the NDKPI Consumer Callback Functions, which are called by NDK providers.

NDKPI Terminology

Article • 12/15/2021

The NDKPI documentation uses the following terms to describe NDK providers and consumers.

provider function

An NDKPI function in the function dispatch table of an NDK object. Provider functions are implemented by NDK providers and called by NDK consumers. All provider functions have as the first parameter a pointer to the object on which they operate. This pointer is similar to the "this" pointer in C++. This pointer is always passed explicitly by the consumer to the provider function.

consumer callback

An NDKPI function implemented by NDK consumers and called by NDK providers. There are 2 types of consumer callbacks: completion callbacks and event callbacks.

completion callback

A consumer callback that is called by the NDK provider to signal the completion of an asynchronous provider function. In NDKPI 1.1 and 1.2, there are 3 completion callbacks:

- *NdkCloseCompletion* (*NDK_FN_CLOSE_COMPLETION*)
- *NdkCreateCompletion* (*NDK_FN_CREATE_COMPLETION*)
- *NdkRequestCompletion* (*NDK_FN_REQUEST_COMPLETION*)

event callback

A consumer callback that can be called by the NDK provider to indicate certain events on an NDK object asynchronously without being triggered by an asynchronous provider function. In NDKPI 1.1 and 1.2, there are 4 event callbacks:

- *NdkCqNotificationCallback* (*NDK_FN_CQ_NOTIFICATION_CALLBACK*)
- *NdkConnectEventCallback* (*NDK_FN_CONNECT_EVENT_CALLBACK*)
- *NdkDisconnectEventCallback* (*NDK_FN_DISCONNECT_EVENT_CALLBACK*)
- *NdkSrqNotificationCallback* (*NDK_FN_SRQ_NOTIFICATION_CALLBACK*)

parent object

An NDK object whose function dispatch table contains one or more *NdkCreate*Xxx** provider functions to create other objects. in NDKPI versions 1.1 and 1.2, there are 2 parent objects:

The NDK adapter object (**NDK_ADAPTER**) is the parent of:

- **NDK_CONNECTOR**
- **NDK_CQ**
- **NDK_LISTENER**
- **NDK_LOGICAL_ADDRESS_MAPPING**
- **NDK_PD**
- **NDK_SHARED_ENDPOINT**

The NDK protection domain (PD) object (**NDK_PD**) is the parent of:

- **NDK_MR**
- **NDK_MW**
- **NDK_QP**
- **NDK_SRQ**

child object

An NDK object which is created by calling one of the *NdkCreate*Xxx** provider functions in a parent object's dispatch table.

antecedent object

An NDK object that another object relies on in order to provide functionality. The antecedent object must be created before the successor object. Note that all parent objects are antecedent objects, but the reverse is not true.

successor object

An NDK object that relies on an antecedent object. The antecedent object must be created before the successor object. Note that all child objects are successor objects but the reverse is not true. Note that an antecedent/successor relationship may be required, optional, and/or deferred to a point after the successor creation in some cases.

The following antecedent/successor relationships are defined by NDKPI versions 1.1 and 1.2 (in addition to the parent/child relationships, which are antecedent/successor relationships by definition):

Antecedent	Successor
NDK_CQ	NDK_QP
NDK_MR	NDK_MW (See *NdkBind* (*NDK_FN_BIND*).)
NDK_SRQ	NDK_QP
NDK_QP	NDK_CONNECTOR (See *NdkConnect* (*NDK_FN_CONNECT*), *NdkAccept* (*NDK_FN_ACCEPT*), and *NdkConnectWithSharedEndpoint* (*NDK_FN_CONNECT_WITH_SHARED_ENDPOINT*).)
NDK_SHARED_ENDPOINT	NDK_CONNECTOR (See *NdkConnectWithSharedEndpoint* (*NDK_FN_CONNECT_WITH_SHARED_ENDPOINT*).)
NDK_LISTENER	NDK_CONNECTOR (See *NdkConnectEventCallback* (*NDK_FN_CONNECT_EVENT_CALLBACK*).)

endpoint

An implicit or explicit representation of a local address and NetworkDirect port number that identify the local point over which connections can be initiated or accepted, for example, 10.1.1.1:445:

- An NDK_LISTENER has an implicit endpoint (which the consumer specifies when calling *NdkListen* (*NDK_FN_LISTEN*)).

- An **NDK_CONNECTOR** that is connected by calling *NdkConnect* (*NDK_FN_CONNECT*) also has an implicit endpoint.
- An **NDK_SHARED_ENDPOINT** represents an explicit endpoint. The NDK consumer directly creates the endpoint and uses it explicitly to initiate one or more connections by calling *NdkConnectWithSharedEndpoint* (*NDK_FN_CONNECT_WITH_SHARED_ENDPOINT*).

Note An NDK endpoint is not the same as the NDSPI version 1 **INDEndpoint** interface or the NDSPI version 2 **INDQueuePair** interface.

Background Reading on RDMA

Article • 12/15/2021

RDMA is a networking technology that provides high-throughput, low-latency communication that minimizes CPU usage. NDK currently supports the following RDMA technologies:

- Infiniband (IB)
- Internet Wide Area RDMA Protocol (iWARP)
- RDMA over Converged Ethernet (RoCE)

For more information about RDMA, Infiniband, iWARP, and RoCE, see the following resources:

- RFC 5040: A Remote Direct Memory Access Protocol Specification
- RFC 5041: Direct Data Placement over Reliable Transports
- RFC 5042: Direct Data Placement Protocol (DDP) / Remote Direct Memory Access Protocol (RDMAP) Security
- RFC 5043: Stream Control Transmission Protocol (SCTP) Direct Data Placement (DDP) Adaptation
- RFC 5044: Marker PDU Aligned Framing for TCP Specification
- RDMA Consortium
- Internet Draft: RDMA Protocol Verbs Specification
- Infiniband Trade Association (for downloadable specifications for Infiniband and RoCE)

Initializing an NDK-Capable Miniport Driver

Article • 12/15/2021

A miniport driver that supports Network Direct kernel (NDK) is initialized in the same way as other miniport drivers. However, it must also register additional NDKPI entry points.

- DriverEntry function
- MiniportSetOptions function
- Related topics

DriverEntry function

Every miniport driver's *DriverEntry* function initializes an **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** structure and passes it to **NdisMRegisterMiniportDriver** as described in the following pages:

- Initializing a Miniport Driver
- **DriverEntry of NDIS Miniport Drivers function**

The NDK-capable miniport driver must do the following when initializing the **NDIS_MINIPORT_DRIVER_CHARACTERISTICS** structure:

- In the **OidRequestHandler** member, the miniport driver must register a *MiniportOidRequest* function that supports:

    - All NDKPI OIDs.

    - Any OIDs that are mandatory for NDIS miniport drivers in general.

      Note For a list of these mandatory OIDs, see Mandatory OIDs for Miniport Drivers.

- In the **SetOptionsHandler** member, the miniport driver must register a *MiniportSetOptions* function as described in Configuring Optional Miniport Driver Services and the following MiniportSetOptions function section.

MiniportSetOptions function

NDIS calls the *MiniportSetOptions* function immediately after the miniport driver's **DriverEntry** function returns. The *MiniportSetOptions* function is called in the context of the miniport driver's call to **NdisMRegisterMiniportDriver**.

In its *MiniportSetOptions* function, the NDK-capable miniport driver registers its NDK capability and registers the following required NDKPI function entry points as described in Configuring Optional Miniport Driver Services:

- *OpenNDKAdapterHandler* (*OPEN_NDK_ADAPTER_HANDLER*)
- *CloseNDKAdapterHandler* (*CLOSE_NDK_ADAPTER_HANDLER*)

To register NDKPI entry points for these functions, the miniport driver's *MiniportSetOptions* function must do the following:

1. Initialize an **NDIS_NDK_PROVIDER_CHARACTERISTICS** structure.

   Note Pay particular attention to the **Header** member description. The miniport driver must set this member correctly to identify itself as an NDK-capable miniport driver.

2. Store the function entry points in the **OpenNDKAdapterHandler** and **CloseNDKAdapterHandler** members of the structure.

3. Call the **NdisSetOptionalHandlers** function, passing the structure in the *OptionalHandlers* parameter.

Initializing an NDK Miniport Adapter

Article • 12/15/2021

A Network Direct kernel (NDK) miniport adapter is initialized in the same way as other miniport adapters: NDIS calls the miniport adapter's *MiniportInitializeEx* function as described in Initializing a Miniport Adapter. This topic describes the NDK-specific requirements for the miniport adapter's *MiniportInitializeEx* function.

In its *MiniportInitializeEx* function, the miniport driver must do the following:

1. Populate an **NDIS_MINIPORT_ADAPTER_NDK_ATTRIBUTES** structure for the adapter as follows:

    - The miniport driver sets the **Header** member as described in the member description to identify the adapter as an NDK-capable miniport adapter.

    - The miniport driver sets the **Enabled** member to **TRUE** if its NDK functionality is enabled, or **FALSE** otherwise.

        > ⓘ Note
        >
        > For more information about querying and setting the current state of the miniport driver's NDK functionality, see **Enabling and Disabling NDK Functionality**.

    - In the **NdkCapabilities** member, the miniport driver stores a pointer to an **NDIS_NDK_CAPABILITIES** structure that specifies the capabilities of the adapter.

2. Call **NdisMSetMiniportAttributes** to set these attributes for the adapter.

Implementing NDKPI Functions

Article • 12/15/2021

An NDK-capable miniport driver must register entry points for all NDK_FN_*XXX* callback functions. All of the NDKPI provider callback functions are mandatory; none are optional.

To register support for these functions, the miniport driver stores their entry points in the structures listed in the "Object's Dispatch Table" column of the following table:

Object Type	Created By This Function	Object's Dispatch Table
NDK_ADAPTER	*OPEN_NDK_ADAPTER_HANDLER*	NDK_ADAPTER_DISPATCH
NDK_CONNECTOR	*NDK_FN_CREATE_CONNECTOR*	NDK_CONNECTOR_DISPATCH
NDK_CQ	*NDK_FN_CREATE_CQ*	NDK_CQ_DISPATCH
NDK_LISTENER	*NDK_FN_CREATE_LISTENER*	NDK_LISTENER_DISPATCH
NDK_MR	*NDK_FN_CREATE_MR*	NDK_MR_DISPATCH
NDK_MW	*NDK_FN_CREATE_MW*	NDK_MW_DISPATCH
NDK_PD	*NDK_FN_CREATE_PD*	NDK_PD_DISPATCH
NDK_QP	*NDK_FN_CREATE_QP* or *NDK_FN_CREATE_QP_WITH_SRQ*	NDK_QP_DISPATCH
NDK_SHARED_ENDPOINT	*NDK_FN_CREATE_SHARED_ENDPOINT*	NDK_SHARED_ENDPOINT_DISPATCH
NDK_SRQ	*NDK_FN_CREATE_SRQ* or *NDK_FN_CREATE_QP_WITH_SRQ*	NDK_SRQ_DISPATCH

INF Requirements for NDKPI

Article • 06/02/2023

The INF file for a miniport driver that supports Network Direct kernel (NDK) must meet the following requirements.

NDIS upper range value

The miniport driver's INF file must specify an NDIS upper range value of "ndis5" in order for Windows components to discover and use the NDK-capable miniport adapters that are serviced by the driver. This value is specified as follows:

INF

```
HKR, Ndi\Interfaces, UpperRange, 0, "ndis5"
```

*NetworkDirect INF keyword

The INF file must specify the ***NetworkDirect** keyword value as follows:

- Once the driver is installed, administrators can update the ***NetworkDirect** keyword value in the **Advanced** property page for the adapter.

Note: The miniport driver is automatically restarted after a change is made in the **Advanced** property page for the adapter.

INF

```
HKR, Ndi\Params\*NetworkDirect,        ParamDesc,  0, "NetworkDirect
Functionality"
HKR, Ndi\Params\*NetworkDirect,        Type,       0, "enum"
HKR, Ndi\Params\*NetworkDirect,        Default,    0, "1"
HKR, Ndi\Params\*NetworkDirect\enum,   "0",        0, "Disabled"
HKR, Ndi\Params\*NetworkDirect\enum,   "1",        0, "Enabled"
```

*NetworkDirectTechnology INF keyword

The INF file must specify the ***NetworkDirectTechnology** keyword value as follows:

- Once the driver is installed, administrators can update the ***NetworkDirectTechnology** keyword value in the **Advanced** property page for the adapter. The enumerations are mutually exclusive, meaning the selection of a NetworkDirectTechnology value excludes all others. This allows for the Platform to define strict device behavior.

- A device must express only the supported transports. The transport values are identifiers which map to WDK **NDK_RDMA_TECHNOLOGY**. A redefinition of the identifiers is prohibited.
- The behavior of devices with multiple concurrent transports is undefined. The device **must** specify a transport type.

Note: The miniport driver is automatically restarted after a change is made in the **Advanced** property page for the adapter.

INF

```
HKR, Ndi\Params\*NetworkDirectTechnology,        ParamDesc,  0,
"NetworkDirect Technology"
HKR, Ndi\Params\*NetworkDirectTechnology,        Default,    0,  "1"
HKR, Ndi\Params\*NetworkDirectTechnology,        Type,       0,  "enum"
HKR, Ndi\Params\*NetworkDirectTechnology\enum,   1,          0,  "iWARP"
HKR, Ndi\Params\*NetworkDirectTechnology\enum,   2,          0,
"InfiniBand"
HKR, Ndi\Params\*NetworkDirectTechnology\enum,   3,          0,  "RoCE"
HKR, Ndi\Params\*NetworkDirectTechnology\enum,   4,          0,  "RoCEv2"
HKR, Ndi\Params\*NetworkDirectTechnology,        Optional,   0,  "0"
```

*NetworkDirectRoCEFrameSize INF keyword

The INF file for a miniport driver that supports ***NetworkDirectRoCEFrameSize** must meet the following requirements:

- The ***NetworkDirectRoCEFrameSize** keyword specifies the administrator requested maximum transmission unit for NetworkDirect communications. Adapters supporting the ***NetworkDirect** keyword with **RoCE** or **RoCEv2** must additionally support this keyword.

- The acceptable registry values for ***NetworkDirectRoCEFrameSize** are 256, 512, 1024, 2048, and 4096. The value of 1024 is required.

- The adapter must use the largest supported size for ***NetworkDirectRoCEFrameSize** that doesn't exceed ***JumboPacket**.

- If the configured value of ***NetworkDirectRoCEFrameSize** differs from the operational (active) RoCE MTU, the driver must log an event in the system event log indicating operational (active) RoCE MTU.

Note: The miniport driver is automatically restarted after a change is made in the **Advanced** property page for the adapter unless the change can be made effective without the restart.

The following table describes the ***NetworkDirectRoCEFrameSize** keyword and values that can be edited. The min and max values define the required limits for supported values. An individual adapter can support a lower minimum value or higher maximum value but must support at least these values.

SubkeyName	ParamDesc	Type	Default value	Min	Max
***NetworkDirectRoCEFrameSize**	Network Direct Maximum Transmission Unit	enum	1024	256	4096

For more information about advanced properties, see Specifying Configuration Parameters for the Advanced Properties Page.

For more information about using standardized INF keywords, see Standardized INF Keywords for Network Devices.

Enabling and Disabling NDK Functionality

Article • 12/15/2021

To enable or disable NDK functionality, NDIS issues an OID_NDK_SET_STATE OID request. An NDK-capable miniport driver must register support for this OID in its *MiniportOidRequest* function.

Determining whether NDK functionality can be enabled

The ***NetworkDirect** keyword determines whether the miniport driver's NDK functionality can be enabled.

If this keyword value is set to 1 ("Enabled"), NDK functionality can be enabled.

If it is set to 0 ("Disabled"), NDK functionality cannot be enabled.

When the miniport driver is installed, its INF file sets this keyword value to 1 ("Enabled") by default. For more information, see INF Requirements for NDKPI.

After the miniport driver is installed, administrators can update the ***NetworkDirect** keyword value by setting a new value in the **Advanced** property page for the adapter. For more information about advanced properties, see Specifying Configuration Parameters for the Advanced Properties Page.

Note The miniport driver is automatically restarted after a change is made in the **Advanced** property page for the adapter.

When to enable or disable NDK functionality

This state change can be triggered by an OID_NDK_SET_STATE OID request, or by a success or failure in the adapter itself.

Enabling or disabling NDK functionality

To enable or disable its NDK functionality, the miniport driver must send a **NetEventNDKEnable** or **NetEventNDKDisable** Plug and Play (PnP) event to NDIS.

To send the PnP event, the miniport driver calls the **NdisMNetPnPEvent** function, setting the **NetPnPEvent** member of the **NET_PNP_EVENT_NOTIFICATION** structure that the *NetPnPEvent* parameter points to as follows:

- **NetEventNDKEnable** if NDK functionality is to be enabled.
- **NetEventNDKDisable** if NDK functionality is to be disabled.

The **NetEventNDKDisable** PnP event triggers NDIS and upper layer drivers to start closing their opened **NDK_ADAPTER** instances over the adapter where the NDK functionality is being disabled. The PnP event will remain pending until all of the opened **NDK_ADAPTER** instances over the adapter are closed.

Network Direct Kernel Provider Interface (NDKPI)

NDKPI Object Lifetime Requirements

Article • 10/05/2022

How NDK Objects Are Created, Used, and Closed

An NDK consumer initiates a create request for an NDK object by calling the NDK provider's create function for that object.

When the consumer calls a create function, it passes an *NdkCreateCompletion* (*NDK_FN_CREATE_COMPLETION*) as a parameter.

The consumer initiates various requests by calling provider functions in the object's dispatch table, passing an *NdkRequestCompletion* (*NDK_FN_REQUEST_COMPLETION*) completion callback as a parameter.

When an object is no longer needed, the consumer calls the provider's *NdkCloseObject* (*NDK_FN_CLOSE_OBJECT*) function to initiate a close request for the object, passing an *NdkCloseCompletion* (*NDK_FN_CLOSE_COMPLETION*) callback as a parameter.

The provider calls the consumer's callback function to complete the request asynchronously. This call indicates to the consumer that the provider has completed the operation (for example, closing the object) and is returning control to the consumer. If the provider completes the close request synchronously, either successfully or in error, it won’t call the consumer’s callback function.

The Rules for Completion Callbacks

When a provider has created an object at the request of a consumer, the provider calls the consumer's *NdkCreateCompletion* callback to indicate that the object is ready for use.

The consumer can call other provider functions for the same object without waiting for the first callback to return.

The consumer will not call the *NdkCloseObject* function for an object until all provider functions for that object have returned.

However, if the provider function initiates a completion request, the consumer is free to call *NdkCloseObject* from inside that completion callback, even if the provider function hasn't returned.

A provider function can initiate a completion request before returning from a callback by doing one of the following:

- Calling the completion callback directly
- Queuing the completion request to another thread

By initiating a completion request, the provider effectively returns control to the consumer. The provider must assume that the object can be closed at any time after the provider initiates the completion request.

Note To prevent deadlock after initiating a completion request, the provider must either:

- Not perform other operations on the object until the completion callback returns.
- Take the necessary measures to keep the object intact, if the provider absolutely must touch the object.

Example: Consumer-Provider Interaction

Consider the following scenario:

1. The consumer creates a connector (**NDK_CONNECTOR**) and then calls *NdkConnect* (*NDK_FN_CONNECT*).
2. The provider processes the connect request, hits a failure, and calls the consumer's completion callback in the context of the *NdkConnect* call (as opposed to returning inline failure due to an internal implementation choice).
3. The consumer calls *NdkCloseObject* in the context of this completion callback, even though the *NdkConnect* call has not yet returned to the consumer.

To avoid deadlock, the provider must not touch the connector object after step 2 (the point when it initiated the completion callback inside the *NdkConnect* call).

Closing Antecedent and Successor Objects

The provider must be prepared for the consumer to call the *NdkCloseObject* function to close an antecedent object before the consumer calls *NdkCloseObject* for successor objects. If the consumer does this, here's what the provider must do:

- The provider must not close the antecedent object until all the successor objects are closed, i.e., provider must return STATUS_PENDING from the close request and complete it (by calling the registered *NdkCloseCompletion* function for the close request) once all successor objects are closed.

- The consumer will not use the antecedent object after calling *NdkCloseObject* on it, so the provider does not have to add any handling for failing further provider functions on the antecedent object (but it may if it chooses to).
- The provider may treat the close request like a simple dereference which has no other side-effect until the last successor object is closed, unless otherwise required (see the NDK listener close case below which has a required side-effect).

The provider must not complete the close request on an antecedent object (including the NDK_ADAPTER close request) before any in-progress close completion callback on any successor object returns to the provider. This is to allow NDK consumers to unload safely.

An NDK consumer will not call *NdkCloseObject* for an NDK_ADAPTER object (which is a blocking call) from inside a consumer callback function.

Closing Adapter Objects

Consider the following scenario:

1. The consumer calls *NdkCloseObject* on a completion queue (CQ) object.
2. The provider returns STATUS_PENDING, and later calls the consumer's completion callback.
3. Inside this completion callback, the consumer signals an event that it's now OK to close the NDK_ADAPTER.
4. Another thread wakes up upon this signal, and closes the NDK_ADAPTER and proceeds to unload.
5. However, the thread in which the consumer's CQ close completion callback was called might still be inside the consumer's callback function (for example, the function epilog), so it's not safe for the consumer driver to unload.
6. Because the completion callback context is the only context the consumer can signal the event, the consumer driver can't solve the safe-unload issue itself.

There must be a point at which the consumer can be assured that all of its callbacks have returned control. In NDKPI, this point is when the close request on a NDK_ADAPTER returns control. Note that **NDK_ADAPTER** close request is a blocking call. When an **NDK_ADAPTER** close request returns, it's guaranteed that all callbacks on all objects that descend from that **NDK_ADAPTER** object have returned control to the provider.

Completing Close Requests

The provider must not complete a close request on an object until:

- All pending asynchronous requests on the object have been completed (in other words, their completion callbacks have returned to the provider).
- All of the consumer's event callbacks (for example, *NdkCqNotificationCallback* (*NDK_FN_CQ_NOTIFICATION_CALLBACK*) on a CQ, *NdkConnectEventCallback* (*NDK_FN_CONNECT_EVENT_CALLBACK*) on a Listener) have returned to the provider.

The provider must guarantee that no more callbacks will happen after the close completion callback is called or after the close request returns STATUS_SUCCESS. Note that a close request must also initiate any needed flushing or cancellation of pending asynchronous requests.

Note It logically follows from the above that an NDK consumer must not call *NdkCloseObject* for an **NDK_ADAPTER** object (which is a blocking call) from inside a consumer callback function.

Network Direct Kernel Provider Interface (NDKPI)

NDKPI Listeners, Connectors, and Endpoints

Article • 12/15/2021

An NDK consumer connects an NDK connector by calling the *NdkConnect* (*NDK_FN_CONNECT*) or *NdkConnectWithSharedEndpoint* (*NDK_FN_CONNECT_WITH_SHARED_ENDPOINT*) function.

Each connector that is in a connected state also has an underlying endpoint that represents the local end of the established NDK connection:

- A connector that is established by accepting an incoming connection over an NDK listener automatically inherits the listener's implicit endpoint as its local implicit endpoint.
- A connector that is connected via the *NdkConnect* function has its own dedicated implicit local endpoint.
- A connector that is connected via the *NdkConnectWithSharedEndpoint* function has an explicit local endpoint that can be shared with other connectors that are also connected via the *NdkConnectWithSharedEndpoint* function.

The NDK provider must keep some sort of reference count for each implicit or explicit endpoint, and release the endpoint (i.e., mark the address/port as available to be used again) when the reference count reaches zero:

Reference Counting for (Non-Shared) Endpoints

When the consumer calls the *NdkListen* (*NDK_FN_LISTEN*) function, the provider creates an implicit endpoint. For this implicit endpoint, the provider must maintain a reference count as follows:

- Add a reference for the listener itself to the endpoint's reference count.
- Add a reference for each connector that is accepted over that listener.
- Remove a reference when a connector that was previously accepted over the listener is closed.
- Remove a reference when the listener itself is closed. **Note** You can't close the listener until all the connectors are closed.
- Release the endpoint when its reference count returns to zero. (This is the case only when the listener and all the connectors accepted over the listener have been

closed.)

- Simply closing the listener does not release the endpoint as long as there are previously accepted connectors that are not yet closed. This means that new *NdkListen*, *NdkConnect*, and *NdkConnectWithSharedEndpoint* requests for the same local address and port will fail until all such connections are closed. Note that the close request on the listener will also remain pending until all such connections are closed (due to the antecedent/successor rules outlined in NDKPI Object Lifetime Requirements). The provider must reject further incoming connections on the listener as soon as a close request is issued (so that no new connections are accepted while the close request is pending).

Reference Counting for Connectors

When the consumer calls *NdkConnect*, the provider creates and implicit endpoint. For this implicit endpoint, the provider must:

- Add a reference by the connector. There is only one connector, hence only one reference.
- Remove the connector's reference to the endpoint when the connector is closed.
- Release the endpoint when that reference is gone.

Reference Counting for Shared Endpoints

When the consumer calls *NdkConnectWithSharedEndpoint*, the provider creates an explicit shared endpoint. For this explicit shared endpoint, the provider must:

- Add a reference for the shared endpoint itself to the shared endpoint's reference count.
- Add a reference for each connector that is connected over that shared endpoint.
- Remove a reference when a connector that was previously connected over the shared endpoint is closed.
- Release the endpoint the reference count returns to zero. (This is the case when the shared endpoint and all the connectors connected over the shared endpoint have been closed.)
- Simply closing the shared endpoint does not release the endpoint as long as there are previously connected connectors that are not yet closed. This means that new *NdkListen*, *NdkConnect*, and *NdkConnectWithSharedEndpoint* requests for the same local address and port will fail until all such connections are closed. Note that the close request on the shared endpoint will also remain pending until all such

connections are closed (due to the antecedent/successor rules outlined in NDKPI Object Lifetime Requirements).

NDKPI Completion Handling Requirements

Article • 12/15/2021

NDK consumers and NDK providers must follow these requirements for NDKPI completion handling.

The Rules for NdkGetCqResults, NdkGetCqResultsEx, and NdkArmCq Functions

The consumer will always serialize its calls to these provider functions on the same completion queue (CQ) object (**NDK_CQ**):

- *NdkGetCqResults* (*NDK_FN_GET_CQ_RESULTS*)
- *NdkGetCqResultsEx* (*NDK_FN_GET_CQ_RESULTS_EX*)
- *NdkArmCq* (*NDK_FN_ARM_CQ*)

This means not only that the consumer will never call the same provider function multiple times concurrently, but also that it will never call any combination of these functions concurrently on the same CQ from multiple threads.

An **NdkOperationTypeReceiveAndInvalidate** completion that occurs as a result of a remote *NdkSendAndInvalidate* (*NDK_FN_SEND_AND_INVALIDATE*) call must still be retrievable using *NdkGetCqResults* (not *NdkGetCqResultsEx*n). Doing so must still invalidate the specified token on the receiver, but will not notify the receiving consumer of this invalidation (the consumer must use *NdkGetCqResultsEx* to get this information). A later *NdkInvalidate* (*NDK_FN_INVALIDATE*) for the same token will fail, as usual.

The Rules for Notification Callbacks

The provider must call the *NdkCqNotificationCallback* (*NDK_FN_CQ_NOTIFICATION_CALLBACK*) callback only once, and only after the consumer has armed the *NdkCqNotificationCallback* callback by calling *NdkArmCq*. That is, the provider must clear the arm and call the *NdkCqNotificationCallback* callback when the conditions for calling the *NdkCqNotificationCallback* callback occur (in other words, when request completions are queued in the CQ).

If there are completions already present in the CQ when the consumer calls *NdkArmCq*, the provider will behave as follows:

- If at least one of the completions was newly placed into the CQ since the last *NdkCqNotificationCallback* callback was called, the provider must satisfy the arm request immediately (see below for serialization requirements).
- However, if all completions in the CQ were present also when the last *NdkCqNotificationCallback* callback was called (in other words, the consumer called *NdkArmCq* without removing all the completions and no new completions got placed into the CQ), then the provider may satisfy the arm request immediately.

When the provider needs to call the *NdkCqNotificationCallback* callback, if there's already a *NdkCqNotificationCallback* callback in progress, then the provider must defer the invocation of the *NdkCqNotificationCallback* callback until after the existing call to the *NdkCqNotificationCallback* callback returns control to the provider. In other words, the provider is responsible for serializing the *NdkCqNotificationCallback* callbacks.

The following table shows the resulting arm type if *NdkArmCq* is called a second time before a previous *NdkArmCq* request is satisfied:

	2nd arm ANY	**2nd arm ERRORS**	**2nd arm SOLICITED**
1st arm ANY	ANY	ANY	ANY
1st arm ERRORS	ANY	ERRORS	SOLICITED
1st arm SOLICITED	ANY	SOLICITED	SOLICITED

NDKPI Work Request Posting Requirements

Article • 12/15/2021

Work Request Posting Rules for the Consumer

The NDK consumer will post the following types of work requests on the initiator queue:

- *NdkBind* (*NDK_FN_BIND*)
- *NdkFastRegister* (*NDK_FN_FAST_REGISTER*)
- *NdkInvalidate* (*NDK_FN_INVALIDATE*)
- *NdkRead* (*NDK_FN_READ*)
- *NdkSend* (*NDK_FN_SEND*)
- *NdkSendAndInvalidate* (*NDK_FN_SEND_AND_INVALIDATE*)
- *NdkWrite* (*NDK_FN_WRITE*)

The consumer will post *NdkReceive* (*NDK_FN_RECEIVE*) requests on the receive queue.

The consumer will post all of these requests to the same individual queue on an **NDK_QP** or **NDK_SRQ** in a serialized fashion. In other words, the consumer will never have two concurrent calls to any work request functions on the same individual queue belonging to an **NDK_QP** or **NDK_SRQ**.

This means, for example, that concurrent *NdkReceive* calls won't be issued, concurrent *NdkSend* and *NdkWrite* calls won't be issued, but concurrent *NdkReceive* and *NdkWrite* calls may be issued on the same **NDK_QP**.

Work Request Posting Rules for the Provider

The provider should not have any redundant locks inside the above work request functions, because they are guaranteed to be serialized by the consumer.

The provider must be able to handle *NdkFlush* (*NDK_FN_FLUSH*) calls that may be called concurrently with a work request call on the same **NDK_QP**.

The provider must be able to handle an **NdkCloseConnector** call (on the successor **NDK_CONNECTOR** object for the **NDK_QP**) that may be called concurrently with a work request call on the same **NDK_QP**.

NetworkDirect Disconnect Scheme

Article • 12/15/2021

The scheme described here applies to both NDSPI version 2 and NDKPI. The following terms are used:

- ND is used to refer to NDSPI or NDK.
- *NdDisconnect* is used to refer to the function call that an ND consumer makes in order to initiate a graceful disconnect. For NDSPI, this is **INDConnector::Disconnect**. For NDKPI, it is *NdkDisconnect* (*NDK_FN_DISCONNECT*).
- *NdDisconnectIndication* is used to refer to the indication delivered by an ND provider to an ND consumer when the ND provider receives a graceful disconnect from the peer or detects that the connection was aborted due to any reason (other than the local NDK consumer's own initiation such as issuing *NdDisconnect* or *NdCloseConnector*).

Below, A and B refer to the two sides of an ND connection. Consumer A refers to the ND consumer on side A, provider A refers to the ND provider on side A, and similarly Consumer B/Provider B refers to those same entities on side B. When consumer A calls *NdDisconnect*, provider A must send a graceful disconnect notification to side B and complete consumer A's *NdDisconnect* request only when both of the following conditions occur:

- Either:
    - A graceful disconnect notification is received from B (which leads to successful completion of consumer A's *NdDisconnect*), or
    - An error such as connection abortion or time-out occurred (which leads to consumer A's *NdDisconnect* to be completed with a failure).
- All DMA activity on the QP is finished (including DMA activity for work requests that were posted with silent-success flag).

When provider B receives a graceful disconnect notification from A or detects that the connection is aborted, provider B must deliver *NdDisconnectIndication* to consumer B if consumer B has not called *NdDisconnect* to provider B already. Since an incoming graceful disconnect notification or an abort event can race with the local consumer initiating *NdDisconnect*, local consumer must be prepared to handle an *NdDisconnectIndication* arriving after local consumer calls *NdDisconnect*. Note that an *NdDisconnectIndication* does not provide any guarantees in terms of work request completions.

A disconnected QP or connector cannot be reused by the consumer.

NetworkDirect does not have any notion of half-closed connections. Once *NdDisconnect* is completed (with success or failure), the connection is fully closed.

A consumer should typically call *NdDisconnect* only after it gets completions for all work requests it posted to the initiator queue. Otherwise, the *NdDisconnect* may not lead to a true graceful disconnect. Providers are not required to support graceful disconnect in the case where a consumer leaves such work requests outstanding.

NDKPI Deferred Processing Scheme

Article • 12/15/2021

There are many cases where an NDK consumer will post a chain of initiator requests to the queue pair (QP). For example, a consumer could post a number of fast register requests followed by a send request. The performance for such request patterns may be improved if the chain of requests is queued to the QP and then indicated to the hardware for processing as a batch, rather than indicating each request in the chain to the hardware, one by one.

The **NDK_OP_FLAG_DEFER** flag value can be used for this purpose with the following request types:

- *NdkBind* (*NDK_FN_BIND*)
- *NdkFastRegister* (*NDK_FN_FAST_REGISTER*)
- *NdkInvalidate* (*NDK_FN_INVALIDATE*)
- *NdkRead* (*NDK_FN_READ*)
- *NdkSend* (*NDK_FN_SEND*)
- *NdkSendAndInvalidate* (*NDK_FN_SEND_AND_INVALIDATE*)
- *NdkWrite* (*NDK_FN_WRITE*)

The presence of the flag is a hint to the NDK provider that it may defer indicating the request to hardware for processing, but the provider may process the new request at any time.

The presence of the **NDK_OP_FLAG_DEFER** flag on an initiator request does not change the NDK provider's existing responsibilities with respect to generating completions. A call to the initiator request that returns a failure status must not result in a completion being queued to the CQ for the failed request. Conversely, a call that returns a success status must eventually result in a completion being queued to the CQ as long as the consumer follows the additional requirements listed below.

In addition to all the existing NDK requirements, two additional requirements (one for the provider and one for the consumer) must be observed to prevent a situation in which requests are successfully posted to the QP with the **NDK_OP_FLAG_DEFER** flag, but are never indicated to the hardware for processing:

- When returning a failure status from a call to an initiator request, the provider must guarantee that all requests that were previously submitted with the **NDK_OP_FLAG_DEFER** flag are indicated to the hardware for processing.
- The consumer guarantees that, in the absence of an inline failure, all initiator request chains will be terminated by an initiator request that does not set the

NDK_OP_FLAG_DEFER flag.

For example, consider a case where a consumer has a chain of two fast register requests and a send that it needs to post to the QP:

1. The consumer posts the first fast register with the **NDK_OP_FLAG_DEFER** flag and *NdkFastRegister* returns STATUS_SUCCESS.
2. Again, the second fast register is posted with the **NDK_OP_FLAG_DEFER** flag set but now *NdkFastRegister* returns a failure status. In this case, the consumer will not post the send request.
3. When returning the inline failure for the second call to *NdkFastRegister*, the NDK provider makes sure that all previously unindicated requests (the first fast register in this case) are indicated to the hardware for processing.
4. Because the first call to *NdkFastRegister* succeeded, a completion must be generated to the CQ.
5. Because the second call to *NdkFastRegister* failed inline, a completion must not be generated to the CQ.

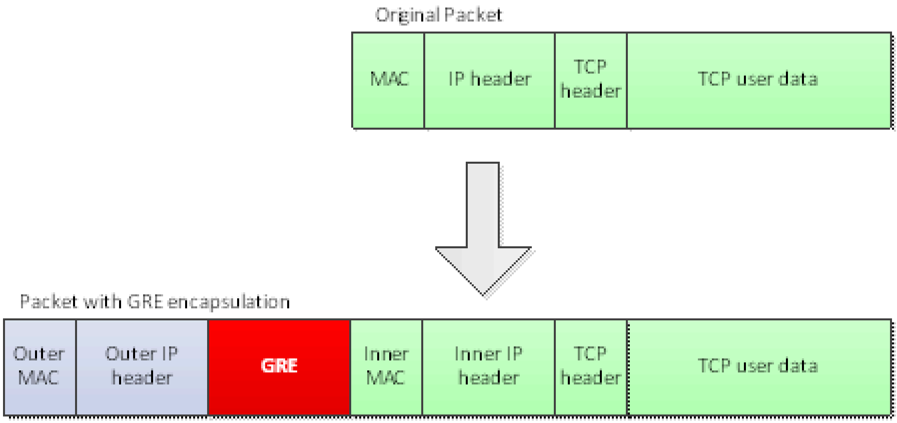
About Network Virtualization using Generic Routing Encapsulation (NVGRE)

Article • 06/15/2023

Hyper-V Network Virtualization supports Network Virtualization using Generic Routing Encapsulation (NVGRE) as the mechanism to virtualize IP addresses. In NVGRE, the virtual machine's packet is encapsulated inside another packet. The header of this new, NVGRE-formatted packet has the appropriate source and destination provider area (PA) IP addresses. In addition, it has a 24-bit Virtual Subnet ID (VSID), which is stored in the GRE header of the new packet.

The following figure shows a GRE-encapsulated packet. On the wire, NVGRE-encapsulated packets look like IP-over-Ethernet packets, except that the payload of the outer IP header is a GRE-encapsulated IP packet (including the Ethernet header).



NDIS 6.30 (available in Windows Server 2012 and later) introduces NVGRE Task Offload, which makes it possible to use NVGRE-formatted packets with:

- Large Send Offload (LSO)
- Virtual Machine Queue (VMQ)
- Transmit (Tx) checksum offload (IPv4, TCP, UDP)
- Receive (Rx) checksum offload (IPv4, TCP, UDP)

NDIS 6.85 introduces support for NVGRE with UDP segmentation offload (USO).

Note: It is possible for a protocol driver to offload "mixed mode" packets, which means packets in which the inner and outer IP header versions are different. For example, a packet could have outer IP header as IPv6 and the inner IP header as IPv4.

Note: It is also possible for a protocol driver to offload an NVGRE-formatted packet that has no inner TCP or UDP header. For example, an IP packet could have an inner payload that is an Internet Control Message Protocol (ICMP) packet.

For more information about NVGRE, see the following Internet Draft:

- NVGRE: Network Virtualization using Generic Routing Encapsulation

NVGRE is based on Generic Routing Encapsulation (GRE). For more information about GRE, see the following resources:

- RFC 2784: Generic Routing Encapsulation (GRE)
- RFC 2890: Key and Sequence Number Extensions to GRE

This section includes:

TCP/IP Task Offload

Overview of Network Virtualization using Generic Routing Encapsulation (NVGRE) Task Offload

Article • 06/15/2023

NVGRE Encapsulation Packet Format

In this case, a protocol or filter driver will generate the (non-LSO) packets, including the GRE encapsulation, and send the packets on the wire. On the receive side, these (non-RSS, VMQ) packets are passed to the protocol driver without any modifications. Note that the NVGRE Task Offload feature does not specify the offloading of the encapsulation and decapsulation operations.

Send and Receive Offloads

On the send path, the following task offloads need to account for encapsulation:

- Checksum computation of IPv4 and TCP or UDP payload
- Large Send Offload version 1 (LSO_v1) and Large Send Offload version 2 (LSO_v2)
- UDP Segmentation Offload (USO)

For send-side offloads, the miniport must perform corresponding operations on the tunnel (outer) IP header, the transport (inner) IP header, and the TCP header.

On the receive path, the following task offloads need to account for encapsulation:

- Checksum validation of IPv4 and TCP or UDP payload
- Receive side scaling (RSS)
- VMQ

For receive-side offloads, the NIC must parse the encapsulation protocol headers. For example, for GRE encapsulation, the NIC must parse the GRE header and perform task offloads on the transport (inner) and/or tunnel (outer) IP headers.

Supporting NVGRE in Large Send Offload (LSO)

Article • 12/15/2021

NDIS 6.30 (Windows Server 2012) introduces Network Virtualization using Generic Routing Encapsulation (NVGRE). NDIS miniport, protocol, and filter drivers and NICs that perform large send offload (LSO) version 2 (LSOV2) should do so in a way that supports NVGRE.

Note This page assumes that you are familiar with the information in Offloading the Segmentation of Large TCP Packets.

If NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO.**IsEncapsulatedPacket** is **TRUE** and the **TcpIpChecksumNetBufferListInfo** out-of-band (OOB) information is valid, this indicates that NVGRE support is required and the NIC must perform LSOV2 offload on the NVGRE-formatted packet, with the following conditions:

- Only the values in the NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO.**LsoV2Transmit** structure are valid. The NIC and miniport driver must not refer to the values in the **NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO.LsoV1Transmit** structure.
- The NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO.**LsoV2Transmit.TcpHeaderOffset** member does not have the correct offset value and must not be used by the NIC or miniport driver.

To support NVGRE in LSOV2, protocol and filter drivers must make the following changes:

- Reduce the **MSS** value in the NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO.**LsoV2Transmit** structure to account for the new GRE header.
- Send down a TCP payload length that may not be an exact multiple of the reduced **MSS** value.
- Adjust the **InnerFrameOffset**, **TransportIpHeaderRelativeOffset**, and **TcpHeaderRelativeOffset** values in the NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO structure to account for the GRE header.

NICs and miniport drivers may use the **InnerFrameOffset**, **TransportIpHeaderRelativeOffset**, and **TcpHeaderRelativeOffset** values provided in the NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO structure. The NIC or miniport driver may perform any needed header checks on the tunnel (outer) IP header or subsequent headers to validate these offsets.

Miniport drivers must handle the case where NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO.**InnerFrameOffset** may be in a different scatter-gather list than the beginning of the packet. The protocol driver will guarantee that all the prepended encapsulation headers (ETH, IP, GRE) will be physically contiguous and will be in the first MDL of the packet.

Protocol and filter drivers do not ensure that the total TCP payload length is an exact multiple of the reduced **MSS** value. For this reason, miniport drivers and NICs must update the tunnel (outer) IP header. NICs must generate as many full-sized segments as possible based on the reduced **MSS** value in the NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO.**LsoV2Transmit** OOB information. Only one sub-**MSS** segment may be generated per LSOv2 send.

Miniport drivers must do the following:

- Compute the checksum for the tunnel (outer) IP header.
- Increment the IP identification (IP ID) value of the tunnel (outer) IP header for every packet. The first packet must use the IP ID in the original tunnel (outer) IP header.
- Increment the IP ID of the transport (inner) IP header for every packet. The first packet must use the IP ID in the original transport (inner) IP header.
- Compute the checksum for the TCP header and the transport (inner) IP header.
- Ensure that the complete headers, including the encapsulation tunnel (outer) headers are added to every generated packet.

Offloading the Segmentation of Large TCP Packets

Supporting NVGRE in UDP Segmentation Offload (USO)

Article • 06/15/2023

NDIS 6.85 introduces Network Virtualization using Generic Routing Encapsulation (NVGRE) with UDP segmentation offload (USO). NDIS miniport, protocol, and filter drivers, as well as NICs that perform USO, should support NVGRE and VXLAN encapsulations.

Note: This article presumes you're familiar with the information in UDP Segmentation Offload (USO).

If NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO.**IsEncapsulatedPacket** is **TRUE** and the **UdpSegmentationOffloadInfo** out-of-band (OOB) information is valid, NVGRE and VXLAN support is required. The NIC must perform USO offload on the NVGRE/VXLAN-encapsulated packet with the following condition:

- The NDIS_UDP_SEGMENTATION_OFFLOAD_NET_BUFFER_LIST_INFO.**Transmit.UdpHeaderOffset** member doesn't have the correct offset value and must not be used by the NIC or miniport driver.

To support NVGRE in USO, protocol and filter drivers must:

- Adjust the **InnerFrameOffset**, **TransportIpHeaderRelativeOffset**, and **TcpHeaderRelativeOffset** values in the NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO structure to account for the encapsulation header. The **TcpHeaderRelativeOffset** refers to the UDP header.

NICs and miniport drivers may use the **InnerFrameOffset**, **TransportIpHeaderRelativeOffset**, and **TcpHeaderRelativeOffset** values provided in the NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO structure. The NIC or miniport driver may perform any needed header checks on the tunnel (outer) IP header or subsequent headers to validate these offsets.

Miniport drivers must handle the case where NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO.**InnerFrameOffset** may be in a different scatter-gather list than the beginning of the packet. The protocol driver will guarantee that all the prepended encapsulation headers (ETH, IP, GRE/VXLAN) will be physically contiguous and will be in the first MDL of the packet.

Protocol and filter drivers don't ensure that the total UDP payload length is an exact multiple of the reduced **MSS** value when **UdpSegmentation.SubMssFinalSegmentSupported** is set in the NDIS_OFFLOAD capabilities. For this reason, miniport drivers and NICs with **SubMssFinalSegmentSupported** must update the tunnel (outer) IP header. NICs must generate as many full-sized segments as possible based on the reduced **MSS** value in the NDIS_UDP_SEGMENTATION_OFFLOAD_NET_BUFFER_LIST_INFO.**Transmit** OOB information. Only one sub-**MSS** segment may be generated per LSOv2 send.

Miniport drivers must:

- Compute the checksum for the tunnel (outer) IP header.
- Increment the IP identification (IP ID) value of the tunnel (outer) IP header for every packet. The first packet must use the IP ID in the original tunnel (outer) IP header.
- Increment the IP ID of the transport (inner) IP header for every packet. The first packet must use the IP ID in the original transport (inner) IP header.
- Compute the checksum for the UDP header and the transport (inner) IP header.
- Ensure that the complete headers, including the encapsulation tunnel (outer) headers are added to every generated packet.

UDP Segmentation Offload (USO)

Supporting NVGRE in Checksum Offload

Article • 12/15/2021

NDIS 6.30 (Windows Server 2012) introduces Network Virtualization using Generic Routing Encapsulation (NVGRE). NDIS miniport, protocol, and filter drivers and NICs that offload checksum tasks should do so in a way that supports NVGRE.

Note This page assumes that you are familiar with the information in Offloading Checksum Tasks.

If NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO.**IsEncapsulatedPacket** is **TRUE** and the **TcpIpChecksumNetBufferListInfo** out-of-band (OOB) information is valid, this indicates that NVGRE support is required and the NIC must compute the checksum for the tunnel (outer) IP header, the transport (inner) IP header, and the TCP or UDP header.

The **IsIPv4** and **IsIPv6** flags in the NDIS_TCP_IP_CHECKSUM_NET_BUFFER_LIST_INFO structure indicate the IP header version of the tunnel (outer) IP header. The NIC must parse the transport (inner) IP header to determine that header's IP version. Because mixed-mode packets are allowed (see NDIS_ENCAPSULATED_PACKET_TASK_OFFLOAD), the NIC must not assume that the inner and outer IP headers will have the same IP header version.

NICs and miniport drivers may use the **InnerFrameOffset**, **TransportIpHeaderRelativeOffset**, and **TcpHeaderRelativeOffset** values provided in the NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO structure. The NIC or miniport driver may perform any needed header checks on the tunnel (outer) IP header or subsequent headers to validate these offsets.

Note that when NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO.**IsEncapsulatedPacket** is TRUE, the existing header offset fields, NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO.**LsoV2Transmit.TcpHeaderOffset** and NDIS_TCP_IP_CHECKSUM_NET_BUFFER_LIST_INFO.**Transmit.TcpHeaderOffset**, will not have correct values and must not be used by the NIC or driver.

Miniport drivers must handle the case where NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO.**InnerFrameOffset** may be in a different scatter-gather list than the beginning of the packet. The protocol driver will guarantee that all the prepended encapsulation headers (ETH, IP, GRE) will be physically contiguous and will be in the first MDL of the packet.

Checksum Validation

Checksum validation for NVGRE is largely the same as it would be otherwise.

If a miniport receives an OID_TCP_OFFLOAD_PARAMETERS OID request and succeeds it for **NDIS_ENCAPSULATION_TYPE_GRE_MAC** (see **NDIS_OFFLOAD_PARAMETERS**), the NIC must perform checksum validation on the tunnel (outer) IP header, transport (inner) IP header, and TCP or UDP header.

For encapsulated packets that have an IPv4 tunnel (outer) header and an IPv4 transport (inner) header, a miniport driver should set the **IpChecksumSucceeded** flag in the **NDIS_TCP_IP_CHECKSUM_NET_BUFFER_LIST_INFO** structure only if both IP header checksum validations succeeded. For encapsulated packets that have both a tunnel (outer) IPv4 header and a transport (inner) IPv4 header, the miniport driver should set the **IpChecksumFailed** flag if either of the IP header checksum validations failed.

Supporting NVGRE in RSS and VMQ Receive Task Offloads

Article • 07/07/2022

NDIS 6.30 (Windows Server 2012) introduces Network Virtualization using Generic Routing Encapsulation (NVGRE). NDIS miniport drivers and NICs that perform Receive Side Scaling (RSS) and Virtual Machine Queue (VMQ) receive task offloads should do so in a way that supports NVGRE.

Note This page assumes that you are familiar with the information in Offloading the Segmentation of Large TCP Packets.

If the miniport driver supports RSS and VMQ for encapsulated packets, it must advertise those capabilities in the **RssSupported** and **VmqSupported** members of the **NDIS_ENCAPSULATED_PACKET_TASK_OFFLOAD** structure. If the miniport advertised these capabilities, received an OID_TCP_OFFLOAD_PARAMETERS OID request, and succeeded the OID, the NIC must perform RSS and VMQ on the advertised encapsulated packet types.

For supported encapsulated packets that it is able to parse, the NIC must perform RSS on the TCP or UDP header in the payload of the transport (inner) IP header and VMQ on the inner MAC header.

For performing RSS and VMQ, the NIC must get to the transport (inner) IP header of the encapsulated packet as described in Locating the Transport Header for Encapsulated Packets in the Receive Path and check the protocol number. If the NIC receives a packet that uses a protocol that the NIC can parse, the NIC should:

- Perform RSS by doing a 4-tuple hash on the transport (inner) IP header and the TCP or UDP header.
  - For encapsulated packets whose protocol the miniport cannot parse, the NIC should perform a 2-tuple hash on the source and destination address fields in the tunnel (outer) IP header.
  - For encapsulated packets that do not contain a TCP or UDP header immediately following the transport (inner) IP header, the NIC should perform a 2-tuple hash on the source and destination address fields in the tunnel (outer) IP header.
- Perform VMQ by using the Ethernet header in the encapsulated packet. For encapsulated packets that do not contain an Ethernet header (within the encapsulated packet), VMQ should be performed using the outermost Ethernet header.

Locating the Transport Header for Encapsulated Packets in the Receive Path

Article • 12/15/2021

On receiving a packet, a NIC that supports Network Virtualization using Generic Routing Encapsulation (NVGRE) must first determine whether the packet is encapsulated and, if so, the type of encapsulation.

Note In the send path, a packet is encapsulated if NDIS_TCP_SEND_OFFLOADS_SUPPLEMENTAL_NET_BUFFER_LIST_INFO.**IsEncapsulatedPacket** is **TRUE**.

In the receive path, the NIC must determine whether the packet is encapsulated by checking the protocol number in the **Protocol** field of the IPv4 tunnel (outer) header or the **NextHeader** field of the IPv6 tunnel (outer) header. The list of assigned protocol numbers can be found at https://www.iana.org/assignments/protocol-numbers/protocol-numbers.xml .

Once a packet is determined to be an encapsulated packet, the NIC must determine the offset to the transport (inner) IP header by parsing the encapsulated packet's protocol.

For NDIS 6.30 (Windows Server 2012) and later, only GRE IP encapsulation is supported. So the NIC should be able to parse the following, depending on the advertised capabilities:

- GRE (RFC 2784: Generic Routing Encapsulation (GRE)) headers
- RFC 2890: Key and Sequence Number Extensions to GRE
- IPv4 (RFC 791: Internet Protocol) headers
- IPv6 (RFC 2460: Internet Protocol, Version 6 (IPv6)) headers

If the NIC finds an unknown or unsupported encapsulation protocol, it must pass the packet unchanged to the host stack.

Thus, on the receive path, the miniport must parse the transport (inner) IP header to determine the IP version as well as to get to the TCP or UDP header. This is a new requirement for NDIS 6.30 (Windows Server 2012) and later.

Determining the NVGRE Task Offload Capabilities of a Network Adapter

Article • 12/15/2021

A miniport driver that supports Network Virtualization using Generic Routing Encapsulation (NVGRE) Task Offload reports this capability by means of the **NDIS_OFFLOAD** structure that its *MiniportInitializeEx* function passes to **NdisMSetMiniportAttributes**.

Reporting NVGRE Task Offload Capability

In the **NDIS_OFFLOAD** structure, the **Header** member must be set as follows:

- The **Revision** member must be set to **NDIS_OFFLOAD_REVISION_3**.
- The **Size** member must be set to **NDIS_SIZEOF_NDIS_OFFLOAD_REVISION_3**.

To report its support for NVGRE task offload, a miniport driver sets the following members in the **NDIS_ENCAPSULATED_PACKET_TASK_OFFLOAD** structure, which is stored in the **EncapsulatedPacketTaskOffloadGre** member of the **NDIS_OFFLOAD** structure that the miniport driver's *MiniportInitializeEx* function passes to **NdisMSetMiniportAttributes**:

- Set the **MaxHeaderSizeSupported** member to the maximum header size from the beginning of the packet to the beginning of the inner TCP or UDP payload (the last byte of TCP or UDP inner header) that the NIC must support for all of these task offloads. The protocol driver is expected to not offload processing of a packet whose combined encapsulation headers exceed this size.

  Note 256 bytes is a good default value that should cover all possible cases.

- Set the other members to indicate which types of task offload the miniport driver supports for encapsulated packets. For a list of the flags that can be set for these members, see the Remarks section of **NDIS_ENCAPSULATED_PACKET_TASK_OFFLOAD**.

Querying NVGRE Task Offload Capability

To determine whether a miniport driver supports NVGRE task offload, protocol and filter drivers can issue the OID_TCP_OFFLOAD_HARDWARE_CAPABILITIES OID request, which returns the **NDIS_OFFLOAD** structure.

Note To determine whether the miniport driver's NVGRE capability is currently enabled, use the OID_TCP_OFFLOAD_CURRENT_CONFIG OID request as described in Querying and Changing NVGRE Task Offload State.

Note To enable or disable the miniport driver's NVGRE capability, use the OID_TCP_OFFLOAD_PARAMETERS OID request as described in Querying and Changing NVGRE Task Offload State.

Querying and Changing NVGRE Task Offload State

Article • 12/15/2021

This section describes how to query or change the current Network Virtualization using Generic Routing Encapsulation (NVGRE) Task Offload state of an NVGRE-capable miniport driver. NVGRE task offload can be enabled by default, but it must not be operationally active by default. A NIC should not begin performing task offloads on encapsulated packets until this feature is enabled explicitly by an NDIS protocol or filter driver.

Querying NVGRE Task Offload State

To query a miniport driver's current NVGRE task offload state, an NDIS protocol or filter driver uses the OID_TCP_OFFLOAD_CURRENT_CONFIG OID request. This will return an **NDIS_OFFLOAD** structure whose **EncapsulatedPacketTaskOffloadGre** member is an **NDIS_ENCAPSULATED_PACKET_TASK_OFFLOAD** structure that contains **NDIS_OFFLOAD_SUPPORTED** if those offloads are currently enabled for GRE-encapsulated packets and **NDIS_OFFLOAD_NOT_SUPPORTED** otherwise. NDIS handles this OID and does not pass it down to the miniport.

Note To determine whether a miniport driver supports NVGRE task offload, use the OID_TCP_OFFLOAD_HARDWARE_CAPABILITIES OID request as described in Determining the NVGRE Task Offload Capabilities of a Network Adapter.

Changing NVGRE Task Offload State

An NDIS protocol or filter driver can enable or disable NVGRE task offload by issuing the OID_TCP_OFFLOAD_PARAMETERS OID request. This OID uses an **NDIS_OFFLOAD_PARAMETERS** structure. In this structure, the **EncapsulatedPacketTaskOffload** member can have the following values:

Term	Description
NDIS_OFFLOAD_SET_NO_CHANGE	The NVGRE task offload state is unchanged.
NDIS_OFFLOAD_SET_ON	Specify this flag to enable NVGRE task offload.
NDIS_OFFLOAD_SET_OFF	Specify this flag to disable NVGRE task offload.

After the miniport driver processes the OID_TCP_OFFLOAD_PARAMETERS OID request, it must issue an **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** status indication with the updated offload state.

When a miniport driver receives a OID_TCP_OFFLOAD_PARAMETERS OID request in which the **NDIS_OFFLOAD_SET_OFF** flag is specified, the driver should indicate any existing encapsulated packets that are partially processed for task offloads up the stack before completing the OID request.

Base task offloads for normal packets are enabled by existing OIDs such as OID_OFFLOAD_ENCAPSULATION and OID_RECEIVE_FILTER_ALLOCATE_QUEUE. The **EncapsulatedPacketTaskOffload** member setting supplements these OIDs and instructs the NIC to also do these offloads for encapsulated packets.

Standardized INF Keywords for NVGRE Task Offload

Article • 12/15/2021

The ***EncapsulatedPacketTaskOffload** standardized enumeration keyword is defined to enable or disable support for Network Virtualization using Generic Routing Encapsulation (NVGRE) Task Offload in miniport adapters.

The following table describes the possible INF entries for this keyword.

SubkeyName	ParamDesc	Value	EnumDesc
***EncapsulatedPacketTaskOffload**	Encapsulated Task Offload	0	Disabled

Overview of Receive Segment Coalescing

Article • 01/12/2023

When receiving data, the miniport driver, NDIS, and TCP/IP must all look at each PDU's header information separately. When large amounts of data are being received, this creates a large amount of overhead. Receive segment coalescing (RSC) reduces this overhead by coalescing a sequence of received segments and passing them to the host TCP/IP stack in one operation, so that NDIS and TCP/IP need only look at one header for the entire sequence.

RSC is intended to support coalescing in a way that:

- Doesn't interfere with the normal operation of TCP's congestion and flow control mechanisms.
- Coalesces packets without discarding information that is used by the TCP stack.

RSC-capable miniport drivers for network cards must:

- Follow a standard set of rules when coalescing segments.
- Provide certain out-of-band information to the host TCP/IP stack.

The following sections provide an overview of RSC.

- Rules for Coalescing TCP/IP Segments
- Updating the IP Headers for Coalesced Segments
- Examples of Receive Segment Coalescing
- Indicating Coalesced Segments
- Exception Conditions that Terminate Coalescing

Rules for Coalescing TCP/IP Segments

Article • 12/15/2021

This section defines the rules that specify when a receive segment coalescing (RSC)-capable miniport driver must coalesce a segment for a given TCP connection. If any of the rules are violated, an exception is generated, and the miniport driver must abort the coalescing of the segment.

The miniport driver must update the IP and TCP headers for the single coalesced unit (SCU). The miniport driver must recompute the TCP and IPv4 checksums over the SCU and chain the TCP payload.

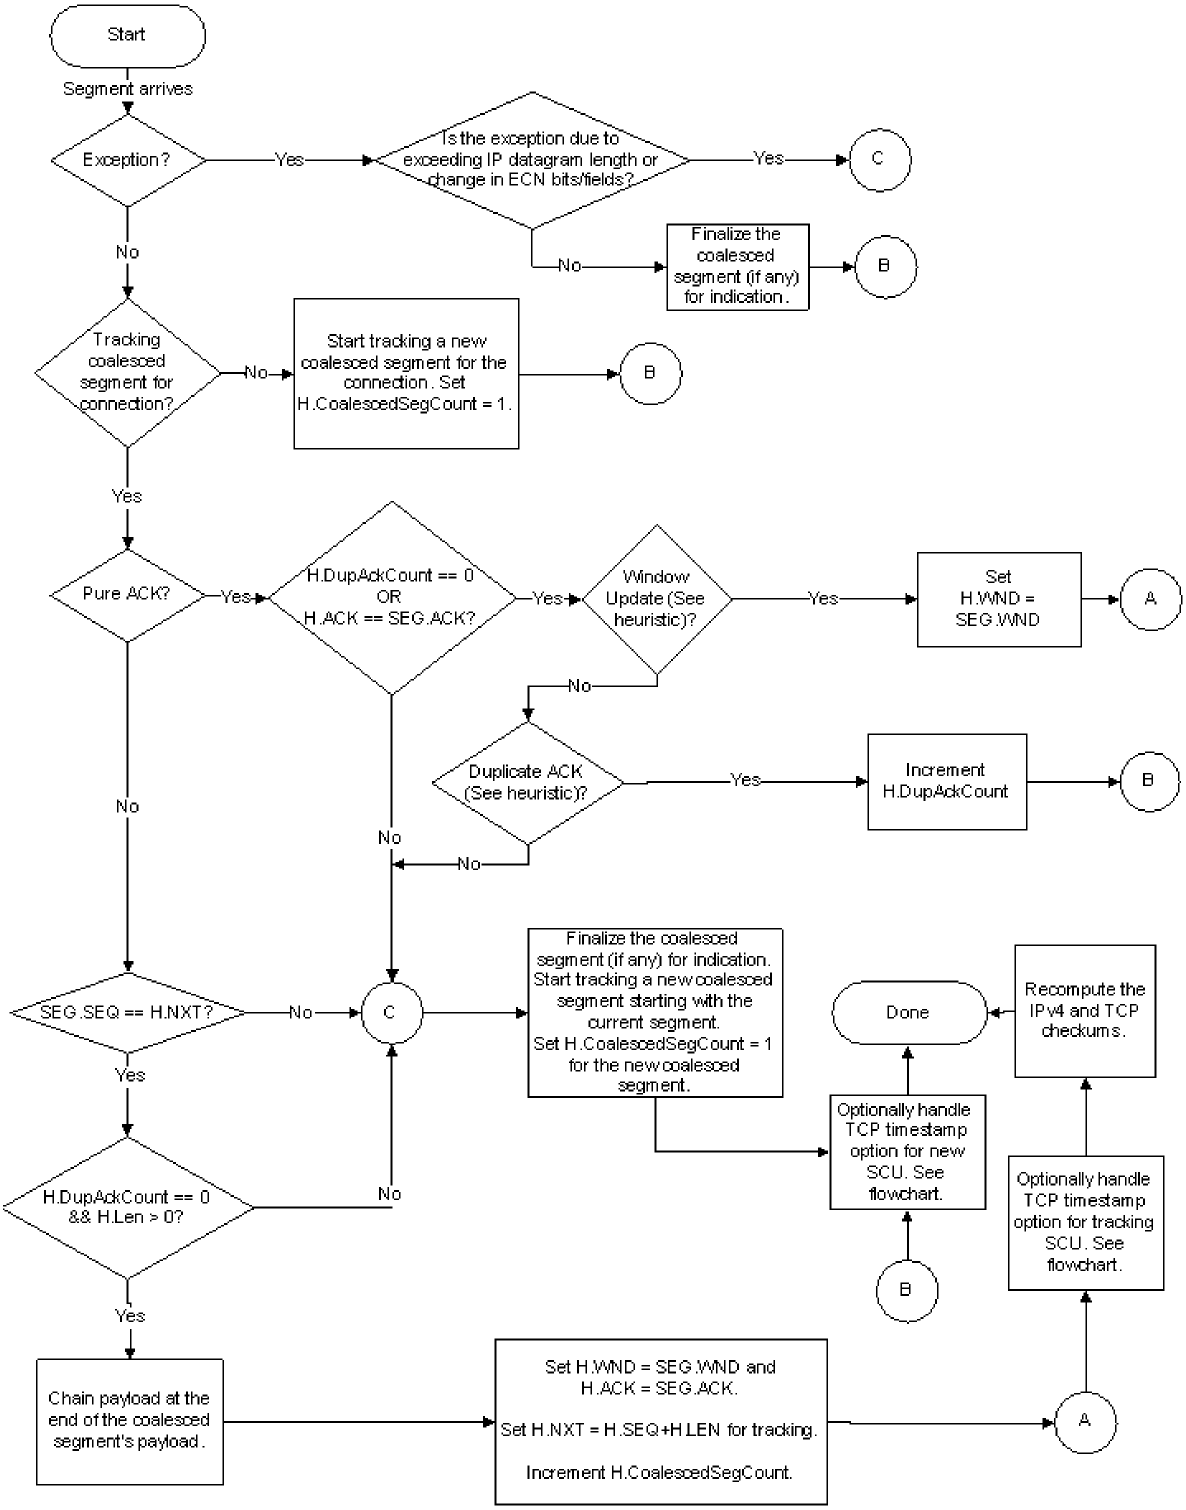
The first of the following two flowcharts describes the rules for coalescing segments and updating the TCP headers. This flowchart refers to mechanisms for distinguishing valid duplicate ACKs and window updates. The second flowchart describes these mechanisms.

These flowcharts are provided as a reference for understanding the RSC rules. A hardware implementation can optimize the flowchart, as long as correctness is maintained.

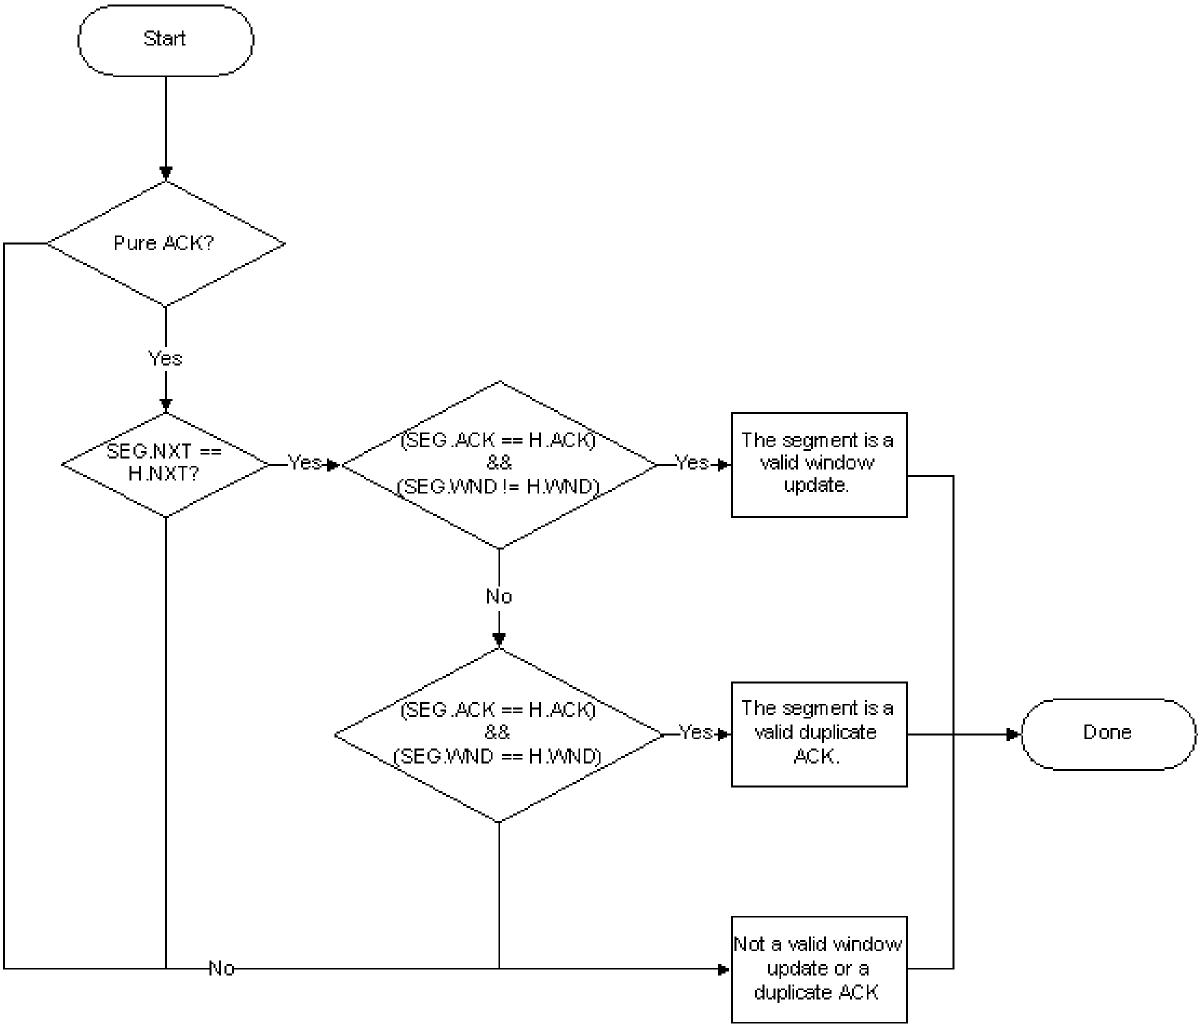
The following terms are used in the flowcharts:

Term	Description
SEG.SEQ	Sequence number of the incoming segment.
H.SEQ	Sequence number of the currently tracked SCU.
SEG.ACK	Acknowledgment number of the incoming segment.
H.ACK	Acknowledgment number of the currently tracked SCU.
SEG.WND	The window that is advertised by the incoming segment.
H.WND	The window that is advertised by the currently tracked SCU.
SEG.LEN	TCP payload length of the incoming segment.
H.LEN	TCP payload length of the currently tracked SCU.
SEG.NXT	The sum of **SEG.SEQ** and **SEG.LEN**.
H.NXT	The sum of **H.SEQ** and **H.LEN**.
H.DupAckCount	The number of duplicate ACKs that have been coalesced into the SCU. This number should be zero.

Term	Description
SEG.Tsval	The **Timestamp** value in the currently received segment. The format for this value is defined in RFC 1323 .
H.Tsval	The **Timestamp** value in the currently tracked SCU.
SEG.TSecr	The **Timestamp Echo Reply** in the currently received segment.
H.TSecr	The **Timestamp Echo Reply** in the currently tracked SCU.



Start
Segment arrives
Exception?
Yes
Is the exception due to exceeding IP datagram length or change in ECN bits/fields?
Yes
C
No
Finalize the coalesced segment (if any) for indication.
B
No
Tracking coalesced segment for connection?
No
Start tracking a new coalesced segment for the connection. Set H.CoalescedSegCount = 1.
B
Yes
Pure ACK?
Yes
H.DupAckCount == 0 OR H.ACK == SEG.ACK?
Yes
Window Update (See heuristic)?
Yes
Set H.WND = SEG.WND
A
No
Duplicate ACK (See heuristic)?
Yes
Increment H.DupAckCount
B
No
No
No
SEG.SEQ == H.NXT?
No
C
Finalize the coalesced segment (if any) for indication. Start tracking a new coalesced segment starting with the current segment. Set H.CoalescedSegCount = 1 for the new coalesced segment.
Done
Recompute the IPv4 and TCP checksums.
Yes
Optionally handle TCP timestamp option for new SCU. See flowchart.
H.DupAckCount == 0 && H.Len > 0?
No
B
Optionally handle TCP timestamp option for tracking SCU. See flowchart.
Yes
Chain payload at the end of the coalesced segment's payload.
Set H.WND = SEG.WND and H.ACK = SEG.ACK.
Set H.NXT = H.SEQ+H.LEN for tracking.
Increment H.CoalescedSegCount.
A



Start
Pure ACK?
Yes
SEG.NXT == H.NXT?
Yes
(SEG.ACK == H.ACK) && (SEG.WND != H.WND)
Yes
The segment is a valid window update.
No
(SEG.ACK == H.ACK) && (SEG.WND == H.WND)
Yes
The segment is a valid duplicate ACK.
Done
No
Not a valid window update or a duplicate ACK

The flowcharts show that the miniport driver may coalesce segments with different ACK numbers. However, the miniport driver must obey the following rules regarding ACK numbers, as shown in the first flowchart above:

- After performing the sequence number check, an incoming pure ACK may be coalesced into the currently tracked SCU if it meets one or both of the following conditions:

    - **H.ACK** == **SEG.ACK**.

    - The duplicate-ACK count in the coalesced segment that is being tracked is zero. In other words, **H.DupAckCount** == 0.

      In other words, any pure ACK that is not a duplicate ACK or a window update triggers an exception and must not be coalesced. All such pure ACKs must be indicated as individual segments. This rule ensures that RSC does not affect the behavior or performance of the Windows TCP congestion control algorithms.

- An incoming data segment (**SEG.ACK** == **H.ACK**) or an incoming piggy-backed ACK (**SEG.ACK** > **H.ACK**) may be coalesced into the currently tracked SCU if both of the following conditions are met:

- The segment is contiguous to the SCU in the sequence space. In other words, **SEG.SEQ** == **H.NXT**.
- The duplicate-ACK count in the coalesced segment that is being tracked is zero. In other words, **H.DupAckCount** == 0.

Additional notes on Duplicate ACK coalescing

Duplicate ACK Behavior

The miniport driver should treat a duplicate ACK segment equivalent to a pure ACK and not coalesce it. In this case, it must finalize the current SCU (if any) for indication and indicate the duplicate ACK segment as an individual segment. Because Windows clients use selective acknowledgments (SACK) by default, a duplicate ACK segment will likely generate an exception. See Examples of Receive Segment Coalescing for an example. If a segment with **DupAckCount** > 0 is indicated, NDIS will disable RSC on the interface.

Handling Duplicate ACK when tracking a SCU consisting of data segments

When tracking an SCU with **H.LEN** > 0 (in other words, a coalesced segment that contains data), if a duplicate ACK arrives next, then the tracking SCU should be finalized as follows:

1. A new SCU should be tracked, starting with the duplicate ACK.

2. The **DupAckCount** for the new SCU should be set to zero.

3. The **DupAckCount** should be incremented if additional duplicate ACKs are received.

In this case, **DupAckCount** will be 1 less than the number of duplicate ACKs. The host stack will handle the counting correctly.

Handling Duplicate ACK when tracking a SCU consisting of a pure cumulative ACK

When tracking an SCU that consists of a single pure cumulative ACK (rules forbid coalescing multiple pure ACKs), if a duplicate ACK arrives next, then the **DupAckCount** for the tracking SCU should be incremented. It should also be incremented if additional duplicate ACKs are received. In this case, **DupAckCount** will be equal to the number of duplicate ACKs that are coalesced.

When the first segment that is received in a DPC is a duplicate ACK

In this case, the NIC cannot determine whether the received segment is a duplicate ACK, because it does not maintain any state. So the segment should be treated as a pure ACK instead as follows:

1. A new SCU should be tracked, starting with this segment.
2. The **DupAckCount** for the new SCU should be set to zero.
3. The **DupAckCount** should be incremented by 1 for each additional duplicate ACK that is received.

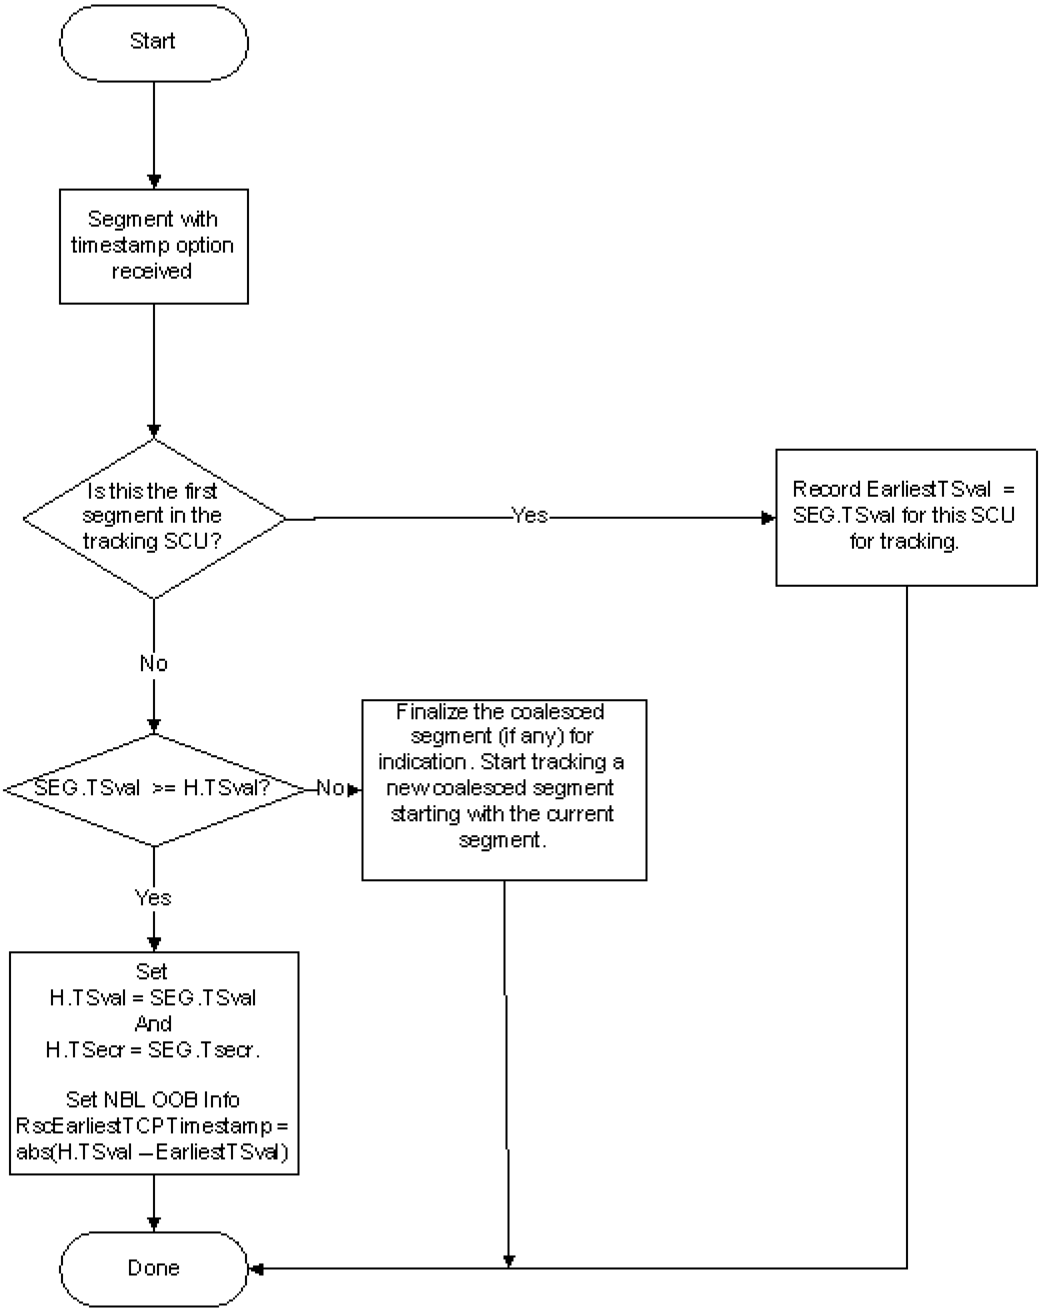
In this case, **DupAckCount** will be equal to 1 less than the actual number of duplicate ACKs. The host stack will handle the counting correctly.

Duplicate ACK Exemption

The miniport driver may treat a duplicate ACK segment equivalent to a pure ACK and not coalesce it. In this case, it must finalize the current SCU (if any) for indication and indicate the duplicate ACK segment as an individual segment. Because Windows clients use SACK by default, a duplicate ACK segment will likely generate an exception. For an example, see Examples of Receive Segment Coalescing. This exemption does not apply to window update segments.

Coalescing Segments with the Timestamp Option

The TCP timestamp option is the only option that may be legally coalesced. Coalescing segments with this option is left as an implementation-specific decision. If the miniport driver coalesces segments with the timestamp option, then it must follow the rules outlined in the following flowchart:



Start
Segment with timestamp option received
Is this the first segment in the tracking SCU?
Yes
Record EarliestTSval = SEG.TSval for this SCU for tracking.
No
SEG.TSval >= H.TSval?
No
Finalize the coalesced segment (if any) for indication. Start tracking a new coalesced segment starting with the current segment.
Yes
Set H.TSval = SEG.TSval And H.TSecr = SEG.Tsecr.
Set NBL OOB Info RscEarliestTCPTimestamp = abs(H.TSval – EarliestTSval)
Done

ⓘ **Note**

The check **SEG.TSval** >= **H.TSval** must be performed using modulo-232 arithmetic similar to that used for TCP sequence numbers. See RFC 793, section 3.3.

When indicating a coalesced segment, the following out-of-band information must be indicated as follows by setting the **NetBufferListInfo** member of the NET_BUFFER_LIST structure that describes the coalesced segment:

- The number of segments that were coalesced must be stored into the **NetBufferListInfo**[**TcpRecvSegCoalesceInfo**].**CoalescedSegCount** member. This number only represents data segments that were coalesced. Pure ACK coalescing is forbidden and window update segments must not be counted as part of this field.

- The duplicate ACK count must be stored into the **NetBufferListInfo**[**TcpRecvSegCoalesceInfo**].**DupAckCount** member. The first flowchart above explains how this value is calculated.

- When segments with the TCP timestamp option are coalesced, **NetBufferListInfo**[**RscTcpTimestampDelta**] must be filled with the absolute delta between the earliest and the latest TCP timestamp value seen in the sequence of coalesced segments comprising the SCU. The SCU itself should contain the latest TCP timestamp value seen in the sequence of coalesced segments.

The **DupAckCount** and **RscTcpTimestampDelta** members are interpreted if and only if the **CoalescedSegCount** member is greater than zero. If the **CoalescedSegCount** is zero, the segment is treated as a non-coalesced non-RSC segment.

For information about the contents of the **NetBufferListInfo** member, see **NDIS_NET_BUFFER_LIST_INFO** and **NDIS_RSC_NBL_INFO**.

The PSH bit should be ORed for all coalesced segments. In other words, if the PSH bit was set in any of the individual segments, the miniport driver should set the PSH bit in the SCU.

Finalizing an SCU involves:

- Recomputing the TCP and, if applicable, the IPv4 checksum.

- Updating the IP headers as described in Updating the IP Headers for Coalesced Segments.

- Setting the ECN bits and ECN fields in the TCP and IP headers to the same values that were set in the individual segments.

Handling TCP/IP IPsec segments

A network card may report both RSC and IPsec task offload capabilities. (See Determining the RSC Capabilities of a Network Adapter.) However, if it supports IPsec task offload, it must not attempt to coalesce segments that are protected by IPsec.

Updating the IP Headers for Coalesced Segments

Article • 12/15/2021

When finalizing a single coalescing unit (SCU), a receive segment coalescing (RSC)-capable miniport driver updates the fields in the IP headers as described in the following tables.

- Updating IPv4 header fields for coalesced segments
- Updating IPv6 header fields for coalesced segments

Updating IPv4 header fields for coalesced segments

Field	Description
Version	The value of this field must be the same for all coalesced segments.
Header Length	The length of a basic IPv4 header without any IP options.
Differentiated Services	The value of this field must be the same for all coalesced segments.
ECN bits	See Exception 8 in Exception Conditions that Terminate Coalescing. Datagrams should be coalesced if they all have the same values for the ECN bits.
Total Length	The value of this field must be recomputed every time a new segment with non-zero TCP payload length is coalesced into an existing SCU. See Exception Conditions that Terminate Coalescing for special cases that arise from the value in this field.
Identification	Must be set to the IP ID of the first coalesced segment.

Field	Description
Flags	- Datagrams may be coalesced as long as they have the same value for the DF (Don’t Fragment) bit: either all set or all clear. - Segments with the MF (More Fragments) bit set must not be coalesced.
Fragment Offset	Not applicable. Fragmented IP datagrams are not coalesced.
Time To Live	Must be set to the minimum time to live (TTL) value of the coalesced segments.
Protocol	Always set to 6, for TCP.
Header Checksum	The value of this field must be recomputed by the miniport driver.
Source Address	The value of this field must be the same for all coalesced segments.
Destination Address	The value of this field must be the same for all coalesced segments.

Updating IPv6 header fields for coalesced segments

Field	Description
Version	The value of this field must be the same for all coalesced segments.
Traffic Class	The value of this field must be the same for all coalesced segments.
Flow Label	The value of this field must be the same for all coalesced segments.
Payload Length	The value of this field must be recomputed whenever a new segment with nonzero TCP payload length is coalesced into an existing segment.
Next Header	Always set to 6, for TCP.

Field	Description
Hop Limit	Must be set to the minimum **Hop Limit** value of the coalesced segments.
Source Address	The value of this field must be the same for all coalesced segments.
Destination Address	The value of this field must be the same for all coalesced segments.

Examples of Receive Segment Coalescing

Article • 12/15/2021

This section illustrates the coalescing algorithm by using examples of segments that are received in order and processed in a single deferred procedure call (DPC).

This page uses X and X′ for labeling successive segments. All other segment and single coalesced unit (SCU) fields are as described in Rules for Coalescing TCP/IP Segments.

Example 1: Data segments

Segment Description

10 successive segments belonging to the same TCP connection are processed. All of the following conditions are true for each:

- X′.SEQ == X.NXT
- X′SEQ > X.SEQ
- X′.ACK == X.ACK

None of these segments generates an exception.

Result

A single SCU is formed out of the 10 segments. This is indicated as a single **NET_BUFFER** in a single **NET_BUFFER_LIST**.

Example 2: Data segments, followed by an exception, followed by data segments

Segment Description

5 successive segments belonging to the same TCP connection are processed. All of the following conditions are true for each:

- X′.SEQ == X.NXT

- X'SEQ > X.SEQ

- X'.ACK == X.ACK

None of these segments generates an exception. The 6th segment is a duplicate ACK segment with a TCP SACK option and generates an exception based on rule number 3 in Rules for Coalescing TCP/IP Segments.

Note In this case, the exception rule for handling a TCP option takes precedence and thus overrides the coalescing rule.

2 successive segments belonging to the same TCP connection are processed. All of the following conditions are true for each:

- X'.SEQ == X.NXT

- X'SEQ > X.SEQ

- X'.ACK == X.ACK

None of these segments generates an exception.

Result

A single SCU is formed out of the first 5 segments. The 6th segment does not form an SCU.

The 7th and 8th segments form an SCU together.

A **NET_BUFFER_LIST** chain is indicated with three **NET_BUFFER_LIST** structures each having a single **NET_BUFFER**. The ordering of received segments is maintained.

Example 3: Data segments, followed by multiple window updates

Segment Description

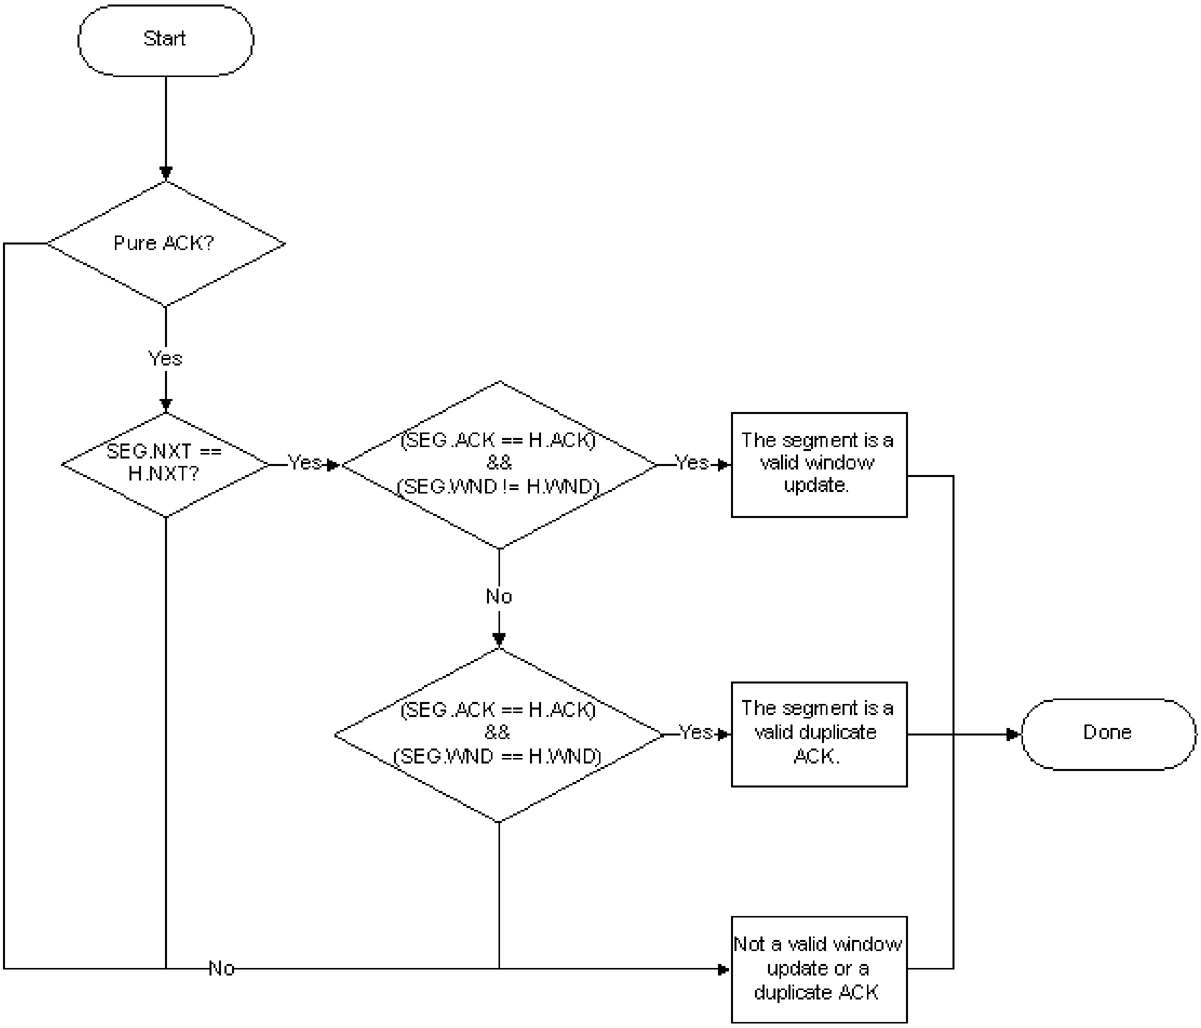
5 successive segments belonging to the same TCP connection are processed. All of the following conditions are true for each:

- X'.SEQ == X.NXT

- X'SEQ > X.SEQ

- X'.ACK == X.ACK

None of these segments generates an exception. The 6th segment is a pure ACK that is a window update with SEG.WND = 65535 as shown in the following flowchart.



Start
Pure ACK?
Yes
SEG.NXT == H.NXT?
Yes
(SEG.ACK == H.ACK) && (SEG.WND != H.WND)
Yes
The segment is a valid window update.
No
(SEG.ACK == H.ACK) && (SEG.WND == H.WND)
Yes
The segment is a valid duplicate ACK.
Done
No
Not a valid window update or a duplicate ACK

The 7th segment is a pure ACK that is a window update with SEG.WND = 131070 as shown in the same flowchart.

Result

A single SCU is formed out of the 7 segments. This is indicated as a single NET_BUFFER in a single NET_BUFFER_LIST.

The SCU.WND = 131070, and the checksum is updated based on this value.

Example 4: Piggybacked ACKs mixed with data segments

Segment Description

3 successive segments belonging to the same TCP connection are processed. All of the following conditions are true for each:

- X'.SEQ == X.NXT
- X'SEQ > X.SEQ
- X'.ACK == X.ACK

None of these segments generates an exception. 2 successive segments belonging to the same TCP connection are processed. All of the following conditions are true for each:

- X'.SEQ == X.NXT
- X'SEQ > X.SEQ
- X'.ACK == X.ACK

None of these segments generates an exception.

Result

A single SCU is formed out of the 5 segments. This is indicated as a single **NET_BUFFER** in a single **NET_BUFFER_LIST**. The SCU.ACK is set to the last SEG.ACK.

Indicating Coalesced Segments

Article • 12/15/2021

A single coalesced unit (SCU) is a sequence of TCP segments that are coalesced into a single TCP segment according to the rules defined in Rules for Coalescing TCP/IP Segments. This section describes how to indicate the resulting coalesced segments.

An SCU must:

- Be indicated by calling **NdisMIndicateReceiveNetBufferLists**.

- Look like a normal TCP segment that is received over the wire.

- Be no larger than the maximum legal IP datagram length, as defined in section 3.1 of RFC 791.

  Note Because segments with IPv6 extension headers cannot be coalesced (see Exception Conditions that Terminate Coalescing), the size of the SCU for IPv6 datagrams is also limited by the maximum legal datagram length.

The NIC or miniport driver should recompute the TCP and IPv4 checksums, if applicable, before indicating the coalesced segment. If the NIC or miniport driver validates the TCP and IPv4 checksums but does not recompute them for the coalesced segment, it must set the **TcpChecksumValueInvalid** and **IpChecksumValueInvalid** flags in the **NDIS_TCP_IP_CHECKSUM_NET_BUFFER_LIST_INFO** structure. Additionally, in this case the NIC or miniport driver may optionally zero out the TCP and IPv4 header checksum values in the segment.

The NIC and miniport driver must always set the **IpChecksumSucceeded** and **TcpChecksumSucceeded** flags in the **NDIS_TCP_IP_CHECKSUM_NET_BUFFER_LIST_INFO** structure before indicating the coalesced segment.

For more information about coalescing rules, see Rules for Coalescing TCP/IP Segments.

For more information about exceptions, see Exception Conditions that Terminate Coalescing.

Coalescing is expected to be performed on a best-effort basis. The hardware might not be able to coalesce in some cases, for example due to lack of resources. The requirements stated here are primarily to specify when not to coalesce and how to coalesce.

At a high level, the NIC and miniport driver must handle the receipt of a TCP segment over the wire as follows:

- Check the incoming segment for an exception as follows:

    1. If no exception was encountered, check whether the segment can be coalesced with the last segment that was received for the same TCP connection per the rules.

    2. If the segment triggered an exception, or if coalescing it with the previously received segment is not possible, then indicate the segment individually.

- The NIC and miniport driver must not indicate coalesced segments until the protocol driver enables RSC as described in Querying and Changing RSC State.

- For a given TCP connection, a data indication from the miniport adapter to the host TCP/IP stack may consist of one or more coalesced segments, separated by one or more individual segments that could not be coalesced.

- The NIC and miniport driver must not delay the indication of TCP segments, whether coalesced or not. Specifically, the NIC and miniport driver must not delay the indication of segments from one deferred procedure call (DPC) to the next in order to attempt to coalesce the segments.

- The NIC and miniport driver may use timers to determine the end of coalescing. However, the handling of latency sensitive workloads must be as effective as the DPC boundary requirement.

Exception Conditions that Terminate Coalescing

Article • 12/15/2021

This section defines the checks that a receive segment coalescing (RSC)-capable miniport driver must perform on a segment before it can be coalesced.

A segment must pass both of the following types of checks before it can be coalesced:

- Checks for presence of a certain condition in the segment. For example, the presence of a SYN flag in the TCP header would trigger an exception and the segment would not be coalesced. These types of checks are defined below.

- Checks that depend on inspecting and correlating information from previously coalesced segments and the currently examined segments. For example, checking if the received segment is a duplicate acknowledgment falls in this category of checks. These types of checks are defined in Rules for Coalescing TCP/IP Segments.

If a check fails, an exception is triggered, and the miniport driver must terminate coalescing for that TCP connection and treat segments as follows:

- TCP segments that were coalesced before the exception was detected should be indicated as a single unit.

- TCP segments that are coalesced after the exception is detected should be indicated as a separate unit.

Note For exceptions 7 and 8 below, the miniport driver should resume coalescing starting with the segment that triggered the exception.

Receiving a segment that meets any of the following criteria must trigger an exception:

1. The hardware resource constraints in the NIC prevent coalescing.

2. The segment has an invalid TCP or IP checksum.

3. The segment contains any of the SYN, URG, RST, FIN in its TCP header, as defined in section 3.1 of RFC 793 . More broadly, if the segment contains any flag other than PSH or ACK, it should trigger an exception. For ECN flags, see exception 8 below.

4. The segment contains one or more TCP options other than the TCP timestamp option. See RFC 1323 for a discussion of the TCP timestamp option.

5. The segment contains IPv4 options or IPv6 extension headers.

6. The segment is an IPv4 fragment.

7. Coalescing the currently received segment will cause the single coalesced unit to exceed the maximum legal IP Datagram length. This exception requires special handling. For more information, see:

   - The first flowchart in Rules for Coalescing TCP/IP Packets

   - "Responding to Queries for RSC Statistics" in Programming Considerations for RSC Drivers.

8. The segment contains ECN flags, as defined in RFC 3168, that meet one or both of the following criteria:

   a. The segment contains a different value for the ECN field (ECT, CE) in the IP header than the previous segment.

   b. The segment has a different value for the ECN flags (ECE and CWR) in the TCP header than the previous segment.

Determining the RSC Capabilities of a Network Adapter

Article • 12/15/2021

A receive segment coalescing (RSC)-capable miniport driver reports its RSC capability by means of the NDIS_OFFLOAD structure that it passes to NdisMSetMiniportAttributes.

Reporting RSC Capability

In the NDIS_OFFLOAD structure, the **Header** member must be set as follows:

- The **Revision** member must be set to **NDIS_OFFLOAD_REVISION_3**.
- The **Size** member must be set to **NDIS_SIZEOF_NDIS_OFFLOAD_REVISION_3**.

To report its support for RSC, a miniport driver can set the following members in the NDIS_TCP_RECV_SEG_COALESCE_OFFLOAD structure, which is stored in the **Rsc** member of the NDIS_OFFLOAD structure:

- Set the **IPv4.Enabled** member to **TRUE** to indicate support for RSC for IPv4.

- Set the **IPv6.Enabled** member to **TRUE** to indicate support for RSC for IPv6.

The miniport driver must support RSC for at least IEEE 802.3 encapsulation. In addition, it can support RSC for any other encapsulations. If it does not support RSC for some encapsulation, and it receives packets of that encapsulation, the driver must indicate the packets up the stack normally.

Querying RSC Capability

To determine whether a miniport driver supports RSC, protocol drivers and other drivers can issue the OID_TCP_OFFLOAD_HARDWARE_CAPABILITIES OID request, which will return an NDIS_OFFLOAD structure.

Querying and Changing RSC State

Article • 12/15/2021

This section describes how to query or change the current receive segment coalescing (RSC) state of an RSC-capable miniport driver.

Querying RSC State

The current RSC state can be queried by issuing the OID_TCP_OFFLOAD_CURRENT_CONFIG OID request. NDIS handles this OID and does not pass it down to the miniport.

Changing RSC State

RSC can be enabled or disabled by issuing the OID_TCP_OFFLOAD_PARAMETERS OID request. This OID uses an **NDIS_OFFLOAD_PARAMETERS** structure. In this structure, the **RscIPv4** and **RscIPv6** members can have the following values:

Term	Description
NDIS_OFFLOAD_PARAMETERS_NO_CHANGE	The RSC state is unchanged.
NDIS_OFFLOAD_PARAMETERS_RSC_DISABLED	Specify this flag to disable RSC.
NDIS_OFFLOAD_PARAMETERS_RSC_ENABLED	Specify this flag to enable RSC.

After the miniport driver processes the OID_TCP_OFFLOAD_PARAMETERS OID request, it must give an **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** status indication with the updated offload state.

When a miniport driver receives a OID_TCP_OFFLOAD_CURRENT_CONFIG OID request in which the **NDIS_OFFLOAD_PARAMETERS_RSC_DISABLED** flag is specified, the driver must indicate any existing coalesced segments up the stack before completing the OID request.

Standardized INF Keywords for RSC

Article • 12/15/2021

In Windows 8, Windows Server 2012, and later, the receive segment coalescing (RSC) interface supports standardized INF keywords that appear in the registry and are specified in INF files.

The following list shows the enumeration standardized INF keywords for RSC:

***RscIPv4**
Enable or disable support for RSC for the IPv4 datagram version.

***RscIPv6**
Enable or disable support for RSC for the IPv6 datagram version.

Enumeration standardized INF keywords have the following attributes:

SubkeyName
The name of the keyword that you must specify in the INF file and that appears in the registry.

ParamDesc
The display text that is associated with **SubkeyName**.

Value
The enumeration integer value that is associated with each option in the list. This value is stored in NDI\params\ *SubkeyName**Value*.

EnumDesc
The display text that is associated with each value that appears in the menu.

Default
The default value for the menu.

The following table describes the possible INF entries for the RSC enumeration keywords.

SubkeyName	ParamDesc	Value	EnumDesc
*RscIPv4	Recv Segment Coalescing (IPv4)	0	Disabled
		1 (Default)	Enabled
*RscIPv6	Recv Segment Coalescing (IPv6)	0	Disabled

SubkeyName	ParamDesc	Value	EnumDesc
		1 (Default)	Enabled

For more information about standardized INF keywords, see Standardized INF Keywords for Network Devices.

For more information about using enumeration keywords, see Enumeration Keywords.

Programming Considerations for RSC Drivers

Article • 12/15/2021

The following sections describe issues to consider when implementing a receive-segment coalescing (RSC)-capable miniport driver.

- Responding to Queries for RSC Statistics
- Forwarded TCP Packets
- RSC Support for Lightweight Filters and MUX Intermediate Drivers
- Windows Filtering Platform (WFP) Inspection and Callout Drivers

Responding to Queries for RSC Statistics

NDIS, overlying drivers, and user-mode applications use the OID_TCP_RSC_STATISTICS OID to get the RSC statistics of a miniport adapter. RSC-capable miniport drivers must support this OID.

Forwarded TCP Packets

The miniport driver shouldn't perform RSC on segments in TCP packets that aren't intended for the host but are being forwarded out on another interface.

The host TCP/IP stack will disable RSC on any interface that has forwarding enabled. Weak host forwarding does not affect RSC.

RSC Support for Lightweight Filters and MUX Intermediate Drivers

All NDIS 6.30 lightweight filter drivers must support receive packets that are larger than the link maximum transmission unit (MTU). For more information about segment size limits, see Indicating Coalesced Segments.

NDIS will disable RSC on an interface if any lightweight filter driver or MUX intermediate driver in the host stack is NDIS 6.20 or lower.

A MUX intermediate driver may disable RSC on an interface, even if the interface's NDIS version is 6.30 or higher.

Windows Filtering Platform (WFP) Inspection and Callout Drivers

WFP callout drivers provide additional filtering functionality by adding custom callout functions to the filter engine at one or more of the kernel-mode filtering layers. Callouts support deep inspection and packet as well as stream modification.

WFP callout drivers may support handling of support receive packets that are larger than the link MTU. (For more information about packet size limits, see Tracking and Indicating Coalesced Segments.) Such WFP callout drivers should do the following:

- Opt in during registration to handle large packets.
- Set the callout driver flag as specified in the reference page for the **FWPS_CALLOUT2** structure.

Whenever a callout driver that has not opted in to handle large packets is registered, WFP will notify TCP/IP in the context of the registration. As part of handling this notification, TCP/IP will disable RSC on the interface.

If there is active TCP traffic during callout registration, TCP/IP will notify WFP. WFP will delay calling the registered filters until RSC is disabled. This will protect callout drivers from large packets.

UDP Receive Segment Coalescing Offload (URO)

Article • 05/22/2024

Starting in Windows 11, version 24H2, UDP Receive Segment Coalescing Offload (URO) enables network interface cards (NICs) to coalesce UDP receive segments. NICs can combine UDP datagrams from the same flow that match a set of rules into a logically contiguous buffer. These combined datagrams are then indicated to the Windows networking stack as a single large packet.

Coalescing UDP datagrams reduces the CPU cost to process packets in high-bandwidth flows, resulting in higher throughput and fewer cycles per byte.

The following sections describe the rules for coalescing UDP packets and how to write a URO miniport driver.

- Rules for coalescing UDP packets
- Write a URO miniport driver
- Programming considerations for URO drivers

Rules for coalescing UDP packets

URO coalescing can only be attempted on packets that meet all the following criteria:

- **IpHeader.Version** is identical for all packets.
- **IpHeader.SourceAddress** and **IpHeader.DestinationAddress** are identical for all packets.
- **UdpHeader.SourcePort** and **UdpHeader.DestinationPort** are identical for all packets.
- **UdpHeader.Length** is identical for all packets, except the last packet, which may be less.
- **UdpHeader.Length** must be nonzero.
- **UdpHeader.Checksum**, if non-zero, must be correct on all packets. This means that receive checksum offload must validate the packet.
- **Layer 2 headers** must be identical for all packets.

If the packets are IPv4, they must also meet the following criteria:

- **IPv4Header.Protocol** == 17 (UDP) for all packets.
- **EthernetHeader.EtherType** == 0x0800 for all packets.

- The **IPv4Header.HeaderChecksum** on received packets must be correct. This means that receive checksum offload must validate the header.
- **IPv4Header.HeaderLength** == 5 (no IPv4 Option Headers) for all packets.
- **IPv4Header.ToS** is identical for all packets.
- **IPv4Header.ECN** is identical for all packets.
- **IPv4Header.DontFragment** is identical for all packets.
- **IPv4Header.TTL** is identical for all packets.
- **IPv4Header.TotalLength** == **UdpHeader.Length** + length(**IPv4Header**) for all packets.

If the packets are IPv6, they must also meet the following criteria:

- **IPv6Header.NextHeader** == 17 (UDP) for all packets (no extension headers).
- **EthernetHeader.EtherType** == 0x86dd (IPv6) for all packets.
- **IPv6Header.TrafficClass** and **IPv6Header.ECN** are identical for all packets.
- **IPv6Header.FlowLabel** is identical for all packets.
- **IPv6Header.HopLimit** is identical for all packets.
- **IPv6Header.PayloadLength** == **UdpHeader.Length** for all packets.

URO packet structure

The resulting Single Coalesced Unit (SCU) must have a single IP header and UDP header, followed by the UDP payload for all coalesced datagrams concatenated together.

URO indications must set the **IPv4Header.TotalLength** field to the total length of the SCU, or **IPv6Header.PayloadLength** field to the length of the UDP payload and **UdpHeader.Length** field to the length of coalesced payloads.

If Layer 2 (L2) headers are present in coalesced datagrams, the SCU must contain a valid L2 header. The L2 header in the SCU must resemble the L2 header of the coalesced datagrams.

Checksum validation and indication

URO indications must set the **IPv4Header.HeaderChecksum** and **UdpHeader.Checksum** fields to zero and fill out the checksum offload out-of-band information on the SCU indicating IPv4 and UDP checksum success.

A packet that matches all conditions for being coalesced but fails checksum validation must be indicated separately. Packets received after it must not be coalesced with packets received before it.

For example, suppose packets 1, 2, 3, 4, and 5 are received from the same flow, but packet 3 fails checksum validation. Packets 1 and 2 can be coalesced together, and packets 4 and 5 can be coalesced together, but packet 3 must not be coalesced with either SCU. Packets 1 and 2 must not be coalesced together with packets 4 and 5. Packet 2 is the last packet in an SCU and packet 4 starts a new SCU. Additionally, the SCU containing packets 1 and 2 must be indicated before packet 3 is indicated and packet 3 must be indicated before the SCU containing packets 4 and 5.

Packet coalescing and flow separation

Packets from multiple flows may be coalesced in parallel, as hardware and memory permit. Packets from different flows must not be coalesced together.

Packets from multiple receives interleaved may be separated and coalesced with their respective flows. For example, given flows A, B, and C, if packets arrive in the order A, A, B, C, B, A, the packets from the A flow may be coalesced into AAA, and the packets from the B flow coalesced into BB, while the packet from the C flow may be indicated normally or coalesced with a pending SCU from flow C.

The packets within a given flow must not be reordered with respect to each other. For example, the packets from the A flow must be coalesced in the order received, regardless of the packets from the B and C flows received in between.

INF keyword for controlling URO

The following keyword can be used to enable/disable URO with a registry key setting.

***UdpRsc**

Enumeration standardized INF keywords have the following attributes:

SubkeyName
The name of the keyword that you must specify in the INF file and that appears in the registry.

ParamDesc
The display text that is associated with SubkeyName.

Value
The enumeration integer value that is associated with each option in the list. This value is stored in NDI\params\ *SubkeyName**Value*.

EnumDesc
The display text that is associated with each value that appears in the menu.

Default
The default value for the menu.

Expand table

SubkeyName	ParamDesc	Value	EnumDesc
***UdpRsc**	URO	0	Disabled
		1 (Default)	Enabled

For more information about using enumeration keywords, see Enumeration Keywords.

Write a URO miniport driver

Starting in NDIS 6.89, the NDIS interface for URO facilitates communication between TCP/IP and the NDIS miniport driver.

Report URO capability

A miniport driver advertises support for URO in the **UdpRsc** member of the **NDIS_OFFLOAD** structure, which it passes to the **NdisMSetMiniportAttributes** function.

Query URO capability

To check if a miniport driver supports URO, NDIS drivers and other applications can query the OID_TCP_OFFLOAD_HARDWARE_CAPABILITIES OID, which returns the **NDIS_OFFLOAD** structure.

Query URO state

To determine the current URO state, NDIS drivers and other applications can query the OID_TCP_OFFLOAD_CURRENT_CONFIG OID request. NDIS handles this OID and doesn't pass it down to the miniport.

Change URO state

URO can be enabled or disabled by issuing the **OID_TCP_OFFLOAD_PARAMETERS** OID request. This OID uses an **NDIS_OFFLOAD_PARAMETERS** structure. In this structure, the

UdpRsc.Enabled member can have the following values:

Expand table

Value	Meaning
NDIS_OFFLOAD_PARAMETERS_UDP_RSC_NO_CHANGE 0	The miniport driver shouldn't change the current setting.
NDIS_OFFLOAD_PARAMETERS_UDP_RSC_DISABLED 1	URO is disabled.
NDIS_OFFLOAD_PARAMETERS_UDP_RSC_ENABLED 2	URO is enabled.

When a driver processes a **OID_TCP_OFFLOAD_PARAMETERS** OID request with the `NDIS_OFFLOAD_PARAMETERS_UDP_RSC_DISABLED` flag set, the NIC must wait to complete the request until all existing coalesced segments and outstanding URO indications are indicated. This ensures synchronization of URO enable/disable events across NDIS components.

After the miniport driver processes the **OID_TCP_OFFLOAD_PARAMETERS** OID request, the miniport driver must issue an NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG status indication with the updated offload state.

The `NDIS_OFFLOAD_PARAMETERS_SKIP_REGISTRY_UPDATE` flag in NDIS_OFFLOAD_PARAMETERS allows for runtime-only disabling of URO. Changes made with this flag aren't saved to the registry.

Opt-out of URO in NDIS 6.89 and later

Drivers targeting NDIS 6.89 and later should understand URO packets and handle them gracefully. To opt-out of URO:

- Lightweight filter (LWF) drivers set the `NDIS_FILTER_DRIVER_UDP_RSC_NOT_SUPPORTED` flag in the NDIS_FILTER_DRIVER_CHARACTERISTICS structure.
- Protocol drivers set the `NDIS_PROTOCOL_DRIVER_UDP_RSC_NOT_SUPPORTED` flag in the NDIS_PROTOCOL_DRIVER_CHARACTERISTICS structure.

This approach ensures components that are unfamiliar with URO don't receive URO NBLs. NDIS disables URO on the miniport during binding if an LWF or protocol driver that doesn’t support URO is present.

Programming considerations for URO drivers

Consider the following issues when implementing a URO-capable miniport driver.

Winsock URO API

For information on the Winsock URO API, see IPPROTO_UDP socket options. See the information on **UDP_RECV_MAX_COALESCED_SIZE** and **UDP_COALESCED_INFO**.

Windows TCP/IP stack updates

The Microsoft TCP/IP transport enables URO at bind time with NDIS, unless configuration prevents it from doing so.

WFP callouts can use `FWP_CALLOUT_FLAG_ALLOW_URO` in **FWPS_CALLOUT2** to advertise their support for URO. If an incompatible WFP callout is registered at a URO-sensitive layer, then the OS will disable URO while the callout is registered.

If a socket opts-in to URO with a max coalesced size greater than or equal to the hardware offload size, then the stack will deliver the NBLs from hardware unmodified to the socket. If a socket opts-in to a smaller max coalesced size, the stack will break the coalesced receive into the smaller size for the socket.

If a socket doesn't opt-in to URO, then the stack will resegment receives for that socket. In the absence of hardware URO, the existing software URO feature will continue to be available.

Introduction to Receive Side Scaling

Article • 09/27/2024

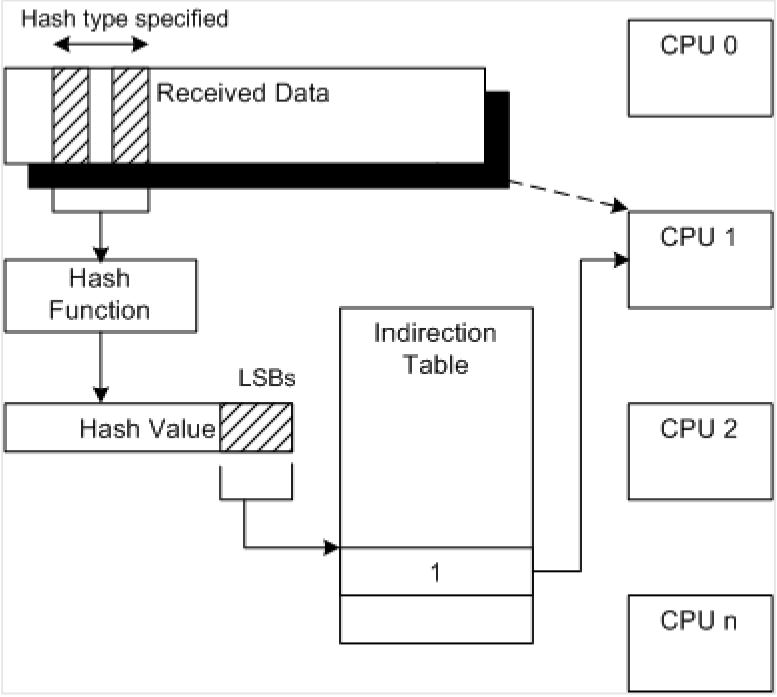
Receive side scaling (RSS) is a network driver technology that enables the efficient distribution of network receive processing across multiple CPUs in multiprocessor systems.

> ⓘ **Note**
>
> Because hyper-threaded CPUs on the same core processor share the same execution engine, the effect is not the same as having multiple core processors. For this reason, RSS does not use hyper-threaded processors.

To process received data efficiently, a miniport driver's receive interrupt service function schedules a deferred procedure call (DPC). Without RSS, a typical DPC indicates all received data within the DPC call. Therefore, all of the receive processing that is associated with the interrupt runs on the CPU where the receive interrupt occurs. For an overview of non-RSS receive processing, see Non-RSS Receive Processing.

RSS allows the NIC and miniport driver to schedule receive DPCs on other processors. The RSS design ensures that processing associated with a given connection stays on an assigned CPU. The NIC implements a hash function, and the resulting hash value helps select a CPU.

The following figure illustrates the RSS mechanism for determining a CPU.



A NIC uses a hashing function to compute a hash value over a defined area (hash type) within the received network data. The defined area can be noncontiguous.

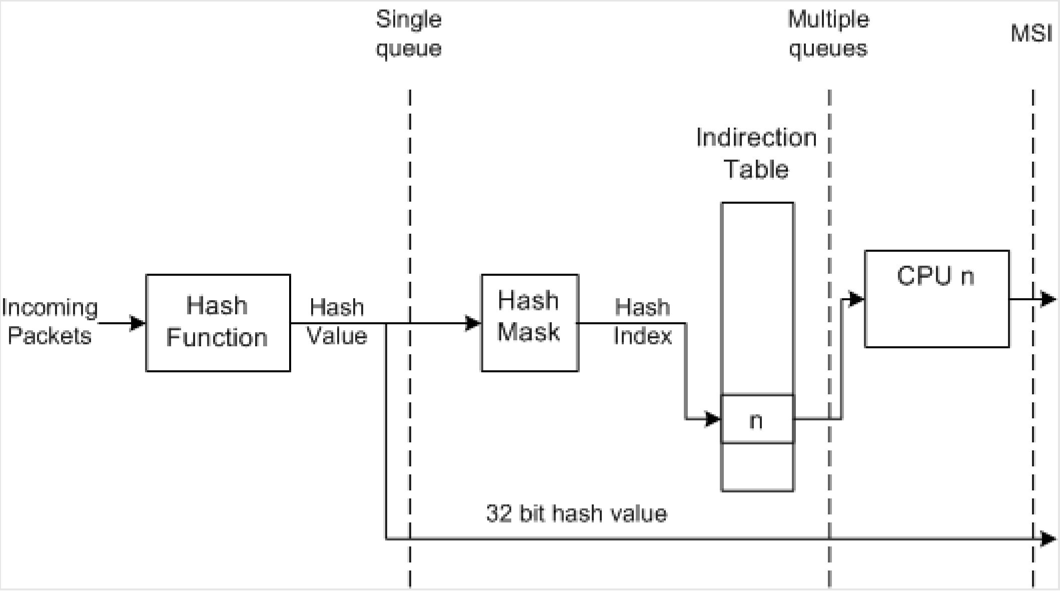
A number of least significant bits (LSBs) of the hash value are used to index an indirection table. The values in the indirection table are used to assign the received data to a CPU.

For more detailed information about specifying indirection tables, hash types, and hashing functions, see RSS Configuration.

With message signaled interrupt (MSI) support, a NIC can also interrupt the associated CPU. For more information about NDIS support for MSIs, see NDIS MSI-X.

Hardware support for RSS

The following figure illustrates the levels of hardware support for RSS.



There are three possible levels of hardware support for RSS:

- Hash calculation with a single queue: The NIC calculates the hash value, and the miniport driver assigns received packets to queues that are associated with CPUs.
- Hash calculation with multiple receive queues: The NIC assigns the received data buffers to queues associated with CPUs.
- Message signaled interrupts (MSIs): The NIC interrupts the CPU that should handle the received packets.

The NIC always passes on the 32-bit hash value.

How RSS improves system performance

RSS can improve network system performance by reducing:

- Processing delays by distributing receive processing from a NIC across multiple CPUs.

  Distributing receive processing helps to ensure that no CPU is heavily loaded while another CPU is idle.

- Spin lock overhead by increasing the probability that software algorithms that share data execute on the same CPU.

  Spin lock overhead occurs, for example, when a function executing on CPU0 possesses a spin lock on data that a function running on CPU1 must access. CPU1 spins (waits) until CPU0 releases the lock.

- Reloading of caches and other resources by increasing the probability that software algorithms that share data execute on the same CPU.

  Such reloading occurs, for example, when a function that is executing and accessing shared data on CPU0, executes on CPU1 in a subsequent interrupt.

To achieve these performance improvements in a secure environment, RSS provides the following mechanisms:

- Distributed processing

  RSS distributes the processing of receive indications from a given NIC in DPCs to multiple CPUs.

- In-order processing

  RSS preserves the order of delivery of received data packets. For each network connection, RSS processes receive indications on an associated CPU. For more information about RSS receive processing, see Indicating RSS Receive Data.

- Dynamic load balancing

  RSS provides a means to rebalance the network processing load between CPUs as host system load varies. To rebalance the load, overlying drivers can change the indirection table. For more information about specifying indirection tables, hash types, and hashing functions, see RSS Configuration.

- Send-side scaling

RSS enables driver stacks to process send and receive-side data for a given connection on the same CPU. Typically, an overlying driver (for example, TCP) sends part of a data block and waits for an acknowledgment before sending the balance of the data. The acknowledgment then triggers subsequent send requests. The RSS indirection table identifies a particular CPU for the receive data processing. By default, the send processing runs on the same CPU if it's triggered by the receive acknowledgment. A driver can also specify the CPU (for example, if a timer is used).

- Secure hash

  RSS includes a signature that provides added security. This signature protects the system from malicious remote hosts that might attempt to force the system into an unbalanced state.

- MSI-X support

  RSS, with support for MSI-X, runs the interrupt service routine (ISR) on the same CPU that later executes the DPC. This reduces spin lock overhead and reloading of caches.

Receive Side Scaling Version 2 (RSSv2)

Article • 12/15/2021

Receive Side Scaling improves the system performance related to handling of network data on multiprocessor systems. NDIS 6.80 and later support RSS Version 2 (RSSv2), which extends RSS by offering dynamic, per-VPort spreading of queues.

Overview

Compared to RSSv1, RSSv2 shortens the time between the measurement of CPU load and updating the indirection table. This avoids slowdown during high-traffic situations. To accomplish this, RSSv2 performs its actions at IRQL = DISPATCH_LEVEL, in the processor context of handling the request, and only operates on a subset of indirection table entries that point to the current processor. This means that RSSv2 can dynamically spread receive queues over multiple processors much more responsively than RSSv1.

Two OIDs, OID_GEN_RECEIVE_SCALE_PARAMETERS_V2 and OID_GEN_RSS_SET_INDIRECTION_TABLE_ENTRIES, have been introduced in RSSv2 for miniport drivers to set proper RSS capabilities and control the indirection table respectively. OID_GEN_RECEIVE_SCALE_PARAMETERS_V2 is a Regular OID, while OID_GEN_RSS_SET_INDIRECTION_ENTRIES is a Synchronous OID that cannot return NDIS_STATUS_PENDING. For more info about these OIDs, see their individual reference pages. For more info about Synchronous OIDs, see Synchronous OID request interface in NDIS 6.80.

RSSv2 terminology

This topic uses the following terms:

Term	Definition
RSSv1	The first generation receive side scaling mechanism. Uses OID_GEN_RECEIVE_SCALE_PARAMETERS.
RSSv2	The second generation receive side scaling mechanism supported in Windows 10, version 1803 and later, described in this topic.
Scaling entity	The miniport adapter itself in Native RSS mode, or a VPort in RSSv2 mode.

Term	Definition
ITE	An indirection table entry (ITE) of a given scaling entity. The total number of ITEs per VPort cannot exceed **NumberOfIndirectionTableEntriesPerNonDefaultPFVPort** or **NumberOfIndirectionTableEntriesForDefaultVPort** in VMQ mode or 128 in the Native RSS case. **NumberOfIndirectionTableEntriesPerNonDefaultPFVPort** and **NumberOfIndirectionTableEntriesForDefaultVPort** are members of the NDIS_NIC_SWITCH_CAPABILITIES structure.
Scaling mode	The per-VPort vmswitch policy that controls how its ITEs are handled at runtime. This can be static (no ITE moves due to load changes) or dyanmic (expansion and coalescing depending on current traffic load).
Queue	An underlying hardware object (queue) that backs an ITE. Depending on the hardware and indirection table, the configuration queue may back multiple ITEs. The total number of queues, including one that is used by the default queue, cannot exceed the preconfigured limit typically set by an administrator.
Default processor	A processor that receives packets for which the hash cannot be calculated. Each VPort has a default processor.
Primary processor	A processor specified as the **ProcessorAffinity** member of the NDIS_NIC_SWITCH_VPORT_PARAMETERS structure during VPort creation. This processor can be updated at runtime and specifies where VMQ traffic is directed.
Source CPU	The processor to which the ITE is currently mapped.
Target CPU	The processor to which the ITE is being re-mapped (using RSSv2).
Actor CPU	The processor on which RSSv2 requests are being made.

Advertising RSSv2 capability in a miniport driver

Miniport drivers advertise RSSv2 support by setting the **CapabilitiesFlags** member of the NDIS_RECEIVE_SCALE_CAPABILITIES structure with the *NDIS_RSS_CAPS_SUPPORTS_INDEPENDENT_ENTRY_MOVE* flag. This capability is required to enable RSSv2's CPU load balancing feature, along with the *NDIS_RECEIVE_FILTER_DYNAMIC_PROCESSOR_AFFINITY_CHANGE_SUPPORTED* flag that enables RSSv1 dynamic balancing for non-default VPorts (VMQs).

ⓘ Note

Upper layer protocols assume that the primary processor of the default VPort can be moved for RSSv2 miniport drivers.

If a miniport adapter does not advertise RSSv2 capability, all VMQ-enabled VPorts stay in static spreading mode even if these VPorts are requested to perform dynamic spreading. The RSSv1 OID for configuration of RSS parameters, OID_GEN_RECEIVE_SCALE_PARAMETERS, is used for these VPorts that are still in static spreading mode.

Miniport drivers only need to implement one RSS control mechanism - either RSSv1 or RSSv2. If the driver advertises RSSv2 support, NDIS will convert RSSv1 OIDs to RSSv2 OIDs if necessary to configure per-VPort spreading. The miniport driver must support the two new OIDs and modify the behavior of the RSSv1 OID_GEN_RECEIVE_SCALE_PARAMETERS OID as follows:

- OID_GEN_RECEIVE_SCALE_PARAMETERS is used only for Query requests in RSSv2 and not for setting RSS parameters.
- OID_GEN_RECEIVE_SCALE_PARAMETERS_V2 is a Query and a Set OID used for configuring the scaling entity's parameters such as the number of queues, the number of ITEs, RSS enablement/disablement, and hash key updates.
- OID_GEN_RSS_SET_INDIRECTION_TABLE_ENTRIES is a Method OID used to perform modification of indirection table entries.

Handling RSSv2 OIDs

OID_GEN_RECEIVE_SCALE_PARAMETERS is only used to query the current RSS parameters of a given scaling entity. In RSSv1, this OID is used to set parameters. For RSSv2-capable miniport drivers, NDIS automatically performs this role conversion for the driver and issues the following two OIDs to set parameters instead.

OID_GEN_RECEIVE_SCALE_PARAMETERS_V2 is a Regular OID and is handled the same as the OID_GEN_RECEIVE_SCALE_PARAMETERS OID was handled in RSSv1. This OID is not visible to NDIS light-weight filter drivers (LWFs) prior to NDIS 6.80.

OID_GEN_RSS_SET_INDIRECTION_TABLE_ENTRIES, however, is a Synchronous OID that cannot return NDIS_STATUS_PENDING. This OID must be executed and completed in the processor context which originated the OID. Like OID_GEN_RECEIVE_SCALE_PARAMETERS_V2, it is also not visible to NDIS LWFs prior to NDIS 6.80. LWFs in NDIS 6.80 and later are not permitted to delay this OID or move to another processor. Its payload contains an array of simple "move ITE" actions, each of which contains a command to move a single ITE for a scaling entity to a different target CPU. Elements of the array can reference different scaling entities (VPorts).

Each type of NDIS driver, miniport, filter, and protocol, have entry points to support the Synchronous OID request interface:

NDIS driver type	Synchronous OID handler(s)	Function to originate Synchronous OIDs
Miniport	*MiniportSynchronousOidRequest*	N/A
Filter	- *FilterSynchronousOidRequest* - *FilterSynchronousOidRequestComplete*	**NdisFSynchronousOidRequest**
Protocol	N/A	**NdisSynchronousOidRequest**

RSS state transitions, ITE updates, and primary/default processors

Steering parameters

In RSSv2, different parameters are used to steer traffic to the correct CPU depending on the RSS state (enabled or disabled). When RSS is disabled, only the primary processor is used for directing traffic. When RSS is enabled, both the default processor and all ITEs are used for directing traffic. These *steering parameters* are labele as "active" or "inactive", summarized in the following table:

Steering parameter	RSS disabled	RSS enabled
Primary processor	Active	Inactive
Default processor	Inactive	Active
ITE[0..N]	Inactive	Active

When a steering parameter is in the *active* state, it directs the traffic. From the moment of an RSS state transition that makes a parameter *inactive*, miniport drivers must track changes to the parameter until the reverse transition activates it again. This means that a miniport driver needs to track all updates to the default processor and indirection table entries while RSS is disabled for that scaling entity. When RSS is enabled, the current tracked state for the default processor and indirection table should take effect.

For example, consider the scenario when software vRSS is already enabled. In this case, the indirection table already exists in the upper layer protocol and is actively used by the upper layer's software spreading code. If, during hardware RSS enablement, all entries start pointing to the primary processor before the updates to *move* the indirection table entries are issued to and executed by the hardware, the primary processor might experience a short jam. If the miniport driver has tracked default processor and ITE information, it can direct traffic to where it is already expected by the upper layer.

Note that while miniport drivers must track all updates to inactive steering parameters, they should defer validation of those parameters until the RSS state change attempts to make these parameters *active*. For example, in the case of software spreading while hardware RSS is disabled, upper layer protocols can use any processor for spreading (including outside the adapter's RSS set). The upper layers ensure that, at the moment of RSS state transition, all *inactive* parameters are valid for the new RSS state. However, the miniport dirver should still validate the parameters and fail the RSS state transition if it discovers that any tracked *inactive* steering parameters are invalid.

Initial state and updates to steering parameters

The following table describes the initial state of the scaling entity after creation (for example, after VPort creation), as well as how the parameters can be updated:

Parameter	Description
Primary processor	• Initialized with the **Affinity** processor specified during VPort creation. • Can be updated using the OID_GEN_RSS_SET_INDIRECTION_TABLE_ENTRIES OID with the **NDIS_RSS_SET_INDIRECTION_ENTRY_FLAG_PRIMARY_PROCESSOR** flag set. • Can be updated using the OID_NIC_SWITCH_VPORT_PARAMETERS OID with the **NDIS_NIC_SWITCH_VPORT_PARAMS_PROCESSOR_AFFINITY_CHANGED** flag set (this is the compatibility path for existing cmdlet's). • Can be read using the OID_NIC_SWITCH_VPORT_PARAMETERS OID with the **NDIS_NIC_SWITCH_VPORT_PARAMS_PROCESSOR_AFFINITY_CHANGED** flag (this is the compatibility path for existing cmdlet's). • Post-initialization moves of the primary processor do not affect the default processor or the contents of the indirection table.
Default processor	• Initialized with the **Affinity** processor specified during VPort creation. • Can be updated using the OID_GEN_RSS_SET_INDIRECTION_TABLE_ENTRIES OID with the **NDIS_RSS_SET_INDIRECTION_ENTRY_FLAG_DEFAULT_PROCESSOR** flag set.

Parameter	Description
Indirection table	- **NumberOfIndirectionTableEntries** is set to **1**. - The only entry is initialized with the **Affinity** processor specified during VPort creation. - Can be updated using the OID_GEN_RSS_SET_INDIRECTION_TABLE_ENTRIES OID.

Updates to ITEs and the primary/default processors (using OID_GEN_RSS_SET_INDIRECTION_TABLE_ENTRIES) is invoked from the processor to which the corresponding entry currently points. For a given VPort, the upper layer ensures that no OID_GEN_RSS_SET_INDIRECTION_TABLE_ENTRIES OIDs to move ITEs or set the primary/default processors will be issued in these circumstances:

1. While OID_GEN_RECEIVE_SCALE_PARAMETERS_V2 is in progress.
2. After the VPort deletion sequence is initiated. For example, the upper layer issues the set filter OID only after the last OID to move ITEs is completed.

RSS disablement

During RSS disablement, the upper layer protocol might choose to either point all the ITEs to the primary processor, then issue the OID to disable RSS, or it might choose to leave the indirection table as-is and disable RSS. In either case, receive traffic should target the primary processor.

RSSv2 maintains a requirement from RSSv1 that permits the upper layer protocol to delete a VPort without first disabling RSS. The upper layer can set the receive filter on the VPort to zero, thus ensuring that no receive traffic flows through the VPort, then proceed with VPort deletion without disabling RSS. The upper layer guarantees that no OID_GEN_RSS_SET_INDIRECTION_TABLE_ENTRIES OIDs will be issued during or after VPort deletion.

During both RSS disablement and VPort deletion, the miniport driver should take care of any pending internal operations that might exist because of previous queue moves.

RSSv2 invariants

The upper layer protocol ensures that important invariants are not violated before performing management functions or ITE moves. For example:

1. Before reducing the number of queues, the upper layer ensures that the indirection table does not reference more processors than the new number of

queues for a VPort.

2. The upper layer should not request an indirection table update that violates the currently configured number of queues for a VPort. The miniport driver should enforce this and return a failure.
3. Before changing the number of indirection table entries for VMMQ-RESTRICTED adapters, the upper layer ensures that the contents of the indirection table are normalized to the power of 2.

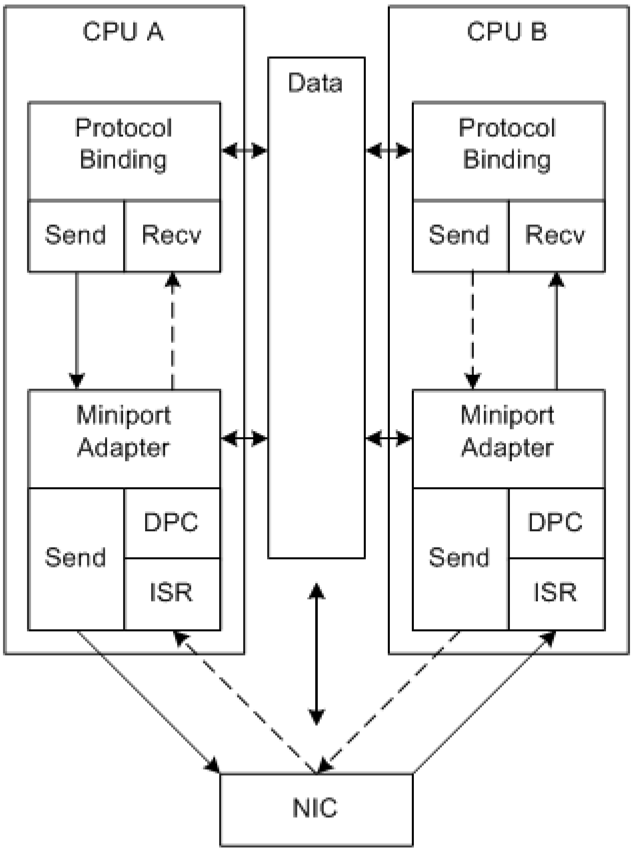
Synchronous OID request interface in NDIS 6.80

Non-RSS Receive Processing

Article • 12/15/2021

Miniport drivers that do not support RSS handle receive processing as described in this topic.

The following figure illustrates non-RSS receive processing.



In the figure, the dashed paths represent an alternate path for the send and receive processing. Because the system controls the scaling, the processing doesn't always occur on the CPU that provides the best performance. Connections are processed on the same CPU over successive interrupts only by chance.

The following process repeats for each non-RSS interrupt cycle:

1. The NIC uses DMA to fill a buffer with received data and interrupts the system.

   The miniport driver allocated the receive buffers in shared memory during initialization.

2. The NIC can continue to fill additional receive buffers at any time in this interrupt cycle. However, the NIC does not interrupt again until the miniport driver enables interrupts.

The received buffers that the system handles in one interrupt cycle can be associated with many different network connections.

3. NDIS calls the miniport driver's *MiniportInterrupt* function (ISR) on a system-determined CPU.

   Ideally, the ISR should go to the least busy CPU. However, in some systems, the system assigns the ISR to an available CPU or to a CPU that is associated with the NIC.

4. The ISR disables the interrupts and requests NDIS to queue a deferred procedure call (DPC) to process the received data.

5. NDIS calls the *MiniportInterruptDPC* function (the DPC) on the current CPU.

6. The DPC builds receive descriptors for all of the received buffers and indicates the data up the driver stack. For more information, see Receiving Network Data.

   There can be many buffers for many different connections and there is potentially a lot of processing to complete. The received data associated with subsequent interrupt cycles can be processed on other CPUs. The send processing for a given network connection can also run on a different CPU.

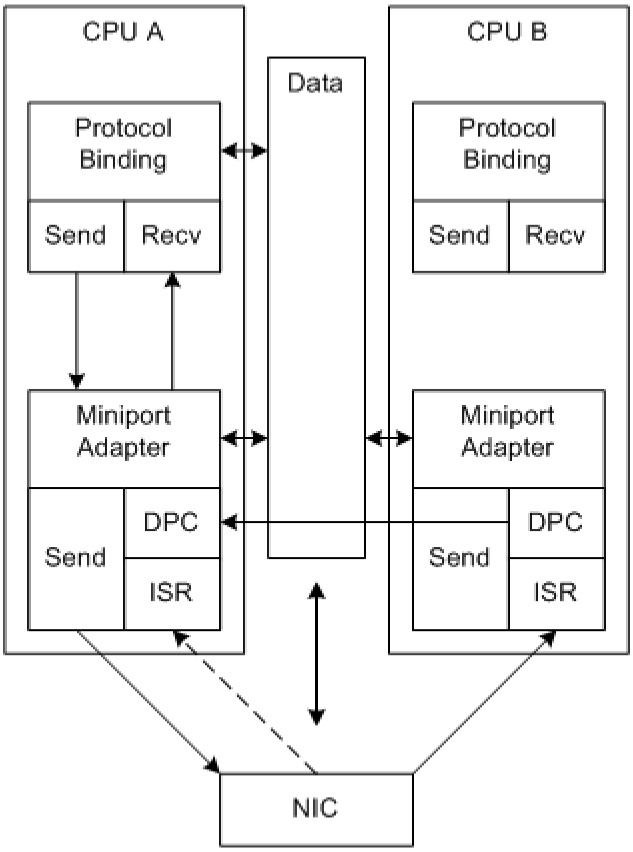
7. The DPC enables the interrupts. This interrupt cycle is complete and the process starts again.

RSS with a Single Hardware Receive Queue

Article • 12/15/2021

Miniport drivers can support RSS for NICs that support RSS hash calculation and a single receive descriptor queue.

The following figure illustrates RSS processing with a single receive descriptor queue.



In the figure, the dashed arrows represent an alternate path for the receive processing. RSS cannot control the CPU that receives the initial ISR call.

Unlike the non-RSS receive processing, RSS-based receive processing is distributed over multiple CPUs. Also, the processing for a given connection can be tied to a given CPU.

The following process repeats for each interrupt:

1. The NIC uses DMA to fill buffers with received data and interrupts the system.

   The miniport driver allocated the receive buffers in shared memory during initialization.

2. The NIC can fill additional receive buffers at any time but does not interrupt again until the miniport driver enables the interrupts.

The received buffers that the system handles in one interrupt can be associated with many different network connections.

3. NDIS calls the miniport driver's *MiniportInterrupt* function (ISR) on a system-determined CPU.

4. The ISR disables the interrupts and requests NDIS to queue a deferred procedure call (DPC) to process the received data.

5. NDIS calls the *MiniportInterruptDPC* function (DPC) on the current CPU. In the DPC:
   a. The miniport driver uses the hash values that the NIC calculated for each received buffer and reassigns each received buffer to a receive queue that is associated with a CPU.
   b. The current DPC requests NDIS to queue a DPC for each of the other CPUs that are associated with a non-empty receive queue.
   c. If the current DPC is running on a CPU that is associated with a non-empty queue, the current DPC processes the associated receive buffers and indicates the received data up the driver stack.

   Assigning queues, and queuing additional DPCs requires additional processing overhead. To achieve improved system performance, this overhead must be offset by better utilization of available CPUs.

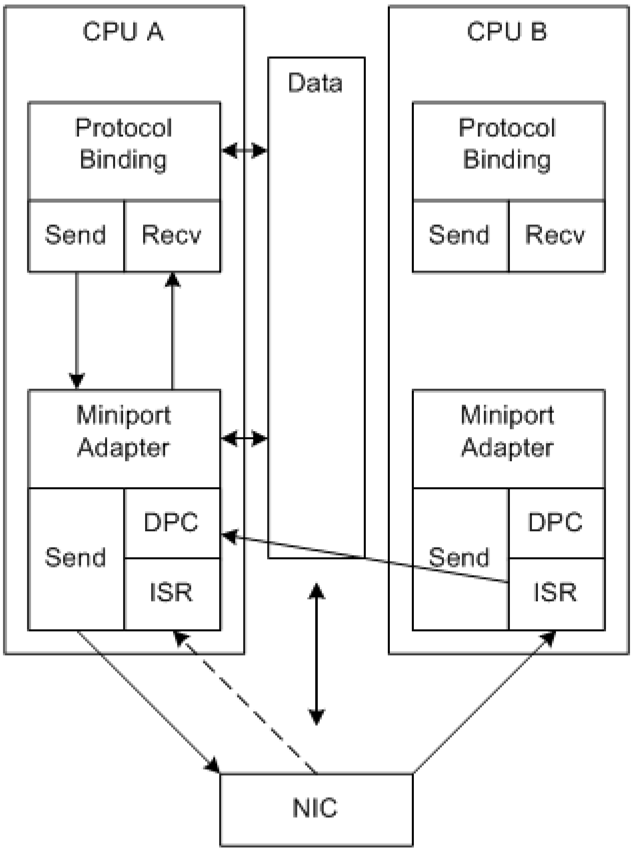
6. The DPC on a given CPU:
   a. Processes the receive buffers that are associated with its receive queue and indicates the data up the driver stack. For more information, see Indicating RSS Receive Data.
   b. Enables the interrupts, if it is the last DPC to complete. This interrupt is complete and the process starts again. The driver must use an atomic operation to identify the last DPC to complete. For example, the driver can use the **NdisInterlockedDecrement** function to implement an atomic counter.

RSS with Hardware Queuing

Article • 12/15/2021

RSS with hardware queuing improves system performance relative to RSS with a single hardware receive queue solution. NICs that support hardware queuing assign received data to multiple receive queues. The receive queues are associated with a CPU. The NIC assigns received data to CPUs based on hash values and an indirection table.

The following figure illustrates RSS with NIC receive queuing.



In the figure, the dashed arrows represent an alternate path for the receive processing. RSS cannot control the CPU that receives the initial ISR call. The driver does not have to queue the data so it can immediately schedule the initial DPCs on the correct CPUs.

The following process repeats for each interrupt:

1. The NIC:

   a. Uses DMA to fill buffers with received data.

      The miniport driver allocated the receive buffers in shared memory during initialization.

   b. Computes a hash value.

c. Queues the buffer for a CPU and provides the queue assignments to the miniport driver.

   For example, the NIC could loop steps 1-3 and DMA a list of CPU assignments after some number of packets are received. The specific mechanism is left to the NIC design.

d. Interrupts the system.

   The received buffers that the system handles in one interrupt are distributed between the CPUs.

2. NDIS calls the miniport driver's *MiniportInterrupt* function (ISR) on a system-determined CPU.

3. The miniport driver requests NDIS to queue deferred procedure calls (DPCs) for each of the CPUs that have a non-empty queue.

   Note that all the DPCs must complete before the driver enables interrupts. Also, note that the ISR might be running on a CPU that has no buffers to process.

4. NDIS calls the *MiniportInterruptDPC* function for each queued DPC. The DPC on a given CPU:

   a. Builds receive descriptors for all of the received buffers in its queue and indicates the data up the driver stack.

      For more information, see Indicating RSS Receive Data.

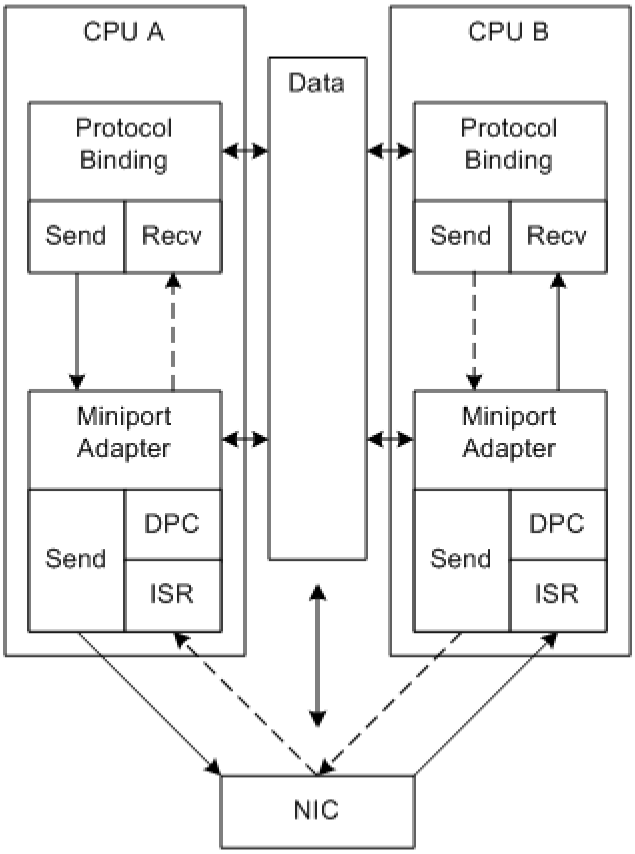
   b. Enables the interrupts, if it is the last DPC to complete. This interrupt is complete and the process starts again. The driver must use an atomic operation to identify the last DPC to complete. For example, the driver can use the **NdisInterlockedDecrement** function to implement an atomic counter.

RSS with Message Signaled Interrupts

Article • 12/15/2021

Miniport drivers can support message signaled interrupts (MSIs) to improve RSS performance. MSIs enable the NIC to request an interrupt on the CPU that will process the received data. For more information about NDIS support for MSI, see NDIS MSI-X.

The following figure illustrates RSS with MSI-X.



In the figure, the dashed arrows represent processing on a different connection. RSS with MSI-X allows the NIC to interrupt the correct CPU for a connection.

The following process repeats for each interrupt:

1. The NIC:

    a. Uses DMA to fill buffers with received data.

    The miniport driver allocated the receive buffers in shared memory during initialization.

    b. Computes a hash value.

    c. Queues the buffer to a CPU and provides the queue assignments to the miniport driver. For example, the NIC could loop steps 1-3 and DMA a list of

CPU assignments after some number of packets are received. The specific mechanism is left to the NIC design.

d. Using MSI-X, interrupts the CPU that is associated with a non-empty queue.

2. The NIC can fill additional receive buffers and add them to the queue at any time but does not interrupt that CPU again until the miniport driver enables the interrupts for that CPU.

3. NDIS calls the miniport driver's ISR (*MiniportInterrupt*) on the current CPU.

4. The ISR disables interrupts on the current CPU and queues a DPC on the current CPU.

   Interrupts can still occur on the other CPUs while the DPC is running on the current CPU.

5. NDIS calls the *MiniportInterruptDPC* function for each queued DPC. Each DPC:
   a. Builds receive descriptors for all of the received buffers in its queue and indicates the data up the driver stack. For more information, see Indicating RSS Receive Data.
   b. Enables interrupts for the current CPU. This interrupt is complete and the process starts again. Note that no atomic operation is required to track the progress of other DPCs.

RSS Hashing Types

Article • 12/15/2021

Overview

The RSS hashing type specifies the portion of received network data that a NIC must use to calculate an RSS hash value.

Overlying drivers set the hash type, function, and indirection table. The hash type that the overlying driver sets can be a subset of the type that the miniport driver can support. For more information, see RSS Configuration.

The hash type is an OR of valid combinations of the following flags:

- NDIS_HASH_IPV4
- NDIS_HASH_TCP_IPV4
- NDIS_HASH_UDP_IPV4
- NDIS_HASH_IPV6
- NDIS_HASH_TCP_IPV6
- NDIS_HASH_UDP_IPV6
- NDIS_HASH_IPV6_EX
- NDIS_HASH_TCP_IPV6_EX
- NDIS_HASH_UDP_IPV6_EX

These are the sets of valid flag combinations:

- IPv4 (combinations of NDIS_HASH_IPV4, NDIS_HASH_TCP_IPV4, and NDIS_HASH_UDP_IPV4)
- IPv6 (combinations of NDIS_HASH_IPV6, NDIS_HASH_TCP_IPV6, and NDIS_HASH_UDP_IPV6)
- IPv6 with extension headers (combinations of NDIS_HASH_IPV6_EX, NDIS_HASH_TCP_IPV6_EX, and NDIS_HASH_UDP_IPV6_EX)

A NIC must support one of the combinations from the IPv4 set. The other sets and combinations are optional. A NIC can support more than one set at a time. In this case, the type of data received determines which hash type the NIC uses.

In general, if the NIC cannot interpret the received data correctly, it must not compute the hash value. For example, if the NIC only supports IPv4 and it receives an IPv6 packet, which it cannot interpret correctly, it must not compute the hash value. If the NIC receives a packet for a transport type that it does not support, it must not compute the hash value. For example, if the NIC receives a UDP packet when it is supposed to be calculating hash values for TCP packets, it must not compute the hash value. In this case, the packet is processed as in the non-RSS case. For more information about the non-RSS receive processing, see Non-RSS Receive Processing.

IPv4 hash type combinations

The valid hash type combinations in the IPv4 set are:

- NDIS_HASH_IPV4
- NDIS_HASH_TCP_IPV4
- NDIS_HASH_UDP_IPV4
- NDIS_HASH_TCP_IPV4 | NDIS_HASH_IPV4
- NDIS_HASH_UDP_IPV4 | NDIS_HASH_IPV4
- NDIS_HASH_TCP_IPV4 | NDIS_HASH_UDP_IPV4 | NDIS_HASH_IPV4

NDIS_HASH_IPV4

If this flag alone is set, the NIC should compute the hash value over the following IPv4 header fields:

- Source-IPv4-Address
- Destination-IPv4-Address

> ⓘ **Note**
>
> If a NIC receives a packet that has both IP and TCP headers, NDIS_HASH_TCP_IPV4 should not always be used. In the case of a fragmented IP packet, NDIS_HASH_IPV4 must be used. This includes the first fragment which contains both IP and TCP headers.

NDIS_HASH_TCP_IPV4

If this flag alone is set, the NIC should parse the received data to identify an IPv4 packet that contains a TCP segment.

The NIC must identify and skip over any IP options that are present. If the NIC cannot skip over any IP options, it should not calculate a hash value.

The NIC should compute the hash value over the following fields:

- Source-IPv4-Address
- Destination-IPv4-Address
- Source TCP Port
- Destination TCP Port

NDIS_HASH_UDP_IPV4

If this flag alone is set, the NIC should parse the received data to identify an IPv4 packet that contains a UDP datagram.

The NIC must identify and skip over any IP options that are present. If the NIC cannot skip over any IP options, it should not calculate a hash value.

The NIC should compute the hash value over the following fields:

- Source-IPv4-Address
- Destination-IPv4-Address
- Source UDP Port
- Destination UDP Port

NDIS_HASH_TCP_IPV4 | NDIS_HASH_IPV4

If this flag combination is set, the NIC should perform the hash calculations as specified for the NDIS_HASH_TCP_IPV4 case. However, if the packet does not contain a TCP header, the NIC should compute the hash value as specified for the NDIS_HASH_IPV4 case.

NDIS_HASH_UDP_IPV4 | NDIS_HASH_IPV4

If this flag combination is set, the NIC should perform the hash calculations as specified for the NDIS_HASH_UDP_IPV4 case. However, if the packet does not contain a UDP header, the NIC should compute the hash value as specified for the NDIS_HASH_IPV4 case.

NDIS_HASH_TCP_IPV4 | NDIS_HASH_UDP_IPV4 | NDIS_HASH_IPV4

If this flag combination is set, the NIC should perform the hash calculation as specified by the transport in the packet. However, if the packet does not contain a TCP or UDP header, the NIC should compute the hash value as specified for the NDIS_HASH_IPV4 case.

IPv6 hash type combinations

The valid hash type combinations in the IPv6 set are:

- NDIS_HASH_IPV6
- NDIS_HASH_TCP_IPV6
- NDIS_HASH_UDP_IPV6
- NDIS_HASH_TCP_IPV6 | NDIS_HASH_IPV6
- NDIS_HASH_UDP_IPV6 | NDIS_HASH_IPV6
- NDIS_HASH_TCP_IPV6 | NDIS_HASH_UDP_IPV6 | NDIS_HASH_IPV6

NDIS_HASH_IPV6

If this flag alone is set, the NIC should compute the hash over the following fields:

- Source-IPv6-Address
- Destination-IPv6-Address

NDIS_HASH_TCP_IPV6

If this flag alone is set, the NIC should parse the received data to identify an IPv6 packet that contains a TCP segment. The NIC must identify and skip over any IPv6 extension headers that are present in the packet. If the NIC cannot skip over any IPv6 extension headers, it should not calculate a hash value.

The NIC should compute the hash value over the following fields:

- Source-IPv6 -Address
- Destination-IPv6 -Address
- Source TCP Port
- Destination TCP Port

NDIS_HASH_UDP_IPV6

If this flag alone is set, the NIC should parse the received data to identify an IPv6 packet that contains a UDP datagram. The NIC must identify and skip over any IPv6 extension headers that are present in the packet. If the NIC cannot skip over any IPv6 extension headers, it should not calculate a hash value.

The NIC should compute the hash value over the following fields:

- Source-IPv6-Address

- Destination-IPv6-Address
- Source UDP Port
- Destination UDP Port

NDIS_HASH_TCP_IPV6 | NDIS_HASH_IPV6

If this flag combination is set, the NIC should perform the hash calculations as specified for the NDIS_HASH_TCP_IPV6 case. However, if the packet does not contain a TCP header, the NIC should compute the hash as specified for the NDIS_HASH_IPV6 case.

For example, if the packet is fragmented, then it may not contain the TCP header. In that case, the NIC should compute the hash only over the IP header.

NDIS_HASH_UDP_IPV6 | NDIS_HASH_IPV6

If this flag combination is set, the NIC should perform the hash calculations as specified for the NDIS_HASH_UDP_IPV6 case. However, if the packet does not contain a UDP header, the NIC should compute the hash as specified for the NDIS_HASH_IPV6 case.

For example, if the packet is fragmented, then it may not contain the UDP header. In that case, the NIC should compute the hash only over the IP header.

NDIS_HASH_TCP_IPV6 | NDIS_HASH_UDP_IPV6 | NDIS_HASH_IPV6

If this flag combination is set, the NIC should perform the hash calculation as specified by the transport in the packet. However, if the packet does not contain a TCP or UDP header, the NIC should compute the hash value as specified in the NDIS_HASH_IPV6 case.

For example, if the packet is fragmented, then it may not contain the TCP or UDP header. In that case, the NIC should compute the hash only over the IP header.

IPv6 with extension headers hash type combinations

The valid combinations in the IPv6 with extension headers set are:

- NDIS_HASH_IPV6_EX
- NDIS_HASH_TCP_IPV6_EX
- NDIS_HASH_UDP_IPV6_EX

- NDIS_HASH_TCP_IPV6_EX | NDIS_HASH_IPV6_EX
- NDIS_HASH_UDP_IPV6_EX | NDIS_HASH_IPV6_EX
- NDIS_HASH_TCP_IPV6_EX | NDIS_HASH_UDP_IPV6_EX | NDIS_HASH_IPV6_EX

NDIS_HASH_IPV6_EX

If this flag alone is set, the NIC should compute the hash over the following fields:

- Home address from the home address option in the IPv6 destination options header. If the extension header is not present, use the Source IPv6 Address.
- IPv6 address that is contained in the Routing-Header-Type-2 from the associated extension header. If the extension header is not present, use the Destination IPv6 Address.

NDIS_HASH_TCP_IPV6_EX

If this flag alone is set, the NIC should compute the hash over the following fields:

- Home address from the home address option in the IPv6 destination options header. If the extension header is not present, use the Source IPv6 Address.
- IPv6 address that is contained in the Routing-Header-Type-2 from the associated extension header. If the extension header is not present, use the Destination IPv6 Address.
- Source TCP Port
- Destination TCP Port

NDIS_HASH_UDP_IPV6_EX

If this flag alone is set, the NIC should compute the hash over the following fields:

- Home address from the home address option in the IPv6 destination options header. If the extension header is not present, use the Source IPv6 Address.
- IPv6 address that is contained in the Routing-Header-Type-2 from the associated extension header. If the extension header is not present, use the Destination IPv6 Address.
- Source UDP Port
- Destination UDP Port

NDIS_HASH_TCP_IPV6_EX | NDIS_HASH_IPV6_EX

If this flag combination is set, the NIC should perform the hash calculations as specified for the NDIS_HASH_TCP_IPV6_EX case. However, if the packet does not contain a TCP header, the NIC should compute the hash as specified for the NDIS_HASH_IPV6_EX case.

NDIS_HASH_UDP_IPV6_EX | NDIS_HASH_IPV6_EX

If this flag combination is set, the NIC should perform the hash calculations as specified for the NDIS_HASH_UDP_IPV6_EX case. However, if the packet does not contain a UDP header, the NIC should compute the hash as specified for the NDIS_HASH_IPV6_EX case.

NDIS_HASH_TCP_IPV6_EX | NDIS_HASH_UDP_IPV6_EX | NDIS_HASH_IPV6_EX

If this flag combination is set, the NIC should perform the hash calculations as specified by the packet transport. However, if the packet does not contain a TCP or UDP header, the NIC should compute the hash as specified for the NDIS_HASH_IPV6_EX case.

> ⓘ **Note**
>
> If a miniport driver reports NDIS_RSS_CAPS_HASH_TYPE_TCP_IPV6_EX and/or NDIS_RSS_CAPS_HASH_TYPE_UDP_IPV6_EX capability for a NIC, the NIC must calculate hash values (over fields in the IPv6 extension headers) in accordance with the IPv6 extension hash types that the protocol driver set. The NIC can store either the extension hash type or the regular hash type in the NET_BUFFER_LIST structure of the IPv6 packet for which a hash value is computed.

A miniport driver sets the hash type in a **NET_BUFFER_LIST** structure before indicating the received data. For more information, see Indicating RSS Receive Data.

RSS Hashing Functions

Article • 12/15/2021

Overview

A NIC or its miniport driver uses the RSS hashing function to calculate an RSS hash value.

Overlying drivers set the hash type, function, and table to assign connections to CPUs. For more information, see RSS Configuration.

The hashing function can be one of the following:

- **NdisHashFunctionToeplitz**
- **NdisHashFunctionReserved1**
- **NdisHashFunctionReserved2**
- **NdisHashFunctionReserved3**

> ⓘ Note
>
> Currently, **NdisHashFunctionToeplitz** is the only hashing function available to miniport drivers. The other hashing functions are reserved for NDIS.

A miniport driver should identify the hashing function and value that it uses in each **NET_BUFFER_LIST** structure before the driver indicates received data. For more information, see Indicating RSS Receive Data.

Examples

The following four pseudocode examples show how to calculate the **NdisHashFunctionToeplitz** hash value. These examples represent the four possible hash types that are available for **NdisHashFunctionToeplitz**. For more information about hash types, see RSS Hashing Types.

To simplify the examples, a generalized algorithm that processes an input byte stream is required. Specific formats for the byte streams are defined later in the four examples.

The overlying driver provides a secret key (K) to the miniport driver for use in the hash calculation. The key is 40 bytes (320 bits) long. For more information about the key, see RSS Configuration.

Given an input array that contains *n* bytes, the byte stream is defined as follows:

C++

```
input[0] input[1] input[2] ... input[n-1]
```

The left-most byte is input[0], and the most-significant bit of input[0] is the left-most bit. The right-most byte is input[n-1], and the least-significant bit of input[n-1] is the right-most bit.

Given the preceding definitions, the pseudocode for processing a general input byte stream is defined as follows:

C++

```
ComputeHash(input[], n)

result = 0
For each bit b in input[] from left to right
{
if (b == 1) result ^= (left-most 32 bits of K)
shift K left 1 bit position
}

return result
```

The pseudocode contains entries of the form @n-m. These entries identify the byte range of each element in the TCP packet.

Example Hash Calculation for IPv4 with the TCP Header

Concatenate the SourceAddress, DestinationAddress, SourcePort, and DestinationPort fields of the packet into a byte array, preserving the order in which they occurred in the packet:

C++

```
Input[12] = @12-15, @16-19, @20-21, @22-23
Result = ComputeHash(Input, 12)
```

Example Hash Calculation for IPv4 Only

Concatenate the SourceAddress and DestinationAddress fields of the packet into a byte array.

```c++
Input[8] = @12-15, @16-19
Result = ComputeHash(Input, 8)
```

Example Hash Calculation for IPv6 with the TCP Header

Concatenate the SourceAddress, DestinationAddress, SourcePort, and DestinationPort fields of the packet into a byte array, preserving the order in which they occurred in the packet.

```c++
Input[36] = @8-23, @24-39, @40-41, @42-43
Result = ComputeHash(Input, 36)
```

Example Hash Calculation for IPv6 Only

Concatenate the SourceAddress and DestinationAddress fields of the packet into a byte array.

```c++
Input[32] = @8-23, @24-39
Result = ComputeHash(Input, 32)
```

Verifying the RSS Hash Calculation

Article • 12/15/2021

You should verify your implementation of the RSS hash calculation. To verify your calculations for the **NdisHashFunctionToeplitz** hash function, use the following secret key data:

```syntax
0x6d, 0x5a, 0x56, 0xda, 0x25, 0x5b, 0x0e, 0xc2,
0x41, 0x67, 0x25, 0x3d, 0x43, 0xa3, 0x8f, 0xb0,
0xd0, 0xca, 0x2b, 0xcb, 0xae, 0x7b, 0x30, 0xb4,
0x77, 0xcb, 0x2d, 0xa3, 0x80, 0x30, 0xf2, 0x0c,
0x6a, 0x42, 0xb7, 0x3b, 0xbe, 0xac, 0x01, 0xfa
```

The following table provides verification data for the IPv4 versions of the **NdisHashFunctionToeplitz** hash function. The destination and source columns contain the input data and the IPv4 columns contain the resulting hash value.

Destination Address :Port	Source Address :Port	IPv4 only	IPv4 with TCP
161.142.100.80 :1766	66.9.149.187 :2794	0x323e8fc2	0x51ccc178
65.69.140.83 :4739	199.92.111.2 :14230	0xd718262a	0xc626b0ea
12.22.207.184 :38024	24.19.198.95 :12898	0xd2d0a5de	0x5c2b394a
209.142.163.6 :2217	38.27.205.30 :48228	0x82989176	0xafc7327f
202.188.127.2 :1303	153.39.163.191 :44251	0x5d1809c5	0x10e828a2

The following table contains verification data for the IPv6 versions of the RSS hash algorithm. The destination and source columns contain the input data and the IPv6 columns contain the resulting hash value. Note that the IPv6 addresses are provided for verification of the algorithm only; they might not make sense as actual addresses.

Destination Address (Port)	Source Address (Port)	IPv6 only	IPv6 with TCP
3ffe:2501:200:3::1 (1766)	3ffe:2501:200:1fff::7 (2794)	0x2cc18cd5	0x40207d3d
ff02::1 (4739)	3ffe:501:8::260:97ff:fe40:efab (14230)	0x0f0c461c	0xdde51bbf

Destination Address (Port)	Source Address (Port)	IPv6 only	IPv6 with TCP
fe80::200:f8ff:fe21:67cf (38024)	3ffe:1900:4545:3:200:f8ff:fe21:67cf (44251)	0x4b61e985	0x02d1feef

RSS Configuration

Article • 09/27/2024

To obtain RSS configuration information, an overlying driver can send an OID query of OID_GEN_RECEIVE_SCALE_CAPABILITIES to a miniport driver. NDIS also provides the RSS configuration information to overlying protocol drivers in the **NDIS_BIND_PARAMETERS** structure during initialization.

The overlying driver chooses a hashing function, type, and indirection table. To set these configuration options, the driver sends an OID set request of OID_GEN_RECEIVE_SCALE_PARAMETERS to the miniport driver. Overlying drivers can also query this OID to obtain the current RSS settings. The information buffer for the OID_GEN_RECEIVE_SCALE_PARAMETERS OID contains a pointer to an **NDIS_RECEIVE_SCALE_PARAMETERS** structure.

The overlying driver can disable RSS on the NIC. In this case, the driver sets the NDIS_RSS_PARAM_FLAG_DISABLE_RSS flag in the **Flags** member of the NDIS_RECEIVE_SCALE_PARAMETERS structure. When this flag is set, the miniport driver should ignore all of the other flags and settings and disable RSS on the NIC.

NDIS processes OID_GEN_RECEIVE_SCALE_PARAMETERS before passing it to the miniport driver and updates the miniport adapter's *RSS standardized keyword, if required. For more information about the ***RSS** keyword, see Standardized INF Keywords for RSS.

After receiving an OID_GEN_RECEIVE_SCALE_PARAMETERS set request with the NDIS_RSS_PARAM_FLAG_DISABLE_RSS flag set, the miniport driver should set the RSS state of the NIC to the initial state of the NIC after initialization. Therefore, if the miniport driver receives a subsequent OID_GEN_RECEIVE_SCALE_PARAMETERS set request with the NDIS_RSS_PARAM_FLAG_DISABLE_RSS flag cleared, all of the parameters should have the same values that were set after the miniport driver received the OID_GEN_RECEIVE_SCALE_PARAMETERS set request for the first time after the miniport adapter was initialized.

An overlying driver can use the OID_GEN_RECEIVE_HASH OID to enable and configure hash calculations on received frames without enabling RSS. Overlying drivers can also query this OID to obtain the current receive hash settings.

The information buffer for the OID_GEN_RECEIVE_HASH OID contains a pointer to an **NDIS_RECEIVE_HASH_PARAMETERS** structure. For a set request, the OID specifies the hash parameters that the miniport adapter should use. For a query request, the OID returns the hash parameters that the miniport adapter is using. This OID is optional for drivers that support RSS.

Note If receive hash calculation is enabled, NDIS disables receive hash calculation before it enables RSS. If RSS is enabled, NDIS disables RSS before it enables receive hash calculation.

All of the miniport adapters that the miniport driver supports must provide the same hash configuration settings to all subsequent protocol bindings. This OID also includes the secret key that the miniport driver or NIC must use for hash calculations. The key is 320 bits long (40 bytes) and can contain any data that the overlying driver chooses, for example, a random stream of bytes.

To rebalance the processing load, the overlying driver can set the RSS parameters and modify the indirection table. Normally, all the parameters are unchanged except for the indirection table. However, after RSS is initialized, the overlying driver might change other RSS initialization parameters. If necessary, the miniport driver can reset the NIC hardware to change the hash function, hash secret key, hash type, base CPU number, or the number of bits that are used to index the indirection table.

Note The overlying driver can set these parameters at any time. This can cause out of order receive indications. Miniport drivers that support TCP are not required to purge their receive queues in this instance.

The following figure provides example contents for two instances of the indirection table.

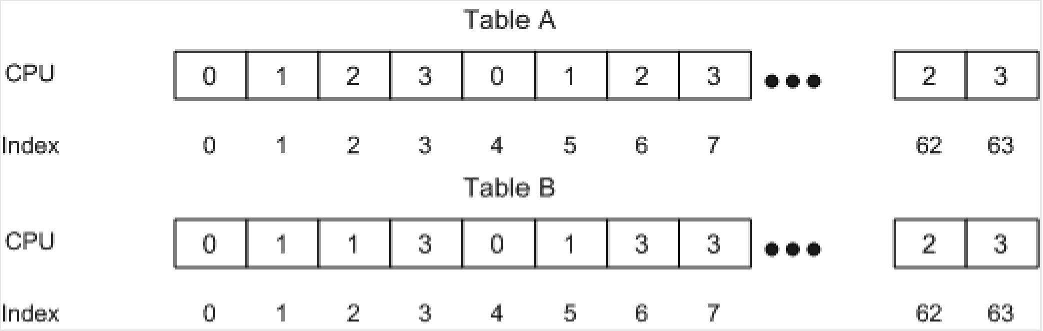


Table A

CPU	0	1	2	3	0	1	2	3	•••	2	3
Index	0	1	2	3	4	5	6	7		62	63

Table B

CPU	0	1	1	3	0	1	3	3	•••	2	3
Index	0	1	2	3	4	5	6	7		62	63

The preceding figure assumes a four processor configuration, and the number of least significant bits used from the hash value is 6 bits. Therefore, the indirection table contains 64 entries.

In the figure, table A lists the values in the indirection table immediately after initialization. Later, as normal traffic load varies, the processor load grows unbalanced. The overlying driver detects the unbalanced condition and attempts to rebalance the load by defining a new indirection table. Table B lists the new indirection table values. In the table B, some of the load from CPU 2 is moved to CPUs 1 and 3.

Note When the indirection table is changed, for a short time (while the current receive descriptor queues are being processed), packets can be processed on the wrong CPU. This is a normal transient condition.

The size of the indirection table is typically two to eight times the number of processors in the system.

When the miniport driver distributes packets to CPUs, if there are far too many CPUs, the effort spent in distributing the load could become prohibitive. In this case, overlying drivers should choose a subset of CPUs on which the processing of network data occurs.

In some cases, the number of available hardware receive queues might be less than the number of CPUs on the system. The miniport driver must examine the indirection table to determine the CPU numbers to associate with hardware queues. If the total number of different CPU numbers that appear in the indirection table is more than the number of hardware queues that the NIC supports, the miniport driver must pick a subset of the CPU numbers from the indirection table. The subset is equal in number to the number of hardware queues. The miniport driver obtained the **IndirectionTableSize** parameter from OID_GEN_RECEIVE_SCALE_PARAMETERS. The miniport driver specified the **NumberOfReceiveQueues** value in response to OID_GEN_RECEIVE_SCALE_CAPABILITIES.

Reserving Processors for Applications

Article • 09/27/2024

The receive side scaling (RSS) interface enables an administrator to reserve a set of processors for applications to use. The administrator can reserve a set of processors starting at logical CPU number 0 and ending at a specified CPU number. The RSS *base CPU number* is the CPU number of the first CPU that RSS can use. RSS cannot use the CPUs that are numbered below the base CPU number. For example, on a quad-core system with hyper-threading turned off, if base CPU number is set to 1, processors 1, 2, and 3 can be used for RSS.

NDIS uses the default value of 0 for base CPU number, but an administrator can change this value. The RSS interface does not permit the administrator to reserve a non-contiguous, arbitrary subset of CPUs for applications to use.

In Microsoft Windows Server 2003 with the Scalable Networking Pack, administrators can set the base CPU number with the **RssBaseCpu** registry keyword in **HKEY_LOCAL_MACHINE\\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters**. The **RssBaseCpu** value is a DWORD type and, if it is not present, NDIS uses the default value of 0.

In Windows Server 2008, administrators can set the base CPU number with the **RssBaseCpu** registry keyword in **HKEY_LOCAL_MACHINE\\SYSTEM\CurrentControlSet\Services\NDIS\Parameters**. The **RssBaseCpu** value is a DWORD type and, if it is not present, NDIS uses the default value of 0. This registry keyword also applies to later versions of Windows Server.

Note Starting in Windows 8 and Windows Server 2012, administrators can control many aspects of Network Adapters by using PowerShell cmdlets. Directly editing the registry is now discouraged.

The PowerShell cmdlet for reserving RSS CPUs is Set-NetAdapterRss. The primary difference between using **Set-NetAdapterRss** and using **RssBaseCpu** is that PowerShell cmdlets operate on a per-Network Adapter basis while **RssBaseCpu** is global, meaning it applies to all Network Adapters. Generally, working with each Network Adapter separately is recommended because it offers more flexibility, granularity, and understandability in giving each Network Adapter its own configuration. However, administrators might still use the global **RssBaseCpu** key if they would like to apply a configuration to all current and all future Network Adapters at the same time.

For a complete list of Network Adapter cmdlets, see Network Adapter Cmdlets in Windows PowerShell.

Setting the Number of RSS Processors

Article • 06/28/2024

Administrators should set the number of receive side scaling (RSS) processors to help the overall performance of a computer.

Concurrent deferred procedure calls (DPCs) that are running on multiple CPUs enable distributed receive processing and remove the CPU bottleneck (for example, in high-speed NICs). However, multiple DPCs do create additional overhead. The interrupt and DPC processing overhead increases as more processors are used for RSS. Therefore, when RSS is active, the total CPU utilization across all CPUs increases. An administrator should select the number of CPUs that are used for RSS to avoid a situation where using RSS leaves less processing power for applications to use and does not improve network throughput.

> ⓘ **Note**
>
> Starting in Windows 8 and Windows Server 2012, administrators can control many aspects of Network Adapters by using PowerShell cmdlets. Directly editing the registry is now discouraged.

The PowerShell cmdlet for setting the number of RSS CPUs is Set-NetAdapterRss.

The primary difference between using **Set-NetAdapterRss** and using the **MaxNumRssCpus** registry keyword is that PowerShell cmdlets operate on a per-Network Adapter basis while **MaxNumRssCpus** is global, meaning it applies to all Network Adapters. Generally, working with each Network Adapter separately is recommended because it offers more flexibility, granularity, and understandability in giving each Network Adapter its own configuration. However, administrators might still use the global **MaxNumRssCpus** key if they would like to apply a configuration to all current and all future Network Adapters at the same time.

For a complete list of Network Adapter cmdlets, see Network Adapter Cmdlets in Windows PowerShell.

In Microsoft Windows Server 2003 with the Scalable Networking Pack, administrators can set the maximum number of RSS CPUs with the **MaxNumRssCpus** registry keyword in **HKEY_LOCAL_MACHINE\\SYSTEM\CurrentControlSet\Services\Tcpip\Parameters**. The **MaxNumRssCpus** value is a DWORD type and, if it is not present, NDIS uses the default value of 4.

In Windows Server 2008, administrators can set the maximum number of RSS CPUs with the **MaxNumRssCpus** registry keyword in **HKEY_LOCAL_MACHINE\\SYSTEM\CurrentControlSet\Services\Ndis\Parameters**. The **MaxNumRssCpus** value is a DWORD type and, if it is not present, NDIS uses the default value of 4. This registry keyword also applies to later versions of Windows Server.

To avoid complicated cases (and unrealistic cases that are not implemented in actual hardware) where the number of available hardware receive queues is less than the number of RSS CPUs, administrators must not set the **MaxNumRssCpus** value to a value that is greater than 16.

The actual number of CPUs that are used for RSS is also limited by the total number of core processors that remain after the RSS base CPU number has been configured. For example, if the administrator sets the maximum number of RSS CPUs on a quad-core computer system to 6, the networking driver stack uses, at most, 4 CPUs for RSS. If the administrator also sets the RSS base CPU number to 1, the networking driver stack uses at most 3 CPUs (CPU numbers 1, 2, and 3).

The number of CPUs that the computer uses for RSS is static and does not change at run time. Therefore, any changes to the **MaxNumRssCpus** registry value require a restart to take effect.

Standardized INF Keywords for RSS

Article • 09/27/2024

The RSS interface supports standardized INF keywords that appear in the registry and are specified in INF files.

The following list shows the enumeration standardized INF keywords for RSS:

***RSS**
Enable or disable support for RSS for miniport adapters.

***RSSProfile**
The processor selection and load-balancing profile.

Note: Changes to the ***RSSProfile** setting require an adapter restart.

Note: If ***RSSProfile** is set to **NdisRssProfileBalanced**, you can't configure advanced keywords such as ***RssBaseProcNumber**, ***RssBaseProcGroup**, ***RssMaxProcNumber**, ***RssMaxProcGroup**, or ***NumaNodeId**. You can configure ***MaxRssProcessors** and ***NumRSSQueues**.

NDIS 6.30 added support for ***RSSProfile**.

Enumeration standardized INF keywords have the following attributes:

SubkeyName
The name of the keyword that you must specify in the INF file and that appears in the registry.

ParamDesc
The display text that is associated with SubkeyName.

Value
The enumeration integer value that is associated with each option in the list. This value is stored in NDI\params\ *SubkeyName\Value*. EnumDesc
The display text that is associated with each value that appears in the menu.

Default
The default value for the menu.

The following table describes the possible INF entries for the RSS enumeration keywords.

Expand table

SubkeyName	ParamDesc	Value	EnumDesc
*RSS	Receive Side Scaling	0	Disabled
		1 (Default)	Enabled
*RSSProfile	RSS load balancing	1	**ClosestProcessor**: Default behavior is consistent with that of Windows Server 2008 R2.

SubkeyName	ParamDesc	Value	EnumDesc
	profile		
		2	**ClosestProcessorStatic**: No dynamic load-balancing - Distribute but don't load-balance at runtime.
		3	**NUMAScaling**: Assign RSS CPUs in a round robin basis across every NUMA node to enable applications that are running on NUMA servers to scale well.
		4 (Default)	**NUMAScalingStatic**: RSS processor selection is the same as for NUMA scalability without dynamic load-balancing.
		5	**ConservativeScaling**: RSS uses as few processors as possible to sustain the load. This option helps reduce the number of interrupts.
		6 (Default on heterogeneous CPU systems)	**NdisRssProfileBalanced**: RSS processor selection is based on traffic workload. Only available in NetAdapterCx, starting in WDK preview version 25197.

The following list shows the standardized INF keywords for RSS that can be edited:

***RssBaseProcGroup**
The number of the processor group for the processor number that is specified in the ***RssBaseProcNumber** keyword.

***NumaNodeId**
The preferred NUMA node that is used for the memory allocations of the network adapter. Also, the operating system attempts to use the CPUs from the preferred NUMA node first for RSS.

A driver for a PCI expansion card should not specify the NUMA node ID statically in its INF, since the closest node depends on which PCI slot the card is plugged into. Only specify ***NumaNodeId** if the network adapter is integrated into the system, the NUMA node is known in advance, and the node cannot be determined at runtime by querying ACPI.

Note: If this keyword is present and its value is less than the number of NUMA nodes in the computer, NDIS uses this value in the **PreferredNumaNode** member in the **NDIS_RSS_PROCESSOR_INFO** structure.

Note: In Windows 8 the ***NumaNodeId** value is ignored if the NIC RSS profile is set to **NUMAScaling**(2) or **NUMAScalingStatic**(3).

***RssBaseProcNumber**
The number of the base RSS processor in the specified group.

***MaxRssProcessors**
The maximum number of RSS processors.

***RssMaxProcNumber**
The maximum processor number of the RSS interface. If ***RssMaxProcNumber** is specified, then ***RssMaxProcGroup** should also be specified.

***NumRSSQueues**
The number of RSS queues.

***RssMaxProcGroup** The maximum processor group of the RSS interface.

***RssBaseProcGroup** together with ***RssBaseProcNumber** form a PROCESSOR_NUMBER structure that identifies the smallest processor number that can be used with RSS. ***RssMaxProcGroup** together with ***RssMaxProcNumber** form a PROCESSOR_NUMBER structure that identifies the maximum processor number that can be used with RSS.

For example, suppose ***RssBaseProcGroup** is set to 1, ***RssBaseProcNumber** is set to 16, ***RssMaxProcGroup** is set to 3, and ***RssMaxProcNumber** is set to 8. Using `<group>:<processor>` notation, the base processor is 1:16 and the max processor is 3:8. Then processors 0:0, 0:32, 1:0, and 1:15 will not be considered candidates for RSS, because they are below the base processor number. Processors 1:16, 1:31, 2:0, 2:63, 3:0, and 3:8 will all be considered candidates for RSS, because they fall in the range 1:16 through 3:8. Processors 3:9, 3:31, and 4:0 will not be considered candidates for RSS, because they are beyond the maximum processor number.

NDIS 6.20 added support for the ***RssBaseProcGroup**, ***NumaNodeId**, ***RssBaseProcNumber**, and ***MaxRssProcessors** keywords.

NDIS 6.30 added support for the ***RssMaxProcNumber**, and ***NumRSSQueues** keywords.

Standardized INF keywords that can be edited have the following attributes:

SubkeyName
The name of the keyword that you must specify in the INF file and that appears in the registry.

ParamDesc
The display text that is associated with SubkeyName.

Type
The type of value that can be edited. The value can be either numeric (Int) or text that can be edited (Edit).

Default value
The default value for the integer or text. <IHV defined> indicates that the value is associated with the particular independent hardware vendor (IHV) requirements.

Min
The minimum value that is allowed for an integer. <IHV defined> indicates that the minimum value is associated with the particular IHV requirements.

Max
The maximum value that is allowed for an integer. <IHV defined> indicates that the minimum value is associated with the particular IHV requirements.

The following table describes all of the RSS keywords that can be edited.

Expand table

SubkeyName	ParamDesc	Type	Default value	Min	Max
***RssBaseProcGroup**	RSS Base Processor Group	Int	0	0	MAXIMUM_GROUPS-1
***NumaNodeId**	Preferred NUMA node	Int	65535 (Any node)	0	System specific - cannot exceed 65535
***RssBaseProcNumber**	RSS Base Processor Number	Int	0	0	MAXIMUM_PROC_PER_GROUP-1
***MaxRssProcessors**	Maximum number of RSS Processors	Int	16	1	MAXIMUM_PROC_PER_SYSTEM
***RssMaxProcNumber**	Maximum RSS Processor Number	Int	MAXIMUM_PROC_PER_GROUP-1 (Default)	0	MAXIMUM_PROC_PER_GROUP-1
***NumRSSQueues**	Maximum Number of RSS Queues	Int	16	1	Device-specific
***RSSMaxProcGroup**	RSS Max Processor Group	Int	0	0	MAXIMUM_GROUPS-1

Note: Although the valid range for ***RssBaseProcGroup** is zero to MAXIMUM_GROUPS-1, in Windows 7 it must be zero. Otherwise, the TCP/IP protocol will not use any processors for RSS.

Note: The default value for ***NumaNodeId** (65535) means the network adapter is agnostic to NUMA node, and NDIS should not attempt to prefer any node over another. If the ***NumaNodeId** keyword is not present, then NDIS automatically selects the closest node based on hints from ACPI.

Note: The max value for ***MaxRssProcessors** may be set to the maximum number of processors that the NIC can support. NDIS will automatically cap this value to be the maximum number of processors on the current system.

For more information about standardized INF keywords, see Standardized INF Keywords for Network Devices.

Feedback

Indicating RSS Receive Data

Article • 12/15/2021

A miniport driver indicates received data by calling the **NdisMIndicateReceiveNetBufferLists** function from its *MiniportInterruptDPC* function.

After the NIC computes the RSS hash value successfully, the driver should store the hash type, hashing function, and hash value in the **NET_BUFFER_LIST** structure with the following macros:

NET_BUFFER_LIST_SET_HASH_TYPE

NET_BUFFER_LIST_SET_HASH_FUNCTION

NET_BUFFER_LIST_SET_HASH_VALUE

The hash type identifies the area of the received packet that the hash should be calculated over. For more information about the hash type, see RSS Hashing Types. The hashing function identifies the function that is used to calculate the hash value. For more information about hashing functions, see RSS Hashing Functions. The protocol driver selects the hash type and function at initialization. For more information, see RSS Configuration.

If the NIC fails to identify the area of the packet that the hash type specifies, then it should not do any hash computation or scaling. In this case, the miniport driver or NIC should assign the received data to the default CPU.

If the NIC runs out of receive buffers, each buffer must be returned as soon as the original receive DPC returns. The miniport driver can indicate the received data with a status of NDIS_STATUS_RESOURCES. In this case, the overlying driver has to go through a slow path of copying the buffer descriptors and relinquishing ownership of the original one immediately.

For more information about receiving network data, see Receiving Network Data.

Supporting RSS in Intermediate Drivers or Filter Drivers

Article • 12/15/2021

All intermediate drivers and filter drivers should, at a minimum, pass on OID requests, other requests, and status indications. Intermediate drivers or filter drivers should provide additional driver-specific support for receive side scaling (RSS) if the driver does any of the following:

- Originates send requests.
- Originates receive indications.
- Queues send requests or receive indications for later processing.

Filter drivers that bypass send and receive processing do not have to do anything additional to support RSS. For more information about bypassing send or receive requests in a filter driver, see Data Bypass Mode.

A QoS scheduler is an example of a filter driver that should support RSS. Such a driver queues send packets for sending at an appropriate time. The filter driver should use the same CPU that the protocol driver uses for a given connection.

An intermediate driver or filter driver that does not support RSS can intercept the RSS OID requests and disable RSS by reporting that RSS is not supported.

A filter driver or intermediate driver that supports RSS can use the information from the RSS OIDs to assign connections to the same CPUs the protocol driver and miniport driver are using.

For more information about the RSS OIDs, see RSS Configuration.

Overview of Virtual Machine Multiple Queues (VMMQ)

Article • 03/14/2023

Virtual Machine Multiple Queues (VMMQ) is a NIC offload technology that extends Native RSS (RSSv1) to a Hyper-V virtual environment.

VMMQ provides scalable network traffic processing for virtual ports (VPorts) in the parent partition of a virtualized node. A VPort represents an internal port on the NIC switch of a network adapter that supports single root I/O virtualization (SR-IOV). For an overview of the SR-IOV interface and its components see SR-IOV Architecture. Previously, RSS processing was not available for VPorts. VMMQ extends the native RSS feature to VPorts that are associated with the physical function (PF) of a NIC, including the default VPort.

VMMQ works by efficiently distributing network traffic within the NIC hardware. You can assign multiple hardware queues from the NIC to a single PF VPort. The NIC distributes network traffic across these queues using RSS hashing, placing packets directly onto the assigned processor. Offloading traffic distribution to the NIC improves CPU performance because the software doesn't have to complete this task.

You may want to enable the VMMQ feature to reduce the host CPU consumption and enable higher throughput to the virtual system by spreading the CPU load across multiple processors. You can add VMMQ support to new or existing NDIS 6.60 and later drivers. If an adapter supports VMMQ, the driver is vendor-supplied, and the OS is Windows Server 2019, then VMMQ is enabled by default. If the adapter doesn’t support VMMQ, the driver is system-supplied, or the OS is Windows Server 2016, then VMMQ is disabled by default or not available. If the OS is earlier than Windows Server 2016 then VMMQ is not available.

VMMQ is available for the VPorts exposed in the parent partition regardless of whether the NIC is operating in SR-IOV or Virtual Machine Queue (VMQ) mode.

Expected feature interactions

- Network Virtualization using Generic Routing Encapsulation (NVGRE) and Virtual Extensive Local Area Network (VXLAN): The NIC will calculate the hash for spreading receive queues based on the inner headers of the packets.
- SR-IOV: The NIC can support VMMQ and SR-IOV simultaneously.

VMMQ send and receive processing

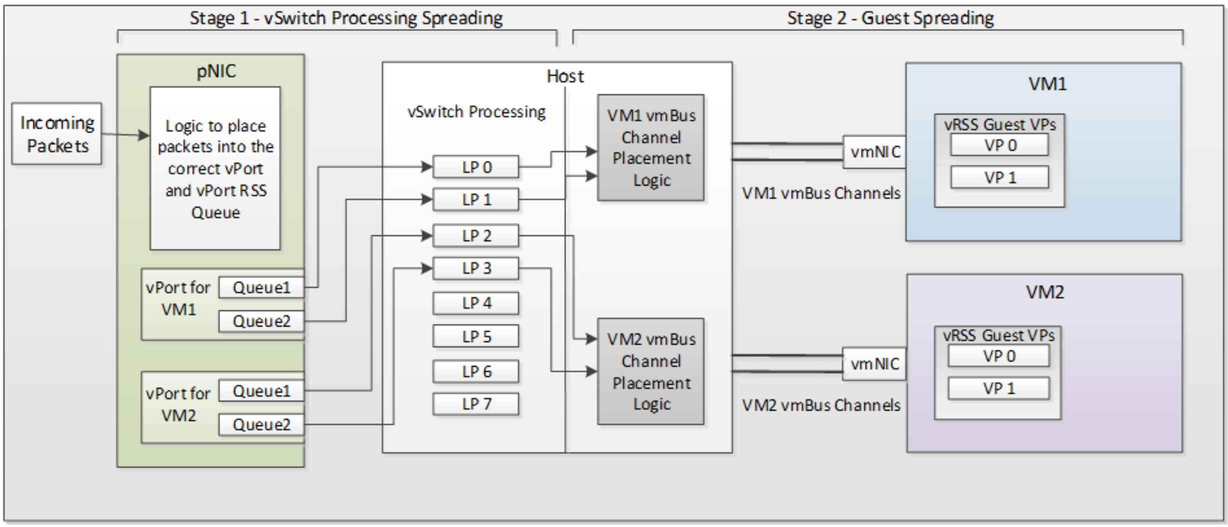
Article • 03/14/2023

Virtual Machine Multiple Queues (VMMQ) efficiently distributes the network traffic for physical function virtual ports (PF VPorts) using RSS processing. For more information on the single root I/O virtualization (SR-IOV) interface and its components, see SR-IOV Architecture.

The following figure shows the network packet receive path within the VMMQ interface.



On the receive path, when a packet arrives at a NIC that supports VMMQ the NIC:

1. Matches the destination MAC address to find the target VPort.

2. Uses the RSS parameters of the VPort (the secret key, hash function, and hash type) to calculate the RSS hash value of the packet.

3. Uses the hash value to index the indirection table associated with the VPort. The values in the indirection table are used to assign the received data to a processor.

4. Interrupts the target processor and the received packet is indicated to the host network stack.

When indicating a received NBL, the miniport adapter sets the VPort ID and RSS related out-of-band (OOB) fields to the appropriate values.

On the transmit path, the NIC must use the RSS hash value in the packet (if present) as an index into the RSS indirection table for the VPort. The NIC uses this indirection table value to determine the processor that handles the transmit complete interrupts and DPCs for the packet.

If the NIC cannot calculate the RSS hash value of a received packet or the RSS hash value is not present in a transmit packet, it should use the default RSS processor of the VPort as the target RSS processor. The default RSS processor for a VPort will be specified in the RSS parameters for the VPort. For more information, see Enabling, disabling, and updating VMMQ on a VPort.

The host networking stack can update the RSS parameters of a VPort dynamically at runtime. The NIC should respond to the changes in the RSS parameters of a VPort with minimal interruption in traffic to and from the VPort.

Advertising VMMQ capabilities

Article • 03/14/2023

Miniport drivers register the Virtual Machine Multiple Queues (VMMQ) capability of a NIC during miniport adapter initialization.

> ⓘ **Note**
>
> If the NIC supports VMMQ, the default VPort and at least one non-default VPort must support VMMQ.

During initialization, the miniport driver must examine the ***RssOnHostVPorts** INF keyword in order to determine if it should enable the VMMQ feature on the NIC. For more information on handling RSS keywords for VMMQ, see Standardized INF keywords for VMMQ.

Additionally, the stack can only activate VMMQ on the NIC if the miniport adapter supports creating a NIC switch. NDIS can create a NIC switch on the miniport adapter when either the ***SriovPreferred** INF keyword is set to **one** or ***SriovPreferred** is set to **zero** and ***RssOrVmqPreference** is set to **one**. For more information, see Standardized INF Keywords for SR-IOV and Standardized INF Keywords for VMQ.

When the miniport driver configures the parameters for the NIC switch, it must set the fields of the **NDIS_NIC_SWITCH_PARAMETERS** structure as follows:

1. Set the **Revision** member of **Header** to **NDIS_NIC_SWITCH_PARAMETERS_REVISION_2**.

2. Set **NumQueuePairsForDefaultVPort** to the number of queue pairs assigned to a default VPort.

Miniport drivers advertise the NIC's VMMQ capability through the **NDIS_NIC_SWITCH_CAPABILITIES** structure. The miniport driver must initialize **NDIS_NIC_SWITCH_CAPABILITIES** as follows:

1. Set the **Revision** member of **Header** to **NDIS_NIC_SWITCH_CAPABILITIES_REVISION_3**.

2. Set the **NicSwitchCapabilities** flags as follows:

    - Set NDIS_NIC_SWITCH_CAPS_SINGLE_VPORT_POOL to **one** to indicate that non-default VPorts can be created on the PF. This flag must be set.

- Set NDIS_NIC_SWITCH_CAPS_ASYMMETRIC_QUEUE_PAIRS_FOR_NONDEFAULT_VPORT_SUPPORTED to indicate that NDIS can allocate an arbitrary number of VMMQ queues on each VPort. Otherwise, all non-default VPorts have the same maximum number of VMMQ queues as the **MaxNumQueuePairsPerNonDefaultVPort** field defines.

- Set NDIS_NIC_SWITCH_CAPS_RSS_ON_PF_VPORTS_SUPPORTED to **one** to indicate that the NIC supports VMMQ for PF VPorts.

> ⓘ **Note**
>
> If any of the following four per PF VPort flags are not set, higher level drivers will use the values that are specified when the RSS parameters of the PF VPorts are set (including the default VPort). For more information see **Enabling, disabling, and updating VMMQ on a VPort**.

- Set NDIS_NIC_SWITCH_CAPS_RSS_PER_PF_VPORT_INDIRECTION_TABLE_SUPPORTED to **one** to indicate that the NIC is able to maintain per PF VPort indirection tables. This flag must be set.

> ⓘ **Note**
>
> The following three flags NDIS_NIC_SWITCH_CAPS_RSS_PER_PF_VPORT_HASH_FUNCTION_SUPPORTED, NDIS_NIC_SWITCH_CAPS_RSS_PER_PF_VPORT_HASH_TYPE_SUPPORTED, and NDIS_NIC_SWITCH_CAPS_RSS_PER_PF_VPORT_HASH_KEY_SUPPORTED must all be set to **zero** or all be set to **one**. If they're all set to **zero**, software will re-calculate the hash.

- Set NDIS_NIC_SWITCH_CAPS_RSS_PER_PF_VPORT_HASH_FUNCTION_SUPPORTED to **one** if the NIC supports setting a different hash function per PF VPort.

- Set NDIS_NIC_SWITCH_CAPS_RSS_PER_PF_VPORT_HASH_TYPE_SUPPORTED to **one** if the NIC supports setting a different hash type per PF VPort.

- Set NDIS_NIC_SWITCH_CAPS_RSS_PER_PF_VPORT_HASH_KEY_SUPPORTED to **one** if the NIC supports setting a different hash secret key per PF VPort.

- Set NDIS_NIC_SWITCH_CAPS_RSS_PER_PF_VPORT_INDIRECTION_TABLE_SIZE_RESTRICTED to **one** if the NIC has a limitation on indirection table size for PF VPorts. This flag forces the issuer of an RSS OID to use a per-PF VPort indirection table size equal to the number of VPort queues rounded up to the next power of two. This flag can be combined with the NDIS_NIC_SWITCH_CAPS_ASYMMETRIC_QUEUE_PAIRS_FOR_NONDEFAULT_VPORT_SUPPORTED flag (different PF VPorts can have different numbers of queues). This flag prevents VMMQ users from performing fine-grained queue steering.

3. Set **MaxNumVPorts** to specify the maximum number of VPorts.

4. Set **MaxNumQueuePairs** to specify the maximum number of queue pairs that can be assigned to all VPorts. This includes the default VPort that is attached to the PF. This number should reflect the actual hardware capabilities.

5. Set **MaxNumQueuePairsPerNonDefaultVPort** to specify the maximum number of queue pairs that can be assigned to a non-default VPort.

6. Set **MaxNumRssCapableNonDefaultPFVPorts** to specify the maximum number of non-default PF VPorts that can support VMMQ.

7. Set **NumberOfIndirectionTableEntriesForDefaultVPort** to specify the number of indirection table entries for the default VPort.

8. Set **NumberOfIndirectionTableEntriesPerNonDefaultPFVPort** to specify the number of indirection table entries for each non-default PF VPort. The size of indirection table should be the same for all non-default PF VPorts.

9. Set **MaxNumQueuePairsForDefaultVPort** to specify the maximum number of queue pairs that can be assigned to a default VPort during NIC Switch creation.

After the VMMQ capabilities are advertised, NDIS is responsible for handling the OID_GEN_RECEIVE_SCALE_CAPABILITIES OID when it is called on either the default VPort or a non-default VPort. When the miniport driver returns the RSS capabilities in the **NDIS_RECEIVE_SCALE_CAPABILITIES** structure, it should not constrain the **NumberOfInterruptMessages** fields by any of the standard RSS keywords (such as ***MaxRssProcessors**). The upper level driver will incorporate this number into the host CPU allocation algorithm.

Standardized INF keywords for VMMQ

Article • 05/29/2024

The ***RssOnHostVPorts** standardized INF keyword is defined to enable or disable support for the network adapter Virtual Machine Multiple Queues (VMMQ) feature.

The ***RssOnHostVPorts** INF keyword is an enumeration keyword. Enumeration standardized INF keywords have the following attributes:

SubkeyName: The name of the keyword that you must specify in the INF file.

ParamDesc: The display text that is associated with the SubkeyName.

Value: The enumeration integer value that is associated with each SubkeyName in the list.

EnumDesc: The display text that is associated with each value that appears in the menu.

Default: The default value for the menu.

The following table describes the possible INF entries for the ***RssOnHostVPorts** INF keyword.

Expand table

SubkeyName	ParamDesc	Value	EnumDesc
*RssOnHostVPorts	Virtual Switch RSS	0	Disabled
		1 (Default)	Enabled

During miniport adapter initialization, the miniport driver must examine the ***RssOnHostVPorts** keyword to determine if it should enable the VMMQ feature on the NIC.

Handling RSS INF keywords for VMMQ

If a NIC supports VMMQ, all Standardized INF Keywords for RSS should also be supported to provide future compatibility even if the OS does not currently use them all. You should use the keywords as normal for RSS functionality except for:

- ***RSSProfile**: The “ClosestProcessor” profile should be supported and used as a policy for VMMQ.

- ***MaxRssProcessors**: When VMMQ is active, this keyword should not restrict the number of MSIx interrupt messages reported in NDIS_RECEIVE_SCALE_CAPABILITIES.

Allocating VPorts for VMMQ

Article • 03/14/2023

NDIS allocates VPorts when the Virtual Machine Multiple Queues (VMMQ) capability is present in the following way.

NDIS creates a non-default VPort on the miniport adapter by issuing the OID_NIC_SWITCH_CREATE_VPORT OID request. When creating an RSS physical function (PF) VPort, NDIS will initialize the **NDIS_NIC_SWITCH_VPORT_PARAMETERS** structure as follows:

- NDIS sets the **AttachedFunctionId** field to **NDIS_PF_FUNCTION_ID**.
- If VMMQ is enabled, NDIS sets the **NumQueuePairs** field to the number of VMMQ queue pairs that should be used for this VPort. This number includes the default RSS processor for this VPort. It is guaranteed that total number of processors will not exceed this number. If VMMQ is disabled, NDIS sets this value to **one**.
- If VMMQ is enabled, the **ProcessorAffinity** field defines a bitmask of the potential RSS processors that the miniport adapter must use for this VPort. The processors that the network stack used to populate the indirection table entries for the VPort are a subset of the processors that this bitmask identifies. The mask will be a subset of the RSS processors returned from the call to **NdisGetRssProcessorInformation** and the number of set bits might exceed the number of RSS queues requested for the VPort. If VMMQ is disabled, the miniport adapter must use the lowest processor number specified in this bitmask when setting the affinity of the VPort queue.
- NDIS sets the NDIS_NIC_SWITCH_VPORT_PARAMS_NUM_QUEUE_PAIRS_CHANGED flag to indicate that the **NumQueuePairs** member has been updated after the VPort has been created. When VMMQ is enabled, the number of queues for default and non-default VPorts can be updated.

Enabling, disabling, and updating VMMQ on a VPort

Article • 03/14/2023

After creating a VPort, an upper layer driver can enable, disable, or update the RSS parameters of the VPort.

The driver can update the RSS indirection table of the VPort in order to change the number queues for a VPort. However the RSS hash type, hash function, and hash secret key of a VPort are considered static parameters and are not changed by the overlying drivers during the lifetime of a VPort. If an upper layer driver wishes to change any of the RSS static parameters, it must delete and recreate the VPort.

The upper layer driver enables, disables, or changes the RSS parameters of a VPort by issuing an OID_GEN_RECEIVE_SCALE_PARAMETERS OID request. The upper layer driver sets the **VPortId** field in the **NDIS_OID_REQUEST** structure to the ID of the target VPort of the new configuration.

The upper layer driver also sets the **NDIS_RECEIVE_SCALE_PARAMETERS** structure used in the OID request as follows. Please note that based on the VMMQ capabilities advertised by the underlying miniport adapter, some of the fields may be set to the same value for all PF VPorts.

- Set the **Revision** member of **Header** to **NDIS_RECEIVE_SCALE_PARAMETERS_REVISION_3**.
- Set the NDIS_RSS_PARAM_FLAG_DEFAULT_PROCESSOR_UNCHANGED flag to specify that the **DefaultProcessorNumber** member has not changed.
- Set **BaseCpuNumber** to **zero**.
- Set **DefaultProcessorNumber** to specify the default RSS processor for this VPort. The miniport can assume that default processor is part of RSS processor list, but it cannot assume that the default RSS processor is in the current indirection table.
- Set **HashInformation** to indicate the hash type and hash function that the NIC should use to calculate the hash value of the packets received for this VPort. The upper layer driver may set this field to a different value for each VPort.
- Set **IndirectionTableSize** to specify the size of the indirection table in bytes. Set this field to the same value for all PF VPorts. The upper layer driver must ensure that the number of entries in the indirection table is a power of two.

- Set **IndirectionTableOffset** to specify the offset of the indirection table from the beginning of the NDIS_RECEIVE_SCALE_PARAMETERS structure.

- Set **HashSecretKeySize** to specify the size of the hash secret key in bytes. The upper layer driver may set a different secret key for each VPort if the miniport adapter supports this. For more information, see Advertising VMMQ capabilities.

- Set **HashSecretKeyOffset** to specify the offset of the hash secret key from the beginning of the NDIS_RECEIVE_SCALE_PARAMETERS structure. The upper layer driver may set a different secret key for each VPort if the miniport adapter supports this. For more information, see Advertising VMMQ capabilities.

- Set **ProcessorMaskOffset**, **NumberOfProcessorMasks**, and **ProcessorMasksEntrySize** appropriately.

When a miniport driver receives an OID request to disable VMMQ for a VPort, it should revert to indicating all packets received for that VPort on the processor specified by the **ProcessorAffinity** field in the NDIS_NIC_SWITCH_VPORT_PARAMETERS structure that was used in the OID_NIC_SWITCH_CREATE_VPORT OID request.

Changing the number of queues for a VPort

The number of unique processors used in the indirection table of a VPort cannot exceed the value of the **NumQueuePairs** field of the NDIS_NIC_SWITCH_VPORT_PARAMETERS structure specified in the last issued OID_NIC_SWITCH_CREATE_VPORT OID request. These processors will be a subset of the RSS processor set returned by a call to NdisGetRssProcessorInformation. For more information, see Allocating VPorts for VMMQ. However, the indirection tables on different VPorts could contain the same processor.

To decrease the number of queues for a PF VPort an upper layer driver must:

1. Send an OID_GEN_RECEIVE_SCALE_PARAMETERS OID with the original indirection table size. However, the indirection table at this step can only reference the number of distinct processors up to the new number of queues. If the new indirection table needs to be smaller than the original table due to the NDIS_NIC_SWITCH_CAPS_RSS_PER_PF_VPORT_INDIRECTION_TABLE_SIZE_RESTRICTED flag of the NDIS_NIC_SWITCH_PARAMETERS structure, the issuer must guarantee that the indirection table at this step will contain the new indirection table replicated as many times as needed to satisfy the RESTRICTED flag requirement for the original number of queues.

2. Send an OID_NIC_SWITCH_VPORT_PARAMETERS OID with new number of queues.

3. Send an OID_GEN_RECEIVE_SCALE_PARAMETERS with the new indirection table size if it has changed.

To increase the number of queues for a PF VPort an upper layer driver must:

1. The driver doesn't need to update the current indirection table before step 2 because the table only references the number of distinct processors up to the current number of queues.

2. Send an OID_NIC_SWITCH_VPORT_PARAMETERS OID with new number of queues. If the RESTRICTED flag is set, the miniport driver should internally replicate the original indirection table as many times as needed to match the indirection table size requirement for the new number of queues.

3. Send an OID_GEN_RECEIVE_SCALE_PARAMETERS OID with new indirection table size if it has changed.

TCP/IP Offload Overview

Article • 12/15/2021

To increase its performance, the Microsoft TCP/IP transport can offload tasks or connections to a NIC that has the appropriate TCP/IP-offload capabilities.

Beginning with Windows Vista, the Windows operating system supports the following TCP/IP offload services:

- Checksum tasks
- Applications Internet protocol security (IPsec) offload version 1
- IPsec offload version 2
  - [The IPsec Task Offload feature is deprecated and should not be used.]
- Large send offload version 1
- Large send offload version 2
- Connection offload

Starting in Windows 10, version 2004, Windows also supports UDP Segmentation Offload (USO).

The TCP/IP transport that is provided beginning with Windows Vista supports TCP/IP offload services for both IPv4 and IPv6 packets.

NDIS 6.0 and later miniport drivers support TCP/IP offload services in a multiple-protocol driver environment. Multiple NDIS 6.0 and later protocol drivers that are bound to a TCP/IP offload-capable miniport adapter can configure TCP/IP offload services.

This section includes:

- Using the TCP/IP Offload Administrator Interface
- Security Guidelines for Offload-Capable Miniport Drivers
- TCP/IP Task Offload
- Connection Offload

Accessing TCP/IP Offload NET_BUFFER_LIST Information

Article • 12/15/2021

NDIS versions 6.0 and later provide TCP/IP offload out-of-band (OOB) data in the **NetBufferListInfo** member of the NET_BUFFER_LIST structure, which specifies a linked list of NET_BUFFER structures. The **NetBufferListInfo** member is an array of values that contain information that is common to all of the NET_BUFFER structures in the list.

Use the following identifiers with the NET_BUFFER_LIST_INFO macro to set and get the TCP/IP offload OOB data in the **NetBufferListInfo** array:

TcpIpChecksumNetBufferListInfo
Specifies checksum information that is used in offloading checksum tasks from the TCP/IP protocol to a miniport driver. When you specify **TcpIpChecksumNetBufferListInfo**, NET_BUFFER_LIST_INFO returns an NDIS_TCP_IP_CHECKSUM_NET_BUFFER_LIST_INFO structure (not a pointer to the structure). This structure contains a union that enables the checksum information to be accessed as a single PVOID value or as bit fields.

IPsecOffloadV1NetBufferListInfo
Specifies Internet protocol security (IPsec) offload information that is used in offloading IPsec tasks from the TCP/IP protocol to a miniport driver. When you specify **IPsecOffloadV1NetBufferListInfo**, NET_BUFFER_LIST_INFO returns an NDIS_IPSEC_OFFLOAD_V1_NET_BUFFER_LIST_INFO structure.

TcpLargeSendNetBufferListInfo
Specifies information that is used in offloading the segmentation of a large TCP packet from the TCP/IP protocol to a miniport driver. When you specify **TcpLargeSendNetBufferListInfo**, NET_BUFFER_LIST_INFO returns an NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO structure (not a pointer to the structure). This structure contains a union that enables the information to be accessed as a single PVOID value or as bit fields.

Ieee8021QNetBufferListInfo
Specifies 802.1Q information about a packet. When you specify **Ieee8021QNetBufferListInfo**, NET_BUFFER_LIST_INFO returns the **Value** member of an NDIS_NET_BUFFER_LIST_8021Q_INFO structure. This structure can specify 802.1p priority and virtual LAN (VLAN) identifier information. 802.1p priority information is used to establish packet priority in shared-media 802 networks.

If a miniport driver reports support for the NDIS_ENCAPSULATION_IEEE_802_3_P_AND_Q_IN_OOB encapsulation, it must insert the **Ieee8021QNetBufferListInfo** data into large send offload version 1 (LSOV1) and large send offload version 2 (LSOV2) Ethernet packets.

TcpOffloadBytesTransferred
Specifies the number of data bytes that were transferred in a TCP chimney offload send, receive, or disconnect operation.

TcpReceiveNoPush
Specifies a Boolean value that represents the push mode of a TCP chimney offload receive request. If **TRUE**, the receive request is in non-push mode. Otherwise, the receive request is in push mode.

For LSOV1, LSOV2, checksum, and IPsec offload types, a miniport driver performs task offload based on the type of OOB data and the offload capabilities that it reported. For example, if a protocol driver requires LSOV1 services for an IPv4 packet, each send request that the protocol driver provides includes the information from the **LsoV1Transmit** member in the NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO OOB data. Note that the protocol driver must verify that the miniport driver supports IPv4, with the specified encapsulation type, before making the send request.

The NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO structure contains the maximum segment size (MSS). The **TcpHeaderOffset** member specifies the location of the TCP header so that the miniport driver does not have to parse IP headers, IP options, or IP extension headers.

An NDIS 6.0 and later miniport driver that supports LSOV2 and LSOV1 must check the **Type** member of NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO to determine whether the driver stack is using LSOV2 or LSOV1 and must perform the appropriate offload.

For LSOv1, before a miniport driver completes the send of a large TCP packet that it has segmented into smaller packets by using LSO, the driver writes the number of TCP payload bytes that it sent in the segmented packets in the **TcpPayload** member of NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO.

If a miniport driver specifies the NDIS_ENCAPSULATION_IEEE_802_3_P_AND_Q flag in its capabilities, the driver can perform task offload services for NET_BUFFER_LIST structures that contain the VLAN header in the buffer data. In the case of received data, this flag indicates that the miniport driver will perform the receive checksum calculation and put the VLAN header in the Ethernet packet.

If a miniport driver specifies the NDIS_ENCAPSULATION_IEEE_802_3_P_AND_Q_IN_OOB flag in its capabilities, the driver can perform offload on NET_BUFFER_LIST structures that contain the VLAN header in the **Ieee8021QnetBufferListInfo** OOB data. In the receive checksum offload case, the miniport inserts the VLAN header into the **Ieee8021QnetBufferListInfo** OOB data.

Using the TCP/IP Offload Administrator Interface

Article • 12/15/2021

In NDIS 6.0 and later versions, user-mode applications (or overlying drivers) can enable or disable TCP/IP offload capabilities. A system administrator can access the settings through the Microsoft Windows Management Instrumentation (WMI) interface. There might also be capabilities that are disabled through registry settings that can be enabled if they are supported in the hardware.

In response to an OID_TCP_OFFLOAD_PARAMETERS object identifier (OID) set request, a miniport driver uses the settings in the **NDIS_OFFLOAD_PARAMETERS** structure to set the current offload or connection offload configuration of the miniport adapter.

NDIS retains the requested settings in the registry in the offload standardized keywords. When NDIS restarts the miniport adapter, the miniport driver reads the offload standardized keywords and uses them to set the default offload configuration of the NIC. If the miniport driver also supports non-standard keywords, the miniport driver is responsible for updating the registry when it changes the task offload settings. For more information about the standardized keywords, see Standardized INF Keywords for Network Devices.

The miniport drivers must use the contents of the **NDIS_OFFLOAD_PARAMETERS** structure to update the currently reported offload configuration. The miniport driver must report the current configuration with the task offload **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** or connection offload NDIS_STATUS_OFFLOAD_RESUME status indication. (For information on NDIS_STATUS_OFFLOAD_RESUME, see NDIS 6.0 TCP chimney offload documentation.) The status indication ensures that all of the overlying protocol drivers are updated with the new capabilities information.

Before user-mode applications (or overlying drivers) set OID_TCP_OFFLOAD_PARAMETERS they can use the OID_TCP_OFFLOAD_HARDWARE_CAPABILITIES OID or OID_TCP_CONNECTION_OFFLOAD_HARDWARE_CAPABILITIES OID to determine what capabilities a miniport adapter's hardware can support. Use the OID_TCP_OFFLOAD_PARAMETERS OID to enable capabilities that the OID_TCP_OFFLOAD_CURRENT_CONFIG OID or OID_TCP_CONNECTION_OFFLOAD_CURRENT_CONFIG OID reports as not currently enabled.

If the hardware capabilities change (for example, because a MUX intermediate driver switches to a difference underlying miniport adapter), the intermediate driver must report any changes in offload hardware capabilities with the **NDIS_STATUS_TASK_OFFLOAD_HARDWARE_CAPABILITIES** or **NDIS_STATUS_TCP_CONNECTION_OFFLOAD_HARDWARE_CAPABILITIES** status indication.

NDIS and overlying drivers can use the OID_OFFLOAD_ENCAPSULATION OID to set or query the task offload encapsulation settings of an underlying miniport adapter. The **InformationBuffer** member of the **NDIS_OID_REQUEST** structure contains an **NDIS_OFFLOAD_ENCAPSULATION** structure.

Security Guidelines for Offload-Capable Miniport Drivers Overview

Article • 12/15/2021

To increase its performance, the Microsoft TCP/IP transport can offload tasks or connections to a network interface card (NIC) that has the appropriate TCP/IP-offload capabilities. Offloaded TCP/IP network communication tasks are handled in the NIC hardware. Miniport drivers advertise the various offload capabilities of the NIC hardware to the operating system and confugure the NIC hardware. The NIC hardware performs the advertised offload tasks on outgoing and incoming packets in the send and receive dispatch handlers. The hardware performs operations such as computing IP header checksum and so on.

To ensure a secure environment, the miniport driver should advertise only those offload capabilities that the NIC hardware can provide and no others. The miniport driver should configure the hardware to offload the advertised tasks on the packets that meet the advertised criteria. On the send path, the operating system does not require a driver to offload a task that the miniport driver did not advertise. On the receive path, the miniport driver and NIC should not perform any tasks that are not included in the capabilities of the NIC hardware that the miniport driver advertised.

If a miniport driver or NIC cannot perform an offload task on a received packet, the miniport driver should indicate such a packet up the driver stack without taking any action. In this case, the overlying drivers handle the packet as a normal packet.

The miniport driver should never advertise capabilities that the NIC hardware does not support. The miniport driver should never use the send or receive dispatch handlers to perform software emulation of the offload operations that the hardware cannot provide. If the miniport driver provides such software emulation, the driver must inspect the packet data in software. If the driver inspects the packet data in software, the computer might be exposed to security attacks.

The following topics provide more information about security attacks and how to avoid security problems in NDIS drivers:

Vulnerability to Security Attacks in NDIS Drivers

Performance Degradation and Denial of Service Attacks in NDIS Drivers

Added Costs for Testing Vulnerable NDIS Drivers

Security Checklist for NDIS Drivers

Vulnerability to Security Attacks in NDIS Drivers

Article • 03/14/2023

If an NDIS driver parses and interprets packet data, the driver and the operating system might be vulnerable to security attacks. Some of these attacks could be started remotely and cause serious problems, including crashing the computer.

For example, consider a network interface card (NIC) that can support IPv4 checksum offload but cannot support IPv6 checksum offload. However, the miniport driver advertises that the NIC can provide IPv6 checksum offload. When the NIC receives IPv4 packets, the NIC hardware computes and verifies the checksum and puts the results in the **NET_BUFFER_LIST** structure out-of-band (OOB) information. If the NIC receives an IPv6 packet with IPv6 extension, the miniport driver computes and verifies the checksum in the receive interrupt handler. In the IPv6 case, it appears to the operating system that the NIC is performing IPv6 offload. However, the interrupt handler would have to parse the received packet and would have to check for error conditions and guard against bad information in the IP header fields in a manner at least as good as the hardware. Such a software implementation must be very robust or it could crash the computer.

Performance Degradation and Denial of Service Attacks in NDIS Drivers

Article • 03/14/2023

If an NDIS driver interrupt handler parses received packets, the interrupt handler implementation might lead to performance degradation and denial of service attacks. For example, a malicious user can target the computer by sending many packets so that the miniport driver is busy computing the checksum on bad packets in the interrupt handler.

Even if you are careful in how your driver handles received packets, the driver would perform receive operations at dispatch IRQL. Instead, you should let the driver stack handle the received packets. In this case, the overlying driver stack might copy the packet and operate on it later at passive IRQL.

Added Costs for Testing Vulnerable NDIS Drivers

Article • 03/14/2023

We recommend that you remove any code that parses the packet payload, particularly in handling offload verification, from your driver's packet handling dispatch routines. To have confidence in such code, you would have to extensively test the drivers to make sure that all potential error conditions are handled safely and correctly. This kind of testing means increased testing costs.

Miniport drivers should avoid parsing the packet data. They should not try to handle offload operations that the hardware cannot handle. In the receive side of the system, be very careful about how your driver inspects packet payload information. The send side of the driver could also be potentially affected with routed/bridged system configurations.

Security Checklist for NDIS Drivers

Article • 03/14/2023

To make sure that your driver follows good security practices, do the following:

- If it is possible, avoid code that parses the packet payload information for any reason. We recommend that you remove any such code, particularly in handling offload verification, from your driver's packet handling dispatch routines.

- Check your driver's send and receive code paths and carefully verify any code that parses the packet payload information for any reason.

- Thoroughly review the driver code for security holes and test your driver before you release the driver. Make sure that you verify all error paths as well as the normal code paths.

- Run random packet generation tests to make sure that your drivers can resist bad packet information. In the future, such tests will be mandatory for device logo certification.

TCP/IP Task Offload Overview

Article • 09/27/2024

To increase its performance, the Microsoft TCP/IP transport can offload tasks to a network interface card (NIC) that has the appropriate task offload capabilities.

Beginning with Windows Vista, the Windows operating system supports the following task offload services:

Checksum tasks

The TCP/IP transport can offload the calculation and validation of IP and TCP checksums.

Large send offload version 1 (LSOV1)

The TCP/IP transport supports large send offload version 1 (LSOV1). With LSOV1, the TCP/IP transport can offload the segmentation of large (up to 64 KB including the IP header) TCP packets for IPv4.

Large send offload version 2 (LSOV2)

The large send offload version 2 (LSOV2) interface is an enhanced version of LSOV1. LSOV2 supports IPv6, IPv4, and segmentation for large TCP packets that are larger than 64K. For more information about offloading the segmentation of large packets, see Offloading the Segmentation of Large TCP Packets.

Beginning with Windows 8 and Windows Server 2012, the Windows operating system supports the following additional task overload services:

Receive Segment Coalescing (RSC)

Receive segment coalescing (RSC) enables network card miniport drivers to coalesce multiple TCP segments and indicate them as a single coalesced unit (SCU) to the operating system's networking subsystem.

Network Virtualization using Generic Routing Encapsulation (NVGRE) Task Offload

Network Virtualization using Generic Routing Encapsulation (NVGRE) Task Offload makes it possible to use Generic Routing Encapsulation (GRE)-encapsulated packets with:

- Large Send Offload (LSO)
- Receive Side Scaling (RSS)
- Virtual Machine Queue (VMQ)

UDP Segmentation Offload (USO)

Beginning with Windows 10, version 2004, Windows supports UDP Segmentation Offload (USO). USO enables network cards to offload the segmentation of UDP datagrams that are larger than the maximum transmission unit (MTU) size of the network medium.

This section includes:

- Determining Task Offload Capabilities
- Enabling and Disabling Task Offload Services
- Determining the Current Task Offload Settings
- Combining Types of Task Offloads
- Using Registry Values to Enable and Disable Task Offloading
- Offloading Checksum Tasks
- Offloading the Segmentation of Large TCP Packets

Determining Task Offload Capabilities

Article • 12/15/2021

NDIS supports task offload services that are enhanced forms of the NDIS 5.1 and earlier task offload services. For more information about how to determine connection offload capabilities, see Determining Connection Offload Capabilities.

NDIS provides the offload hardware capabilities and the current configuration of the underlying miniport adapter to protocol drivers in the **NDIS_BIND_PARAMETERS** structure. NDIS provides the task offload hardware capabilities and current configuration of the underlying miniport adapter to filter drivers in the **NDIS_FILTER_ATTACH_PARAMETERS** structure.

Administrative applications use object identifier (OID) queries to obtain task offload capabilities of a miniport adapter. However, overlying drivers should avoid using OID queries. Protocol drivers must handle changes in the task offload capabilities that underlying drivers report. Miniport drivers can report changes in task offload capabilities in status indications. For a list of status indications, see NDIS 6.0 TCP/IP Offload Status Indications.

Administrative applications (or overlying drivers) can determine the current task offload configuration of a network interface card (NIC) by querying the OID_TCP_OFFLOAD_CURRENT_CONFIG OID.

The **NDIS_OFFLOAD** structure that is associated with OID_TCP_OFFLOAD_CURRENT_CONFIG specifies the following:

- The header information, which includes the task offload version that the TCP/IP transport supports.
- The checksum offload information, in an **NDIS_TCP_IP_CHECKSUM_OFFLOAD** structure.
- The large send offload version 1 (LSOV1) information, in an **NDIS_TCP_LARGE_SEND_OFFLOAD_V1** structure.
- The Internet protocol security (IPsec) information, in an **NDIS_IPSEC_OFFLOAD_V1** structure.
- The large send offload version 2 (LSOV2) information, in an **NDIS_TCP_LARGE_SEND_OFFLOAD_V2** structure.

- The Internet protocol security (IPsecvOV) information in an **NDIS_IPSEC_OFFLOAD_V2** structure.

The following topics contain specific information for each type of offload service:

- Reporting a NIC's Checksum Capabilities
- Reporting a NIC's LSOV1 TCP-Packet-Segmentation Capabilities
- Reporting a NIC's LSOV2 TCP-Packet-Segmentation Capabilities
- Reporting a NIC's IPsec Capabilities
  - [The IPsec Task Offload feature is deprecated and should not be used.]

Reporting a NIC's Checksum Capabilities

Article • 12/15/2021

An NDIS miniport driver reports whether a NIC is currently configured to calculate and validate IP, TCP, and UDP checksums in an **NDIS_TCP_IP_CHECKSUM_OFFLOAD** structure. Miniport drivers must include the current checksum offload configuration in the **NDIS_MINIPORT_ADAPTER_OFFLOAD_ATTRIBUTES** structure. Miniport drivers call the **NdisMSetMiniportAttributes** function from the *MiniportInitializeEx* function and pass in the information in NDIS_MINIPORT_ADAPTER_OFFLOAD_ATTRIBUTES.

Miniport drivers must report changes in the current checksum offload configuration, if any, in the **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** status indication.

In response to a query of OID_TCP_OFFLOAD_CURRENT_CONFIG, NDIS includes the NDIS_TCP_IP_CHECKSUM_OFFLOAD structure in the **NDIS_OFFLOAD** structure that NDIS returns in the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure. NDIS uses the information that the miniport driver provided.

A miniport driver indicates the following checksum information for IPv4 and IPv6 send and receive packets:

- The types of checksums (IP, TCP, or UDP) that a NIC can calculate for send packets and can validate for receive packets.

- Encapsulation settings, in the **Encapsulation** member. For more information about this member, see the Remarks section in **NDIS_TCP_IP_CHECKSUM_OFFLOAD**.

- Whether the NIC can calculate or validate (or calculate and validate) checksums for a packet whose IP headers contain IPv4 options.

- Whether the NIC can calculate or validate (or calculate and validate) checksums for an IPv6 packet whose IP headers contain IPv6 extension headers.

- Whether the NIC can calculate or validate (or calculate and validate) checksums for a packet whose TCP header contain TCP options.

Determining Task Offload Capabilities

Reporting a NIC's LSOV1 TCP-Packet-Segmentation Capabilities

Article • 12/15/2021

An NDIS miniport driver specifies the current large send offload version 1 (LSOV1)-TCP-packet-segmentation configuration of a NIC in an **NDIS_TCP_LARGE_SEND_OFFLOAD_V1** structure.Miniport drivers must include the current LSOV1 offload configuration in the **NDIS_MINIPORT_ADAPTER_OFFLOAD_ATTRIBUTES** structure. Miniport drivers call the **NdisMSetMiniportAttributes** function from the *MiniportInitializeEx* function and pass in the information in NDIS_MINIPORT_ADAPTER_OFFLOAD_ATTRIBUTES.

Miniport drivers must report changes in the LSOV1 configuration, if any, in the **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** status indication.

In response to a query of OID_TCP_OFFLOAD_CURRENT_CONFIG, NDIS includes the NDIS_TCP_LARGE_SEND_OFFLOAD_V1 structure in the **NDIS_OFFLOAD** structure that NDIS returns in the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure. NDIS uses the information that the miniport driver provided.

NDIS supports large send offload version 2 (LSOV2), which is an enhanced version of LSO. For more information about LSOV2 capabilities, see Reporting a NIC's LSOV2 TCP-Packet-Segmentation Capabilities.

The miniport driver must specify the following information in the NDIS_TCP_LARGE_SEND_OFFLOAD_V1 structure:

- Encapsulation settings, in the **Encapsulation** member. For more information about this member, see the Remarks section in **NDIS_TCP_LARGE_SEND_OFFLOAD_V1**.

- The maximum bytes of user data that the TCP/IP transport can pass to the miniport driver in a large TCP packet, in the **MaxOffLoadSize** member. The maximum size cannot exceed 64K bytes.

- The minimum number of segments that a large TCP packet must be divisible by before the TCP/IP transport can offload it to a NIC for segmentation, in the **MinSegmentCount** member.

- Whether a NIC can segment a large TCP packet that contains TCP options.

- Whether a NIC can segment a large TCP packet that contains IPv4 options.

Related topics

Determining Task Offload Capabilities

Reporting a NIC's LSOV2 TCP-Packet-Segmentation Capabilities

Article • 12/15/2021

An NDIS miniport driver specifies the current large send offload version 2 (LSOV2) TCP-packet-segmentation configuration of a NIC in an **NDIS_TCP_LARGE_SEND_OFFLOAD_V2** structure.Miniport drivers must include the current LSOV2 configuration in the **NDIS_MINIPORT_ADAPTER_OFFLOAD_ATTRIBUTES** structure. Miniport drivers call the **NdisMSetMiniportAttributes** function from the *MiniportInitializeEx* function and pass in the information in NDIS_MINIPORT_ADAPTER_OFFLOAD_ATTRIBUTES.

Miniport drivers must report changes in the LSOV2 configuration, if any, in the **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** status indication.

In response to a query of OID_TCP_OFFLOAD_CURRENT_CONFIG, NDIS includes the NDIS_TCP_LARGE_SEND_OFFLOAD_V2 structure in the **NDIS_OFFLOAD** structure that NDIS returns in the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure. NDIS uses the information that the miniport driver provided.

We recommend that a miniport driver that supports LSOV2 hardware should also support LSOV1. This support will enable the TCP/IP transport to use LSOV1 if an NDIS 5.*x* intermediate driver is installed over a miniport adapter. For more information about LSOV1 capabilities, see Reporting a NIC's LSOV1 TCP-Packet-Segmentation Capabilities.

LSOV2 supports IPv4 and IPv6 packets. The miniport driver must specify the following information for both IPv4 and IPv6 in the **NDIS_TCP_LARGE_SEND_OFFLOAD_V2** structure:

- Encapsulation settings, in the **Encapsulation** member. For more information about this member, see the Remarks section in **NDIS_TCP_LARGE_SEND_OFFLOAD_V2**.

- The maximum bytes of user data that the TCP/IP transport can pass to the miniport driver in a large TCP packet, in the **MaxOffLoadSize** member.

- The minimum number of segments that a large TCP packet must be divisible by before the TCP/IP transport can offload it to a NIC for segmentation, in the **MinSegmentCount** member.

Determining Task Offload Capabilities

Reporting a NIC's IPsec Capabilities

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

An NDIS miniport driver specifies the current Internet protocol security (IPsec) offload configuration of a NIC in an **NDIS_IPSEC_OFFLOAD_V1** structure.Miniport drivers must include the current IPsec offload configuration in the **NDIS_MINIPORT_ADAPTER_OFFLOAD_ATTRIBUTES** structure. Miniport drivers call the **NdisMSetMiniportAttributes** function from the *MiniportInitializeEx* function and pass in the information in NDIS_MINIPORT_ADAPTER_OFFLOAD_ATTRIBUTES.

Miniport drivers must report changes in the IPsec offload capabilities, if any, in the **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** status indication.

In response to a query of OID_TCP_OFFLOAD_CURRENT_CONFIG, NDIS includes the NDIS_IPSEC_OFFLOAD_V1 structure in the **NDIS_OFFLOAD** structure that NDIS returns in the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure. NDIS uses the information that the miniport driver provided.

A miniport driver indicates the following information in the NDIS_IPSEC_OFFLOAD_V1 structure:

- Encapsulation settings, in the **Encapsulation** member. For more information about this member, see the Remarks section in **NDIS_IPSEC_OFFLOAD_V1**.

- Whether a NIC can perform combined IPsec operations on a packet--that is, whether the NIC can process a packet that contains both an authentication header (AH) and an encapsulating security payload (ESP) in a packet with the following format:

  [IP][AH][ESP][rest of packet]

- Whether a NIC can perform IP security processing on both the transport-mode portion and the tunnel-mode portion of send and receive packets. The transport-mode portion of a packet pertains to an end-to-end security association, and the tunnel-mode portion of a packet pertains to a tunnel security association.

- Whether a NIC can perform IP security operations on packets if the packet's IP headers contain IP options.

A miniport driver specifies the following capabilities of a NIC to calculate or validate (or calculate and validate) encrypted checksums for AH payloads and authentication information:

- The integrity algorithms (MD5 or SHA 1) that the NIC can use

- Whether the NIC can process AH security payloads for:
  - The transport-mode portion of a packet
  - The tunnel-mode portion of a packet
  - Send packets
  - Receive packets

A miniport driver specifies the following capabilities of a NIC to process ESP payloads:

- The confidentiality algorithms (DES, triple DES, or both) that the NIC can use

- Whether the NIC supports null encryption (that is, the ESP payload without encryption but with authentication hashes)

- Whether the NIC can do ESP processing for:
  - The transport-mode portion of a packet
  - The tunnel-mode portion of a packet
  - Send packets
  - Receive packets

Determining Task Offload Capabilities

Enabling and Disabling Task Offload Services

Article • 12/15/2021

A protocol driver can enable or disable task offload services for an underlying miniport adapter by issuing an OID_OFFLOAD_ENCAPSULATION OID set request. This OID request sets the required encapsulation type and tells the miniport driver to activate all of the available task offload services.

Before issuing the OID_OFFLOAD_ENCAPSULATION OID set request, the protocol driver should make sure that the underlying miniport adapter supports the required encapsulation type. There are two ways to do this:

- Check the **NDIS_BIND_PARAMETERS** structure that the protocol driver received in its *ProtocolBindAdapterEx* function.
- Issue an OID_TCP_OFFLOAD_CURRENT_CONFIG query request.

If the miniport driver supports any task offload type that supports the requested encapsulation type, the miniport driver must return NDIS_STATUS_SUCCESS in response to the OID_OFFLOAD_ENCAPSULATION set request. Otherwise, the miniport driver should return NDIS_STATUS_INVALID_PARAMETER.

Determining the Current Task Offload Settings

Article • 12/15/2021

A protocol driver can determine the current task offload encapsulation settings of an underlying miniport adapter by issuing an OID_OFFLOAD_ENCAPSULATION OID query request.

For more information about issuing an OID request, see Generating OID Requests from an NDIS Protocol Driver.

Combining Types of Task Offloads

Article • 12/15/2021

The following restrictions determine which combinations of NDIS 6.0 and later task offload services can be active on the system:

- A task offload-capable miniport adapter can support checksum offload alone.
- A large send offload version 1 (LSOV1)-capable network interface card (NIC) must support V4 TCP and IPv4 checksum transmit offload services. If an LSOV1-capable miniport adapter also supports Internet protocol security (IPsec) offload, NDIS will configure the adapter to offload either IPsec or LSOV1, but not both.
- A large send offload version 2 (LSOV2)-capable miniport adapter must support TCP and IP Checksum transmit offload. If a LSOV2-capable miniport adapter also supports IPsec offload, NDIS will configure it to offload IPsec or LSOV2, but not both.

Miniport drivers are not required to support both IPv4 and IPv6. All NDIS 6.0 and later miniport drivers must support Ethernet 802.3 encapsulations with the ability to support Ethernet 802.1Q tags. The following table describes the hardware requirements when the miniport driver reports support for various offload capabilities.

Type of offload	IPv4	IpV6
Checksum Offload		
UDP Checksum	Optional	Optional
TCP Checksum	Optional	Optional
TCP Options	Optional	Required (for TCP Checksum)
IP Checksum	Optional	Not Applicable
IP Options	Required (for TCP checksum)	Not Applicable
IP Extension Header	Not Applicable	Required (128 bytes)
Large Send Offload version 1 (LSOv1)		
Max Offload Size	<= 64K	Not Applicable
TCP Options	Required	Not Applicable
IP Options	Required	Not Applicable

Type of offload	IPv4	IpV6
Large Send Offload version 2 (LSOv2)		
Max Offload Size	Unlimited	Unlimited
IP Options	Required	Required (128 bytes)
IP ID Support	0x0000 to 0xffff	0x0000 to 0x7fff reserved for segmentation offload

Using Registry Values to Enable and Disable Task Offloading

Article • 09/27/2024

When you debug a driver's task offload functionality, you might find it useful to enable or disable task offload services with a registry key setting. There are standardized keywords that you can define in INF files and in the registry. For more information about standardized keywords, see Standardized INF Keywords for Network Devices.

Task offload keywords belong to one of two groups: granular keywords or grouped keywords. *Granular keywords* provide keywords per offload capability--Transport Layer differentiation, IP protocol differentiation. *Grouped keywords* provide combined keywords capability at the transport layer.

Granular keywords

The granular keywords are defined as follows:

Expand table

Keyword	Description
***IPChecksumOffloadIPv4**	Describes whether the device enabled or disabled the calculation of IPv4 checksums.
***TCPChecksumOffloadIPv4**	Describes whether the device enabled or disabled the calculation of TCP Checksum over IPv4 packets.
***TCPChecksumOffloadIPv6**	Describes whether the device enabled or disabled the calculation of TCP checksum over IPv6 packets.
***UDPChecksumOffloadIPv4**	Describes whether the device enabled or disabled the calculation of UDP Checksum over IPv4 packets.
***UDPChecksumOffloadIPv6**	Describes whether the device enabled or disabled the calculation of UDP Checksum over IPv6 packets.
***LsoV1IPv4**	Describes whether the device enabled or disabled the segmentation of large TCP packets over IPv4 for large send offload version 1 (LSOv1).
***LsoV2IPv4**	Describes whether the device enabled or disabled the segmentation of large TCP packets over IPv4 for large send offload version 2 (LSOv2).

Keyword	Description
***LsoV2IPv6**	Describes whether the device enabled or disabled the segmentation of large TCP packets over IPv6 for large send offload version 2 (LSOv2).
***IPsecOffloadV1IPv4**	Describes whether the device enabled or disabled the calculation of IPsec headers over IPv4.
***IPsecOffloadV2**	Describes whether the device enabled or disabled IPsec offload version 2 (IPsecOV2). IPsecOV2 provides support for additional crypto-algorithms, IPv6, and co-existence with large send offload version 2 (LSOv2).
***IPsecOffloadV2IPv4**	Describes whether the device enabled or disabled IPsecOV2 for IPv4 only.

The following table describes the granular keywords that you can use to configure offload services.

Expand table

SubkeyName	ParamDesc	Value	EnumDesc
IPChecksumOffloadIPv4	IPv4 Checksum Offload	0	Disabled
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Rx & Tx Enabled
TCPChecksumOffloadIPv4	TCP Checksum Offload (IPv4)	0	Disabled
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Rx & Tx Enabled
TCPChecksumOffloadIPv6	TCP Checksum Offload (IPv6)	0	Disabled
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Rx & Tx Enabled

SubkeyName	ParamDesc	Value	EnumDesc
UDPChecksumOffloadIPv4	UDP Checksum Offload (IPv4)	0	Disabled
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Rx & Tx Enabled
UDPChecksumOffloadIPv6	UDP Checksum Offload (IPv6)	0	Disabled
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Rx & Tx Enabled
LsoV1IPv4	Large Send Offload Version 1 (IPv4)	0	Disabled
		1 (Default)	Enabled
LsoV2IPv4	Large Send Offload V2 (IPv4)	0	Disabled
		1 (Default)	Enabled
LsoV2IPv6	Large Send Offload V2 (IPv6)	0	Disabled
		1 (Default)	Enabled
IPsecOffloadV1IPv4	IPsec Offload Version 1 (IPv4)	0	Disabled
		1	Auth Header Enabled
		2	ESP Enabled
		3 (Default)	Auth Header & ESP Enabled
IPsecOffloadV2	IPsec Offload	0	Disabled
		1	Auth Header Enabled
		2	ESP Enabled

SubkeyName	ParamDesc	Value	EnumDesc
		3 (Default)	Auth Header & ESP Enabled
*IPsecOffloadV2IPv4	IPsec Offload (IPv4 only)	0	Disabled
		1	Auth Header Enabled
		2	ESP Enabled
		3 (Default)	Auth Header & ESP Enabled

ⓘ Note

The INF file can support granular keywords that are displayed in the Advanced Property page of the UI. The miniport driver must read all of the granular settings from the registry at initialization, including settings that are not displayed, to register NDIS offload capabilities.

Grouped keywords

The grouped keywords are defined as follows:

Expand table

Keyword	Description
***TCPUDPChecksumOffloadIPv4**	Describes whether the device enabled or disabled the calculation of IP, TCP, and UDP checksum over IPv4.
***TCPUDPChecksumOffloadIPv6**	Describes whether the device enabled or disabled the calculation of TCP and UDP checksum over IPv6.

The following table describes the grouped keywords that you can use to configure offload services.

Expand table

SubkeyName	ParamDesc	Value	EnumDesc
TCPUDPChecksumOffloadIPv4	TCP/UDP Checksum Offload (IPv4)	0	Disabled

SubkeyName	ParamDesc	Value	EnumDesc
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Tx & Rx Enabled
TCPUDPChecksumOffloadIPv6	TCP/UDP Checksum Offload (IPv6)	0	Disabled
		1	Tx Enabled
		2	Rx Enabled
		3 (Default)	Tx & Rx Enabled

There are restrictions on the combinations of offloads that can be enabled. For example, if a miniport adapter supports LSOV1 or LSOV2, the miniport adapter also calculates the IP and TCP checksums. For more information about valid combinations of offloads, see Combining Types of Task Offloads.

If task offload services are disabled with a registry key setting, protocol drivers must not issue the OID_OFFLOAD_ENCAPSULATION object identifier (OID).

You can use the following registry values to enable or disable task offloading for the TCP/IP protocol:

HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\TCPIP\Parameters\DisableTaskOffload
Setting this value to one disables all of the task offloads from the TCP/IP transport. Setting this value to zero enables all of the task offloads.

HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\Ipsec\EnabledOffload
Setting this value to zero disables Internet protocol security (IPsec) offloads from the TCP/IP transport. The offloading of TCP/IP checksum tasks, large send offload version 1 (LSOV1), and large send offload version 2 (LSOV2) are not affected. Setting this value to one enables IPsec offloads.

Offloading Checksum Tasks

Article • 12/15/2021

NDIS supports offloading TCP/IP checksum tasks at run time.

> ⓘ **Note**
>
> Checksum offload out-of-band (OOB) data is stored in the **NET_BUFFER_LIST** information array. For more information about OOB data, see **Accessing TCP/IP Offload NET_BUFFER_LIST Information**.

Before passing to the miniport driver a NET_BUFFER_LIST structure for a packet on which the miniport driver will perform checksum tasks, the TCP/IP transport specifies the checksum information that is associated with the NET_BUFFER_LIST structure. This information is specified by an **NDIS_TCP_IP_CHECKSUM_NET_BUFFER_LIST_INFO** structure, which is part of the NET_BUFFER_LIST information (out-of-band data) that is associated with the NET_BUFFER_LIST structure.

Before offloading the checksum calculation for a TCP packet, the TCP/IP transport calculates the one's complement sum for the TCP pseudoheader. The TCP/IP transport calculates the one's complement sum across all fields in the pseudoheader, including Source IP Address, Destination IP Address, Protocol, and the TCP length for TCP packets. The TCP/IP transport enters the one's complement sum for the pseudoheader in the Checksum field of the TCP header.

The one's complement sum for the pseudoheader provided by the TCP/IP transport gives the NIC an early start in calculating the real TCP checksum for the send packet. To calculate the actual TCP checksum, the NIC calculates the variable part of the TCP checksum (for the TCP header and payload), adds this checksum to the one's complement sum for the pseudoheader calculated by the TCP/IP transport, and calculates the 16-bit one's complement for the checksum. For more information about calculating such checksums, see RFC 793 and RFC 1122.

> ⓘ **Note**
>
> The TCP/IP transport computes the one's complement sum for the pseudoheader of a UDP packet using the same steps as it does for a TCP packet, and stores the value in the Checksum field of the UDP header.

Note that the TCP/IP transport always ensures that the checksum field in the IP header of a packet is set to zero before passing the packet to an underlying miniport driver. The miniport driver should ignore the checksum field in an IP header. The miniport driver does not need to verify that the checksum field is set to zero and does not need to set this field to zero.

After it receives the NET_BUFFER_LIST structure in its *MiniportSendNetBufferLists* or **MiniportCoSendNetBufferLists** function, a miniport driver typically does the following checksum processing:

1. The miniport driver calls the **NET_BUFFER_LIST_INFO** macro with an *_Id* of **TcpIpChecksumNetBufferListInfo** to obtain an **NDIS_TCP_IP_CHECKSUM_NET_BUFFER_LIST_INFO** structure.

2. The miniport driver tests the **IsIPv4** and **IsIPv6** flags in the NDIS_TCP_IP_CHECKSUM_NET_BUFFER_LIST_INFO structure. If both the **IsIPv4** and **IsIPv6** flags are not set, the NIC should not perform any checksum operations on the packet.

3. If the **IsIPv4** or **IsIPv6** flag is set, the miniport driver tests the **TcpChecksum**, **UdpChecksum**, and **IpHeaderChecksum** flags to determine which checksums the NIC should calculate for the packet.

4. The miniport driver passes the packet to the NIC, which calculates the appropriate checksums for the packet. If a packet has both a tunnel IP header and a transport IP header, a NIC that supports IP checksum offloads performs IP checksum tasks only on the tunnel header. The TCP/IP transport performs IP checksum tasks on the transport IP header.

Before indicating a **NET_BUFFER_LIST** structure for a receive packet on which it performs checksum tasks, the miniport driver validates the appropriate checksums and sets the appropriate *Xxx***ChecksumFailed** or *Xxx***ChecksumSucceeded** flags in the NDIS_TCP_IP_CHECKSUM_NET_BUFFER_LIST_INFO structure.

Turning off Address Checksum Offloads when Large Send Offload (LSO) is enabled does not prevent the miniport driver from computing and inserting checksums in the packets generated by the LSO feature. To disable Address Checksum Offloads in this case the user must also disable LSO.

Background Reading on IPsec

Article • 01/29/2022

[The IPsec Task Offload feature is deprecated and should not be used.]

To comprehend this section, you must understand Internet protocol security (IPsec) as specified in the following RFCs and drafts published by the IP Security Working Group of the Internet Engineering Task Force (IETF):

- Security Architecture for the Internet Protocol (RFC 2401)

Authentication header (AH):

- IP Authentication Header (RFC 2402)
- The Use of HMAC-MD5-96 within ESP and AH (RFC 2403)
- The Use of HMAC-SHA-1-96 within ESP and AH (RFC 2404)
- HMAC-MD5 IP Authentication with Replay Prevention (RFC 2085)

Encapsulating security payload (ESP):

- IP Encapsulating Security Payload (ESP) (RFC 2406)
- The ESP CBC-Mode Cipher Algorithms (RFC 2451)
- The ESP DES-CBC Cipher Algorithm with Explicit IV (RFC 2405)
- The NULL Encryption Algorithm and Its Use with IPsec (RFC 2410)

Requirements and Restrictions That Apply to IPsec Offloads

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

The following requirements and restrictions apply to Internet protocol security (IPsec) offloads:

- The NIC must maintain the security association (SA) tables. This improves performance by eliminating the need to include keys or other information that is required for AH and ESP processing in send packets.

- A NIC might be able to process both AH and ESP payloads for a single packet. In this case, the NIC must support the following possible combinations of integrity (authentication) algorithms for AH and ESP:

AH	ESP
MD5	MD5
SHA 1	SHA 1
MD5	SHA 1
SHA 1	MD5
MD5	Null (only if the NIC supports null encryption)
SHA 1	Null (only if the NIC supports null encryption)

- A NIC that supports DES algorithms must generate the initialization vector (IV) that these algorithms require.

- The only IPsec tasks that a NIC performs are processing encrypted AH checksums or ESP checksums (or both) and encrypting and decrypting ESP payloads. For send packets, the TCP/IP transport creates all headers, padding, and replay numbers and chooses SPI values that are unique to destination address/IPsec protocol pairs. For receive packets, the TCP/IP transport performs inbound policy checks, handles replay detection and prevention, and handles audit events.

- For a send packet, the TCP/IP transport does not provide explicit offsets (such as indicating the start of encrypted data) because the offload driver can easily determine this information from the particular security association (SA) that it uses to process the packet.

- A packet with IPsec protocols must have authentication information in an authentication header (AH) or the encapsulating security payload (ESP) header (or both). It is not permissible for a IPsec packet to have no authentication.

- IPsec tasks are not offloaded for send packets that require IP fragmentation or for receive packets that require reassembly from IP fragmentation.

- IPsec tasks are not offloaded for send and receive packets that pass through a load-balancing miniport driver. For more information about load balancing, see Load Balancing and Failover.

Adding a Security Association to a NIC

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

After the TCP/IP transport determines that a NIC can perform Internet protocol security (IPsec) operations (see Reporting a NIC's IPsec Capabilities), the transport must request the NIC's miniport driver to add one or more inbound and outbound security associations (SAs) to the NIC before the transport can offload IPsec tasks to the NIC. To request that a miniport driver add one or more SAs to the NIC, the TCP/IP transport sets OID_TCP_TASK_IPSEC_ADD_SA.

Deleting a Security Association from a NIC

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

If necessary, the TCP/IP transport can set OID_TCP_TASK_IPSEC_DELETE_SA to request that the miniport driver delete a security association (SA) from the NIC.

To create space for another SA on the NIC, the miniport driver can set the **SaDeleteReq** flag in the **NDIS_IPSEC_OFFLOAD_V1_NET_BUFFER_LIST_INFO** structure for a receive packet. The TCP/IP transport subsequently issues OID_TCP_TASK_IPSEC_DELETE_SA one time to delete the inbound security association (SA) over which the packet was received and another time to delete the outbound SA that corresponds to the deleted inbound SA. A NIC must not remove either of these SAs before it receives the corresponding OID_TCP_TASK_IPSEC_DELETE_SA request. The miniport driver can set **SaDeleteReq** independently of the **CryptoDone** flag.

Offloading IPsec Tasks in the Send Path

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

Before the TCP/IP transport passes to the miniport driver a **NET_BUFFER_LIST** structure for a packet on which a NIC will perform Internet protocol security (IPsec) tasks, it updates the IPsec information that is associated with the NET_BUFFER_LIST structure. The TCP/IP transport specifies this information in an **NDIS_IPSEC_OFFLOAD_V1_NET_BUFFER_LIST_INFO** structure, which is part of the NET_BUFFER_LIST information (out-of-band data) that is associated with the NET_BUFFER_LIST structure.

The TCP/IP transport supplies *OffloadHandle*, which specifies the handle to the outbound SA for the transport (end-to-end connection) portion of the send packet. If the packet will be transmitted through a tunnel, the TCP/IP transport also supplies *NextOffloadHandle*, which specifies the handle to the outbound SA for the tunnel portion of the send packet.

After a miniport driver receives the **NET_BUFFER_LIST** structure in its *MiniportSendNetBufferLists* or **MiniportCoSendNetBufferLists** function, it can call the **NET_BUFFER_LIST_INFO** macro with an *_Id* of **IPsecOffloadV1NetBufferListInfo** to obtain the NDIS_IPSEC_OFFLOAD_V1_NET_BUFFER_LIST_INFO structure that is associated with the NET_BUFFER_LIST structure.

When the NIC performs IPsec processing on a send packet, it calculates the AH or ESP encryption checksums (or both) for the packet and, if the packet contains an ESP payload, encrypts the packet. The TCP/IP transport has already framed the packet, padded it (if necessary), and assigned it a sequence number and SPI.

Offloading IPsec Tasks in the Receive Path

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

When a NIC performs Internet protocol security (IPsec) processing on a receive packet, it decrypts the packet if the packet contains an ESP payload and calculates the AH or ESP encryption checksums (or both) for the packet. Before indicating the NET_BUFFER_LIST structure for the packet up to the TCP/IP transport, the miniport driver calls the NET_BUFFER_LIST_INFO macro with an *_Id* of **IPsecOffloadV1NetBufferListInfo** to obtain the NDIS_IPSEC_OFFLOAD_V1_NET_BUFFER_LIST_INFO structure that is associated with a packet.

The miniport driver sets the **CryptoDone** flag in the NDIS_IPSEC_OFFLOAD_V1_NET_BUFFER_LIST_INFO structure to indicate that the NIC performed IPsec checking on at least one IPsec payload in the receive packet. If a NIC performed IPsec checking on both the tunnel and transport portions of a receive packet, the miniport driver also sets the **NextCryptoDone** flag in the NDIS_IPSEC_OFFLOAD_V1_NET_BUFFER_LIST_INFO structure. The miniport driver sets **NextCryptoDone** only if a packet has both tunnel and transport IPsec payloads. Otherwise, the miniport driver sets **NextCryptoDone** to zero. To indicate the results of the IPsec checks, the miniport driver must also supply a value for the **CryptoStatus** member in the NDIS_IPSEC_OFFLOAD_V1_NET_BUFFER_LIST_INFO structure. If the NIC detects a checksum failure or a decryption failure, the miniport driver must indicate a NET_BUFFER_LIST structure for the receive packet in whatever form it is and specify the appropriate **CryptoStatus** value.

Note that, if the miniport driver is not decrypting an incoming packet, it clears both the **CryptoDone** and the **NextCryptoDone** flags. The miniport driver does this for all receive packets that it does not decrypt, regardless of whether the packet is AH-protected or ESP-protected. The miniport driver sets **CryptoStatus** to CRYPTO_SUCCESS for all packets that it does not decrypt.

After the miniport driver indicates the NET_BUFFER_LIST structure to the TCP/IP transport, the transport examines the results of the IPsec checks that the NIC performed, checks the sequence numbers for the packet, and determines what to do with a packet that fails the checksum or sequencing tests.

Impact of Network Interface Changes on IPsec Offloads

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

The following events in the network interface affect the offloading of Internet protocol security (IPsec) tasks:

- A NIC is removed.

  Before a NIC to which tasks are being offloaded is removed from the system, its miniport driver should delete all security associations (SAs) from the NIC. The miniport driver does not have to request that the TCP/IP transport delete the SAs.

- A routing interface is changed.

  When network traffic is routed through a new interface, the TCP/IP stack temporarily performs IPsec tasks until it has added the appropriate SAs to the NIC that is used in the new interface. The TCP/IP stack adds an SA to a NIC by issuing OID_TCP_TASK_IPSEC_ADD_SA. After the SAs on the NIC that is used for the old interface expire, the TCP/IP transport issues OID_TCP_TASK_IPSEC_DELETE_SA as many times as necessary to request that the NIC's miniport driver delete the SAs from the NIC.

Traversing NATs and NAPTs with UDP-Encapsulated ESP Packets

Article • 09/06/2024

[The IPsec Task Offload feature is deprecated and should not be used.]

Network address translators (NATs) and network address port translators (NAPTs) convert multiple private network addresses into one routeable IP public address and vice versa, thereby allowing many systems to share a single IP address. In this way, NATs and NAPTs help to alleviate the shortage of routeable IPv4 addresses.

However, NATs and NAPTs can cause problems with Internet protocol security (IPsec). Because NATs and NAPTs modify the IP header of a packet, they cause AH-protected packets to fail checksum validation. NAPTs, which modify TCP and UDP ports, cannot modify the ports in the encrypted TCP header of an ESP-protected packet.

UDP encapsulation solves this problem. In practice, UDP encapsulation is used only on ESP packets. A NAT or NAPT can modify the unencrypted IP and UDP headers of a UDP-encapsulated ESP packet without breaking ESP authentication and without being stymied by ESP encryption.

Microsoft supports UDP encapsulation of ESP packets on port 4500. After IKE peers initiate negotiation on port 500, detect support for NAT-traversal, and detect a NAT or NAPT along the path, they can negotiate to "float" IKE and UDP-ESP traffic to port 4500.

Floating to port 4500 for NAT traversal provides the following benefits:

- It bypasses "IPsec-aware" NATs or NAPTs that break UDP-ESP encapsulation on port 500.
- It improves performance. The UDP encapsulation of ESP data packets is more efficient on port 4500 than on port 500. For more information, see UDP-ESP Encapsulation Types.

To support UDP-ESP encapsulation, a miniport driver or the NIC (or both) must:

- Be able to process ESP packets in the receive path, as described in Offloading IPsec Tasks in the Receive Path.
- Maintain a list of parser entries. A parser entry contains information that a NIC requires to parse incoming UDP-ESP packets on one or more security associations (SAs). For more information about parser entries, see UDP-ESP SAs and Parser Entries.

- Maintain a list of SAs that the transport has offloaded to the NIC.
- Support the following OIDs:
  - OID_TCP_TASK_IPSEC_ADD_UDPESP_SA
  - OID_TCP_TASK_IPSEC_DELETE_UDPESP_SA

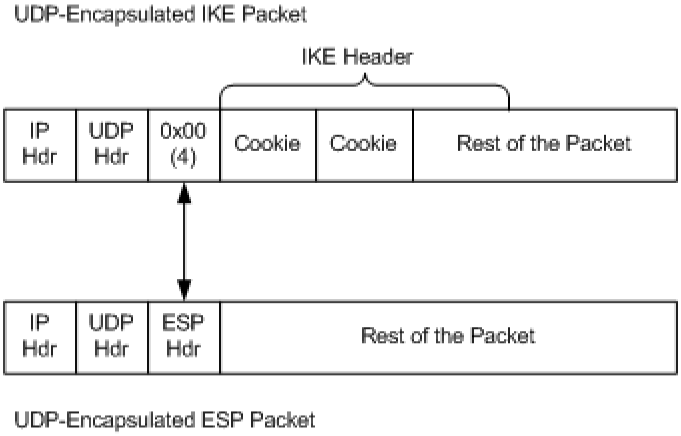
UDP-ESP Encapsulation Types

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

The following figure shows the UDP encapsulation of Internet Key Exchange (IKE) packets and ESP-protected data packets that are received on port 4500.



Note the four bytes of zeros that follow the UDP header in IKE packets. This field of zeros differentiates IKE packets from UDP-encapsulated ESP packets on port 4500. Instead of zeros, ESP headers have a nonzero ESP header at this location in the packet.

UDP-ESP Encapsulation Subtypes

ESP packets on port 4500 can be formatted according to one of the following UDP-ESP encapsulation subtypes:

- UDP-encapsulated transport.

  An ESP-encapsulated transport-mode packet is encapsulated by UDP.

- UDP-encapsulated tunnel.

  The tunnel-mode portion of a packet is UDP-encapsulated. The transport-mode portion of the packet is not UDP-encapsulated and is not ESP-protected.

- Transport over UDP-encapsulated tunnel.

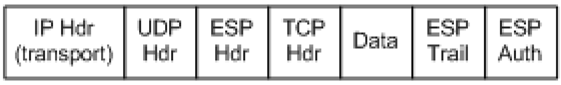
  The tunnel-mode portion of a packet is UDP-encapsulated. The transport-mode portion of a packet is not UDP-encapsulated, but is ESP-protected.

- UDP-encapsulated transport over tunnel.

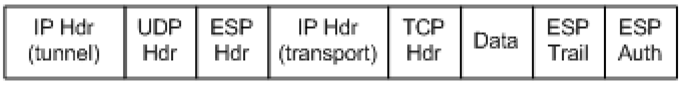
The tunnel-mode portion of a packet is not UDP-encapsulated. The transport-mode portion of a packet is UDP-encapsulated and ESP-protected.

Note that a UDP-encapsulated transport over a UDP-encapsulated tunnel is not a supported encapsulation subtype.

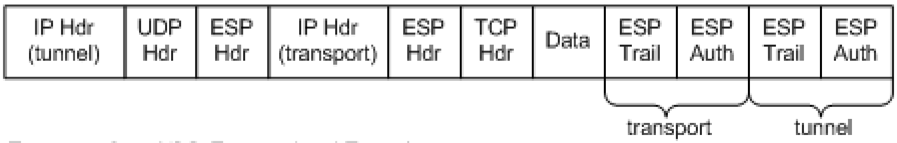
The following figure shows the UDP-ESP encapsulation subtypes for port 4500.



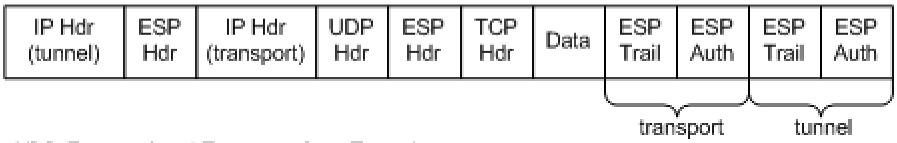
UDP-Encapsulated Transport



UDP-Encapsulated Tunnel



Transport Over UDP-Encapsulated Tunnel



UDP-Encapsulated Transport Over Tunnel

Reporting, Enabling, and Disabling a NIC's Ability to Parse UDP-ESP Packets

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

A miniport driver specifies a NIC's Internet protocol security (IPsec) capabilities in an **NDIS_IPSEC_OFFLOAD_V1** structure. For more information, see Reporting a NIC's IPsec Capabilities.

The miniport reports the NIC's ability to parse incoming UDP-encapsulated ESP packets by setting one or more flags in the **Supported** . **Reserved** member of the NDIS_IPSEC_OFFLOAD_V1 structure. The miniport driver can specify any or all of the four UDP-ESP encapsulation subtypes that are described in UDP-ESP Encapsulation Types.

For information about enabling and disableing UDP ESP parsing capabilities, see Enabling and Disabling TCP/IP Offload Services.

UDP-ESP SAs and Parser Entries

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

A miniport driver that supports UDP-ESP encapsulation must maintain a list of parser entries. A parser entry contains information that a NIC requires to parse incoming UDP-ESP packets on offloaded security associations (SAs).

A parser entry contains the following information:

- The UDP-ESP encapsulation type.

  Currently, only one encapsulation type is supported. For a description of the basic UDP-ESP encapsulation types, see UDP-ESP Encapsulation Types.

- The destination encapsulation port.

  The NIC should look for the destination port in the UDP header of inbound UDP-encapsulated packets that it processes on the offloaded SAs. Currently, UDP encapsulation of ESP packets is supported only on port 4500.

The TCP/IP transport maintains its own list of parser entries that it has offloaded to the miniport driver. When adding or deleting a UDP-ESP SA, the transport and miniport driver use a handle to identify a particular parser entry.

Note that parser entries allow UDP-ESP functionality to be extended, if necessary, to accommodate different encapsulation types and more than one port for each encapsulation type.

Adding a UDP-ESP SA and Parser Entry

The TCP/IP transport requests a miniport driver to add one or more UDP-ESP SAs, and the parser entry for these SAs, by issuing an OID_TCP_TASK_IPSEC_ADD_UDPESP_SA request. The **EncapTypeEntry** member of the OFFLOAD_IPSEC_ADD_UDPESP_SA structure contains the parser entry information.

Before issuing an OID_TCP_TASK_IPSEC_ADD_UDPESP_SA request, the TCP/IP transport determines whether the parser entry for the SAs that is being offloaded is in its parser entry list for the specified IP interface.

- If the parser entry is not in the transport's list, the transport creates its own copy of the entry and sets the **EncapTypeEntryOffloadHandle** member of the

OFFLOAD_IPSEC_ADD_UDPESP_SA structure to **NULL**. The transport then issues the OID_TCP_TASK_IPSEC_ADD_UDPESP_SA request. After receiving the request, the miniport driver determines whether the parser entry that the **EncapTypeEntry** specified is in the NIC's parser entry list.

  - If the specified parser entry is not in the NIC's parser entry list, the miniport driver creates the parser entry by using the encapsulation type and destination port specified in **EncapTypeEntry** and adds the parser entry to the NIC's parser entry list. The miniport driver then offloads the SAs specified in the OID_TCP_TASK_IPSEC_ADD_UDPESP_SA request. After successfully completing the OID request, the miniport driver returns a handle in **EncapTypeEntryOffloadHandle** that identifies the newly created parser entry. The miniport driver also returns a handle that identifies the offloaded SAs in the **OffloadHandle** member of the OFFLOAD_IPSEC_ADD_UDPESP_SA structure.
  - If the specified parser entry is already in the NIC's parser entry list, the miniport driver simply returns the handle in **EncapTypeEntryOffloadHandle** for the existing parser entry. The miniport driver also returns a handle that identifies the offloaded SAs in the **OffloadHandle** member of the OFFLOAD_IPSEC_ADD_UDPESP_SA structure.

If the miniport driver completes the OID_TCP_TASK_IPSEC_ADD_UDPESP_SA request successfully, the transport adds its copy of the new parser entry to its own parser entry list for the given IP interface. In addition, the transport increments the reference count for the parser entry by one. The transport uses this reference count to enumerate how many offloaded UDP-ESP SAs are associated with the parser entry.

If the miniport driver fails the OID_TCP_TASK_IPSEC_ADD_UDPESP_SA request, the transport discards its copy of the parser entry. If the miniport driver fails such a request, it must ensure that it has not, in fact, added the parser entry and offloaded the SAs.

- If the parser entry is already in the transport's parser entry list, the miniport driver has already added the parser entry in response to a previous OID_TCP_TASK_IPSEC_ADD_UDPESP_SA request. In this case, the transport increments the reference count for the parser entry by one and sets the **EncapTypeEntryOffloadHandle** to the value that the miniport driver previously returned. The transport then issues an OID_TCP_TASK_IPSEC_ADD_UDPESP_SA request This requests the miniport driver to use an existing parser entry for the additional SAs that are being offloaded. In this case, the miniport driver should simply return an **OffloadHandle** that identifies the offloaded SAs. If the OID_TCP_TASK_IPSEC_ADD_UDPESP_SA request fails, the transport decrements the reference count for the parser entry.

Deleting a UDP-ESP SA and Parser Entry

The TCP/IP transport requests a miniport driver to delete one or more SAs and possibly the parser entry for these SAs by issuing an OID_TCP_TASK_IPSEC_DELETE_UDPESP_SA request.

Before issuing this request, the TCP/IP transport decrements the reference count for the parser entry that is associated with the SAs to be deleted. The transport then tests whether the reference count is zero.

- If the reference count is not zero, the parser entry is associated with one or more other SAs that are currently offloaded to the NIC. In this case, the transport sets the **EncapTypeEntryOffldHandle** member of the OFFLOAD_IPSEC_DELETE_UDPESP_SA structure to **NULL**. After it receives the OID_TCP_TASK_IPSEC_DELETE_UDPESP_SA request, the miniport driver simply deletes the SAs that are specified in the OID_TCP_TASK_IPSEC_DELETE_UDPESP_SA request.

- If the reference count is zero, the parser entry is not associated with any other SAs that have been offloaded to the NIC. In this case, the transport sets the **EncapTypeEntryOffldHandle** member to the value of the parser entry handle that the miniport driver previously returned. The miniport driver deletes both the specified parser entry and the specified SAs.

If the miniport driver fails the OID_TCP_TASK_IPSEC_DELETE_UDPESP_SA request, it should mark the specified SAs and, if appropriate, the specified parser entry for deletion and perform the deletion later. To process incoming packets, the miniport driver must not use a parser entry or SA that is marked for deletion.

Note that a transport could request a miniport driver to delete an SA or a parser entry (or both) before the miniport driver completes adding that SA or parser entry (or both). The miniport driver must therefore serialize the deletion operation with the addition operation.

Processing UDP-Encapsulated ESP Packets

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

When a NIC receives a UDP-encapsulated packet on port 4500, it checks whether the packet is an IKE (control) packet or an ESP (data) packet. For a description of the UDP encapsulation types for IKE and ESP packets, see UDP-ESP Encapsulation Types.

- If the packet is an IKE packet, the NIC passes the packet to the miniport driver without further IPsec-related processing.

- If the packet is an ESP packet, the NIC checks whether the packet's inbound SA (or SAs in the case of a transport-over-tunnel packet) is currently offloaded to the NIC.
  - If the inbound SAs are not currently offloaded to the NIC, the NIC passes the packet to the miniport driver without further IPsec-related processing.
  - If the inbound SAs are currently offloaded to the NIC, the NIC parses the packet by using the encapsulation type specified by the parser entry that is associated with the SAs. The NIC then processes the ESP payloads in the packet, as described in Offloading IPsec Tasks in the Receive Path.

If the incoming ESP packet is a UDP-encapsulated transport-over-tunnel packet, as described in UDP-ESP Encapsulation Types, the NIC first decrypts the ESP payload of tunnel-mode portion of the packet, which is not UDP-encapsulated. Then the NIC processes the UDP-encapsulated tunnel-mode portion of the packet.

Introduction to IPsec Offload Version 2

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

IPsec offload version 2 (IPsecOV2) extends services that are provided in IPsec offload version 1 (IPsecOV1). For more information about IPsecOV1 offload and IPsec, see IPsec Offload Version 1.

An NDIS 6.1 and later miniport driver reports the IPsecOV2 offload capabilities of a miniport adapter to NDIS. To report IPsec capabilities:

- During initialization, a miniport driver reports the task offload default configuration and the hardware capabilities of a miniport adapter in the **NDIS_MINIPORT_ADAPTER_OFFLOAD_ATTRIBUTES** structure.

- If the configured capabilities change, the miniport driver reports the current configuration with the **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** status indication. The configuration can change if the OID_TCP_OFFLOAD_PARAMETERS OID sets the current task offload configuration of a miniport adapter. Also, if the hardware configuration under a MUX intermediate driver changes, the MUX intermediate driver must report the hardware configuration changes with the **NDIS_STATUS_TASK_OFFLOAD_HARDWARE_CAPABILITIES** status indication.

NDIS reports the default configuration of the offload capabilities of a miniport adapter to overlying protocol drivers in the **NDIS_BIND_PARAMETERS** structure. Overlying protocol drivers can choose IPsecOV2 task offload services from the services that are supported in the current configuration. The **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** status indication ensures that all of the overlying protocol drivers are updated with the new capabilities information.

When reporting hardware capabilities during initialization, the miniport driver must read the standardized keywords from the registry. For more information about IPsecOV2 offload capabilities, see Reporting a NIC's IPsec Offload Version 2 Capabilities.

Note NDIS provides a direct OID request interface for NDIS 6.1 and later drivers. The direct OID request path supports OID requests that are queried or set frequently.

IPsecOV2 provides the OID_TCP_TASK_IPSEC_OFFLOAD_V2_ADD_SA, OID_TCP_TASK_IPSEC_OFFLOAD_V2_UPDATE_SA, and OID_TCP_TASK_IPSEC_OFFLOAD_V2_DELETE_SA direct OID requests to enable protocol drivers to add, update, and delete security associations (SAs). For more information about SAs, see Managing Security Associations in IPsec Offload Version 2.

A NIC can perform IPsec offload tasks on the send and receive paths. NDIS drivers use the **NDIS_IPSEC_OFFLOAD_V2_NET_BUFFER_LIST_INFO**, **NDIS_IPSEC_OFFLOAD_V2_HEADER_NET_BUFFER_LIST_INFO**, and **NDIS_IPSEC_OFFLOAD_V2_TUNNEL_NET_BUFFER_LIST_INFO** structures to access the IPsec out-of-band (OOB) information.

On the send path, the overlying drivers set the handle to the outbound SA and IPsec header information in OOB information in the **NET_BUFFER_LIST** structure to specify that the NIC should perform IPsecOV2 offload tasks.

On the receive path, after the SA is offloaded, the NIC must perform the IPsec processing on all the received packets that match the capabilities that the miniport driver reported to NDIS. The miniport driver sets the appropriate flags in OOB information in the **NET_BUFFER_LIST** structure to specify specific offload tasks that the NIC performed and the result of those operations.

For more information about send and receive processing in IPsecOV2, see Sending Network Data with IPsec Offload Version 2 and Receiving Network Data with IPsec Offload Version 2.

Reporting a NIC's IPsec Offload Version 2 Capabilities

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

To specify IPsec offload version 2 (IPsecOV2) capabilities, an NDIS 6.1 and later miniport driver specifies the current or default configuration of a NIC in an **NDIS_IPSEC_OFFLOAD_V2** structure. Miniport drivers must include the default IPsecOV2 configuration in the **NDIS_MINIPORT_ADAPTER_OFFLOAD_ATTRIBUTES** structure. Miniport drivers call the **NdisMSetMiniportAttributes** function from the *MiniportInitializeEx* function and pass in the information in NDIS_MINIPORT_ADAPTER_OFFLOAD_ATTRIBUTES.

Miniport drivers must report changes in the IPsecOV2 capabilities, if any, in the **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** status indication.

Note NDIS provides a direct OID request interface for NDIS 6.1 and later drivers. The direct OID request path supports OID requests that are queried or set frequently.

In response to a query of OID_TCP_OFFLOAD_CURRENT_CONFIG, NDIS includes the NDIS_IPSEC_OFFLOAD_V2 structure in the **NDIS_OFFLOAD** structure that NDIS returns in the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure. NDIS uses the information that the miniport driver provided.

Accessing NET_BUFFER_LIST Information in IPsec Offload Version 2

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

NDIS provides out-of-band (OOB) data in the **NetBufferListInfo** member of the NET_BUFFER_LIST structure, which specifies a linked list of NET_BUFFER structures. The **NetBufferListInfo** member is an array of values that contain information that is common to all of the NET_BUFFER structures in the list.

Use the following identifiers with the NET_BUFFER_LIST_INFO macro to set and get the IPsec offload version 2 (IPsecOV2) OOB data in the **NetBufferListInfo** array:

IPsecOffloadV2NetBufferListInfo
Specifies IPsecOV2 information that is used in offloading IPsec tasks from the TCP/IP protocol to a NIC. When you specify **IPsecOffloadV2NetBufferListInfo**, NET_BUFFER_LIST_INFO returns an NDIS_IPSEC_OFFLOAD_V2_NET_BUFFER_LIST_INFO structure.

IPsecOffloadV2TunnelNetBufferListInfo
Specifies IPsecOV2 tunnel information that is used in offloading IPsec tasks from the TCP/IP protocol to a NIC. When you specify **IPsecOffloadV2TunnelNetBufferListInfo**, NET_BUFFER_LIST_INFO returns an NDIS_IPSEC_OFFLOAD_V2_TUNNEL_NET_BUFFER_LIST_INFO structure.

IPsecOffloadV2HeaderNetBufferListInfo
Specifies the header offsets for IPsec headers in the NET_BUFFER_LIST and the values for the next header and pad length. When you specify **IPsecOffloadV2HeaderNetBufferListInfo**, NET_BUFFER_LIST_INFO returns an NDIS_IPSEC_OFFLOAD_V2_HEADER_NET_BUFFER_LIST_INFO structure.

Managing Security Associations in IPsec Offload Version 2

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

After the TCP/IP transport determines that a NIC can perform IPsec offload version 2 (IPsecOV2) operations (see Reporting a NIC's IPsec Offload Version 2 Capabilities), the transport requests that the NIC's miniport driver add one or more security associations (SAs) to the NIC before the transport can offload IPsec tasks to the NIC. After adding SAs, the TCP/IP transport can also delete or update them. The IPsecOV2 interface requires the NDIS direct OID interface for add, delete, and update OIDs.

Note NDIS provides a direct OID request interface for NDIS 6.1 and later drivers. The direct OID request path supports OID requests that are queried or set frequently.

To request that a miniport driver add one or more SAs to a NIC, the TCP/IP transport sets the OID_TCP_TASK_IPSEC_OFFLOAD_V2_ADD_SA OID. The miniport driver receives an **IPSEC_OFFLOAD_V2_ADD_SA** structure and configures the NIC for IPsecOV2 processing on an SA. With a successful set to OID_TCP_TASK_IPSEC_OFFLOAD_V2_ADD_SA, the miniport driver initializes a handle that identifies the offloaded SA in the IPSEC_OFFLOAD_V2_ADD_SA structure. The transport uses this handle in subsequent requests to the miniport driver (that is, on the send path or in the calls to modify or delete the SA). For more information about using the SA handle in the send path, see Sending Network Data with IPsec Offload Version 2.

The miniport driver reports the number of SAs that a NIC can support in the **SaOffloadCapacity** member of the **NDIS_IPSEC_OFFLOAD_V2** structure.

The miniport driver can set the **SaDeleteReq** flag in the **NDIS_IPSEC_OFFLOAD_V2_NET_BUFFER_LIST_INFO** structure for a receive packet. The TCP/IP transport subsequently issues OID_TCP_TASK_IPSEC_OFFLOAD_V2_DELETE_SA one time to delete the inbound SA that the packet was received over and one time again to delete the outbound SA that corresponds to the deleted inbound SA.

The TCP/IP transport issues OID_TCP_TASK_IPSEC_OFFLOAD_V2_DELETE_SA to delete an inbound SAs over which a packet was received and to delete the outbound SAs that correspond to the deleted inbound SAs. A NIC must not remove these SAs before it receives the corresponding OID_TCP_TASK_IPSEC_OFFLOAD_V2_DELETE_SA request.

The TCP/IP transport sets the OID_TCP_TASK_IPSEC_OFFLOAD_V2_UPDATE_SA OID to request that a miniport driver update a NIC with the higher order bits for an SA with extended sequence numbers (ESN). For NICs that support ESN, when the miniport driver receives this request, the driver should update the sequence number of the specified SA in the NIC in accordance with the **IPSEC_OFFLOAD_V2_OPERATION** enumeration value that is specified in the **Operation** member of the **IPSEC_OFFLOAD_V2_UPDATE_SA** structure.

Sending Network Data with IPsec Offload Version 2

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

The TCP/IP transport provides IPsec Offload Version 2 (IPsecOV2) information for one or more SAs with the OID_TCP_TASK_IPSEC_OFFLOAD_V2_ADD_SA OID. Before the miniport driver returns a successful result for OID_TCP_TASK_IPSEC_OFFLOAD_V2_ADD_SA, the miniport driver initializes an offload handle. The TCP/IP transport requests the miniport driver to offload the processing of a **NET_BUFFER_LIST** structure by specifying IPsecOV2 information in the **NDIS_IPSEC_OFFLOAD_V2_NET_BUFFER_LIST_INFO** and **NDIS_IPSEC_OFFLOAD_V2_HEADER_NET_BUFFER_LIST_INFO** structures, which are part of the **NET_BUFFER_LIST** out-of-band (OOB) information.

The TCP/IP transport supplies an offload handle in the **OffloadHandle** member of **NDIS_IPSEC_OFFLOAD_V2_NET_BUFFER_LIST_INFO** that specifies the handle to the outbound security association (SA) for the transport (end-to-end connection) portion of the send packet.

The TCP/IP transport supplies the following header information in the **NDIS_IPSEC_OFFLOAD_V2_HEADER_NET_BUFFER_LIST_INFO** structure:

- Header offsets for an AH header, ESP header, or both.
- The next protocol value (identical to the one that is contained in the ESP trailer).
- The pad length that is used for a combined large send offload (LSO) and IPsec offload.

Also, if the send packet will be transmitted through a tunnel, the TCP/IP transport supplies an **NDIS_IPSEC_OFFLOAD_V2_TUNNEL_NET_BUFFER_LIST_INFO** structure. This structure specifies the offload handle to the outbound SA for the tunnel portion of the send packet. For more information about accessing OOB information, see Accessing NET_BUFFER_LIST Information in IPsec Offload Version 2.

The miniport driver provided the offload handles in response to an OID set request of OID_TCP_TASK_IPSEC_OFFLOAD_V2_ADD_SA. For more information about SAs, see Managing Security Associations in IPsec Offload Version 2.

When a miniport driver handles a send request in the *MiniportSendNetBufferLists* function, the miniport driver:

- Verifies that the hardware is configured to handle IPsec offload services. If the hardware is not configured to handle IPsec offload services, the miniport driver should handle the send request without providing the offload services.

- Verifies the handles in the NDIS_IPSEC_OFFLOAD_V2_NET_BUFFER_LIST_INFO and NDIS_IPSEC_OFFLOAD_V2_TUNNEL_NET_BUFFER_LIST_INFO structures to determine if IPsec cryptographic processing is required. An offload handle value of zero indicates that no IPsec task offload should be performed for the NET_BUFFER_LIST. If the miniport driver cannot find the offloaded SA that corresponds to the specified offload handle, the send packet should fail with an **NDIS_STATUS_FAILURE** value.

- Verifies the handles in the NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO structures to determine if segmentation offload should be performed for the NET_BUFFER_LIST.

- Completes the required AH and ESP processing for all of the send packets in the NET_BUFFER_LIST. When the NIC performs IPsec processing on a send packet, it performs the cryptographic operations on the packet data. The TCP/IP transport has already framed the packet, padded it (if necessary), and assigned it a sequence number and security parameters index (SPI). For a combined LSO and IPsec offload, the NET_BUFFER might have padding that will be discarded while the NIC segments the large packet. The amount of padding is specified in the **PadLength** member of the NDIS_IPSEC_OFFLOAD_V2_HEADER_NET_BUFFER_LIST_INFO structure. Segmented packets might require padding to support IPsec operations.

When a protocol driver transmits a packet that requests both LSO and IPsecOV2, it will not frame the ESP trailer. This is because the information in the ESP trailer, such as the padding length, will not be accurate for the last segment that was generated by the NIC.

Receiving Network Data with IPsec Offload Version 2

Article • 12/15/2021

[The IPsec Task Offload feature is deprecated and should not be used.]

A NIC performs IPsec offload version 2 (IPsecOV2) processing on a receive packet as specified in a security association (SA) that was offloaded from the transport.

The miniport driver sets the IPsecOV2 out-of-band (OOB) information before indicating the received data to overlying drivers. For more information about accessing OOB information, see Accessing NET_BUFFER_LIST Information in IPsec Offload Version 2.

Note A miniport driver should indicate all received packets to overlying drivers even if an error occurs while processing the IPsec data in the NIC. The driver must indicate packets with errors to enable the driver stack to monitor and troubleshoot the network traffic.

Before the miniport driver indicates the received data packet up the driver stack, the miniport driver:

- Verifies that the hardware is configured to handle IPsec offload tasks. If not, the miniport driver does a receive indication with no additional IPsec offload processing.

- Looks at the security parameters index (SPI) to determine if a matching offloaded SA exists. The miniport driver confirms the destination address on the packet is same as the one specified in offloaded SA. If there is no matching SA, the NIC indicates the received data without setting the IPsecOV2 OOB information.

- Verifies that it can process the packet based on the capabilities that the miniport driver reported to the transport or it makes a receive indication without further IPsec processing. For example, the packet might have IP options where the NIC does not support IPsec offload processing for such packets and the miniport driver does the IPsec processing.

- Sets the **CryptoDone** flag in the NDIS_IPSEC_OFFLOAD_V2_NET_BUFFER_LIST_INFO structure to indicate that a NIC performed IPsec checking on at least one IPsec payload in the received packet.

- Sets the **NextCryptoDone** flag in the NDIS_IPSEC_OFFLOAD_V2_NET_BUFFER_LIST_INFO structure to indicate that a NIC performed IPsec checking on both the tunnel and transport portions of a receive packet. The miniport driver sets this flag only if a packet has both tunnel and transport payloads; otherwise, this flag should be zero.

- Sets the correct **CryptoStatus** value of the NDIS_IPSEC_OFFLOAD_V2_NET_BUFFER_LIST_INFO structure to indicate the results of the IPsec checks.

If the NIC did not perform offload processing on an incoming packet, the miniport driver clears both the **CryptoDone** and the **NextCryptoDone** flags. The miniport driver clears these flags for all receive packets where a NIC does not decrypt, regardless of whether the packet is AH-protected or ESP-protected.

A miniport driver can set **SaDeleteReq**, in the **NDIS_IPSEC_OFFLOAD_V2_NET_BUFFER_LIST_INFO** structure for a receive **NET_BUFFER_LIST**. The TCP/IP transport subsequently issues OID_TCP_TASK_IPSEC_OFFLOAD_V2_DELETE_SA once to delete the inbound SA that the packet was received over and once again to delete the outbound SA that corresponds to the deleted inbound SA. For more information about adding and deleting SAs, see Managing Security Associations in IPsec Offload Version 2.

After the miniport driver indicates the NET_BUFFER_LIST structure to the TCP/IP transport, the TCP/IP transport examines the results of the IPsec checks that the NIC performed on the packet, checks the sequence numbers for the packet, and determines what to do with a packet that fails the checksum or sequencing tests.

Offloading the Segmentation of Large TCP Packets

Article • 12/15/2021

NDIS miniport drivers can offload the segmentation of large TCP packets that are larger than the maximum transmission unit (MTU) of the network medium. A NIC that supports the segmentation of large TCP packets must also be able to:

- Calculate IP checksums for send packets that contain IP options.
- Calculate TCP checksums for send packets that contain TCP options.

NDIS versions 6.0 and later support large send offload version 1 (LSOv1), which is similar to large send offload (LSO) in NDIS 5.*x*. NDIS versions 6.0 and later also support large send offload version 2 (LSOv2), which provides enhanced large packet segmentation services, including support for IPv6.

A miniport driver that supports LSOv2 and LSOv1 must determine the offload type from the **NET_BUFFER_LIST** structure OOB information. The driver can use the **Type** member of the **NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO** structure to determine whether the driver stack is using LSOv2 or LSOv1 and perform the appropriate offload services. Any NET_BUFFER_LIST structure that contains the LSOv1 or LSOv2 OOB data also contains a single **NET_BUFFER** structure. For more information about NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO, see Accessing TCP/IP Offload NET_BUFFER_LIST Information.

However, in a case where the miniport has received **OID_TCP_OFFLOAD_PARAMETERS** to turn off LSO feature on the miniport and after the miniport has completed the OID successfully, the miniport shall drop all **NET_BUFFER_LIST** which contain any non-zero LSOv1 or LSOv2 OOB data(**NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO**).

The TCP/IP transport offloads only those large TCP packets that meet the following criteria:

- The packet is a TCP packet. The TCP/IP transport does not offload large UDP packets for segmentation.
- The packet must be divisible by at least the minimum number of segments specified by the miniport driver. For more information, see Reporting a NIC's LSOv1 TCP-Packet-Segmentation Capabilities and Reporting a NIC's LSOv2 TCP-Packet-Segmentation Capabilities.

- The packet is not a loopback packet.
- The packet will not be sent through a tunnel.

Before offloading a large TCP packet for segmentation, the TCP/IP transport:

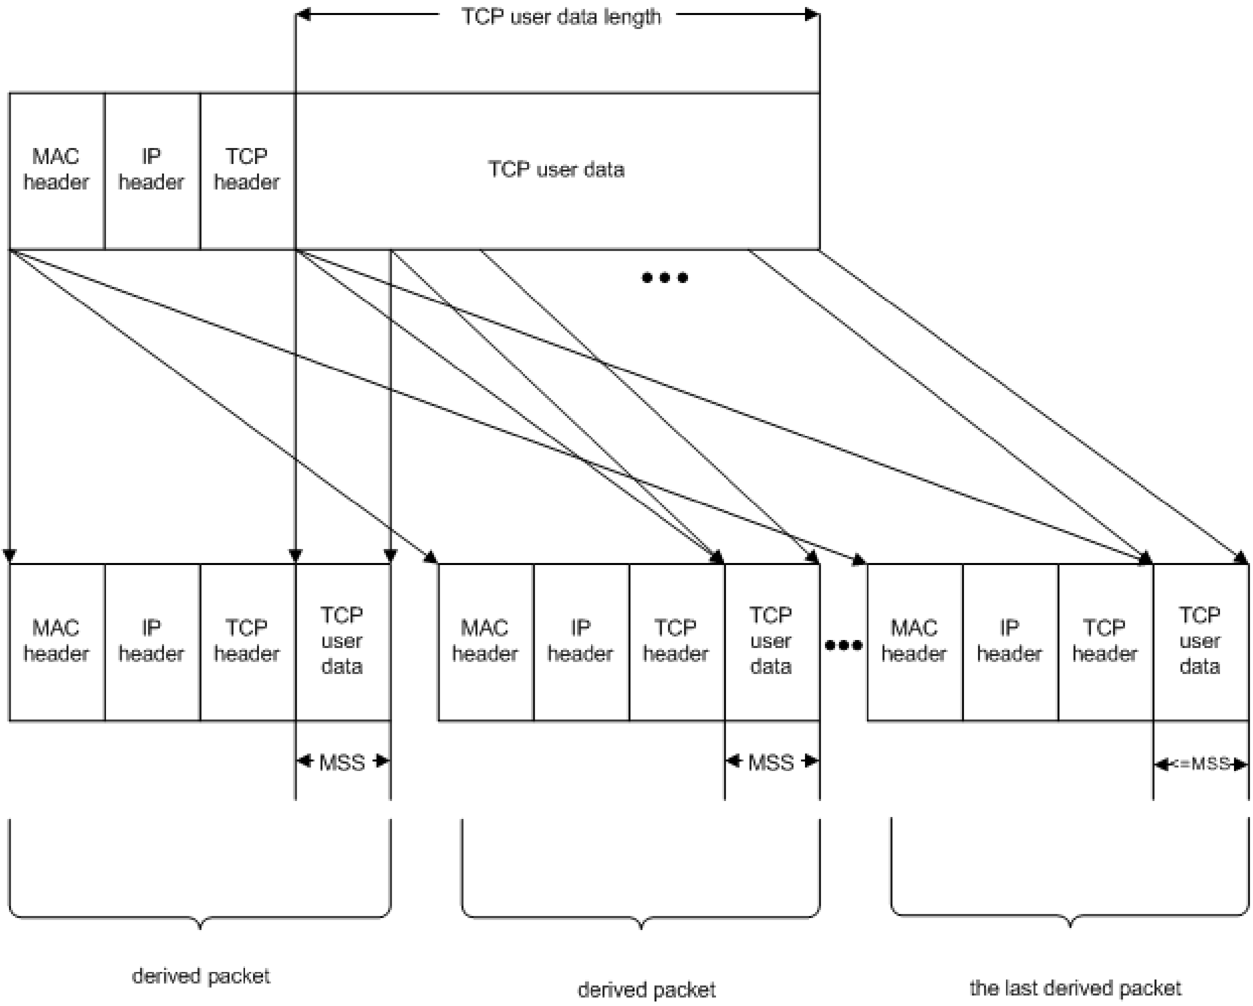
- Updates the large-packet segmentation information that is associated with the NET_BUFFER_LIST structure. This information is an NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO structure that is part of the **NET_BUFFER_LIST** information that is associated with the **NET_BUFFER_LIST** structure. For more information about **NET_BUFFER_LIST** information, see Accessing TCP/IP Offload NET_BUFFER_LIST Information. The TCP/IP transport sets the **MSS** value to the maximum segment size (MSS).
- For LSOv1, writes the total length of the large TCP packet to the Total Length field of the packet's IP header. The total length includes the length of the IP header, the length of the IP options if they are present, the length of the TCP header, the length of the TCP options if they are present, and the length of the TCP payload. For LSOv2, sets the Total Length field of the packet's IP header to 0. Miniport drivers should determine the length of the packet from the length of the first NET_BUFFER structure in the NET_BUFFER_LIST structure.
- Calculates a one's complement sum for the TCP pseudoheader and writes this sum to the Checksum field of the TCP header. The TCP/IP transport calculates the one's complement sum over the following fields in the pseudoheader: Source IP Address, Destination IP Address, and Protocol. The one's complement sum for the pseudoheader provided by the TCP/IP transport gives the NIC an early start in calculating the real TCP checksum for each packet that the NIC derives from the large TCP packet without having to examine the IP header. Note that RFC 793 stipulates that the pseudo-header checksum is calculated over the Source IP Address, Destination IP Address, Protocol, and TCP Length. (The TCP Length is the length of the TCP header plus the length of the TCP payload. The TCP Length does not include the length of the pseudo-header.) However, because the underlying miniport driver and NIC generate TCP segments from the large packet that is passed down by the TCP/IP transport, the transport does not know the size of the TCP payload for each TCP segment and therefore cannot include the TCP Length in the pseudo-header. Instead, as described below, the NIC extends the pseudo-header checksum that was supplied by the TCP/IP transport to cover the TCP Length of each generated TCP segment.
- Writes the correct sequence number to the Sequence Number field of the TCP header. The sequence number identifies the first byte of the TCP payload.

After the miniport driver obtains the **NET_BUFFER_LIST** structure in its *MiniportSendNetBufferLists* or **MiniportCoSendNetBufferLists** function, it can call the **NET_BUFFER_LIST_INFO** macro with an *_Id* of **TcpLargeSendNetBufferListInfo** to obtain the MSS value written by the TCP/IP transport.

The miniport driver obtains the total length of the large packet from the packet's IP header and uses the MSS value to divide the large TCP packet into smaller packets. Each of the smaller packets contains MSS or less user data bytes. Note that only the last packet that was created from the segmented large packet should contain less than MSS user data bytes. All other packets that were created from the segmented packet should contain MSS user data bytes. If you do not follow this rule, the creation and transmission of unnecessary extra packets could degrade performance.

The miniport driver affixes MAC, IP, and TCP headers to each segment that is derived from the large packet. The miniport driver must calculate the IP and TCP checksums for these derived packets. To calculate the TCP checksum for each packet that was derived from the large TCP packet, the NIC calculates the variable part of the TCP checksum (for the TCP header and TCP payload), adds this checksum to the one's complement sum for the pseudoheader calculated by the TCP/IP transport, and then calculates the 16-bit one's complement for the checksum. For more information about calculating such checksums, see RFC 793 and RFC 1122.

The following figure shows the segmentation of a large packet.



The length of the TCP user data in the large TCP packet should be equal to or less than the value that the miniport driver assigns to the **MaxOffLoadSize** value. For more information about the **MaxOffLoadSize** value, see Reporting a NIC's LSOv1 TCP-Packet-Segmentation Capabilities and Reporting a NIC's LSOv2 TCP-Packet-Segmentation Capabilities.

After a driver issues a status indication to indicate a change to the **MaxOffLoadSize** value, the driver must not crash if it receives an LSO send request that uses the previous **MaxOffLoadSize** value. Instead, the driver can fail the send request.

An intermediate driver that independently issues status indications that report a change in the **MaxOffLoadSize** value must ensure that the underlying miniport adapter that has not issued a status indication does not get any packets that are larger in size than the **MaxOffLoadSize** value that the miniport adapter reported.

A miniport-intermediate driver that responds to OID_TCP_OFFLOAD_PARAMETERS to turn off LSO services must be prepared for a small window of time where LSO send requests could still reach the miniport driver.

The length of the TCP user data in a segment packet must be less than or equal to the MSS. The MSS is the ULONG value that the TCP transport passes down by using the LSO

NET_BUFFER_LIST information that is associated with the **NET_BUFFER_LIST** structure. Note that only the last packet that was created from the segmented large packet should contain less than MSS user data bytes. All other packets that were created from the segmented packet should contain MSS user data bytes. If you do not follow this rule, the creation and transmission of unnecessary extra packets could degrade performance.

The number of segment packets that were derived from the large TCP packet must be equal to or greater than the **MinSegmentCount** value that is specified by the miniport driver. For more information about the **MinSegmentCount** value, see Reporting a NIC's LSOv1 TCP-Packet-Segmentation Capabilities and Reporting a NIC's LSOv2 TCP-Packet-Segmentation Capabilities.

The following assumptions and restrictions apply to processing IP and TCP headers for any LSO-capable miniport driver regardless of version:

- The MF bit in the IP header of the large TCP packet that the TCP/IP transport offloaded will not be set, and the Fragment Offset in the IP header will be zero.
- The URG, RST, and SYN flags in the TCP header of the large TCP packet will not be set, and the urgent offset (pointer) in the TCP header will be zero.
- If the FIN bit in the TCP header of the large packet is set, the miniport driver must set this bit in the TCP header of the last packet that it creates from the large TCP packet.
- If the PSH bit in the TCP header of the large TCP packet is set, the miniport driver must set this bit in the TCP header of the last packet that it creates from the large TCP packet.
- If the CWR bit in the TCP header of the large TCP packet is set, the miniport driver must set this bit in the TCP header of the first packet that it creates from the large TCP packet. The miniport driver may choose to set this bit in the TCP header of the last packet that it creates from the large TCP packet, although this is less desirable.
- If the large TCP packet contains IP options or TCP options (or both), the miniport driver copies these options, unaltered, to each packet that it derived from the large TCP packet. Specifically, the NIC will not increment the Time Stamp option.
- All packet headers (Ethernet, IP, TCP) will be in the first MDL of the packet. The headers will not be split across multiple MDLs.

  > **Tip**

> This assumption is valid when LSO is enabled. Otherwise, when LSO is not enabled, miniport drivers cannot assume that IP headers are in the same MDL as Ethernet headers.

The miniport driver must send the packets in NET_BUFFER_LIST structures in the order that it receives the NET_BUFFER_LIST structures from the TCP/IP transport.

When processing a large TCP packet, the miniport adapter is responsible only for segmenting the packet and affixing MAC, IP, and TCP headers to the packets that are derived from the large TCP packet. The TCP/IP transport performs all other tasks (such as adjusting the send window size based on the remote host's receive window size).

Before completing the send operation for the large packet (such as with NdisMSendNetBufferListsComplete or NdisMCoSendNetBufferListsComplete), the miniport driver writes the NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO value (NET_BUFFER_LIST information for large-send offloads) with the total number of TCP user data bytes that are sent successfully in all packets that were created from the large TCP packet.

In addition to the previous LSO requirements, LSOv2-capable miniport drivers must also:

- Support IPv4 or IPv6 or both IPv4 and IPv6.

- Support replication of the IPv4 options, from the large packet, in each segment packet that the network interface card (NIC) generates.

- Support replication of the IPv6 extension header, from the large TCP packet, in each TCP segment packet.

- Support replication of TCP options in each TCP segment packet that the miniport driver generates.

- Use the IP and TCP header in the NET_BUFFER_LIST structure as a template to generate TCP/IP headers for each segment packet.

- Use IP identification (IP ID) values in the range from 0x0000 to 0x7FFF. (The range from 0x8000 to 0xFFFF is reserved for TCP chimney offload-capable devices.) For example, if the template IP header starts with an Identification field value of 0x7FFE, the first TCP segment packet must have an IP ID value of 0x7FFE, followed by 0x7FFF, 0x0000, 0x0001, and so on.

- Use the byte offset in the **TcpHeaderOffset** member of NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO to determine the location of the TCP header, starting from the first byte of the packet.

- Limit the number of NET_BUFFER structures that are associated with each LSOv2 NET_BUFFER_LIST structure to one.

  > ⓘ **Note**
  >
  > This is a new requirement for LSOv2-capable miniport drivers. This rule is not enforced for LSOv1 miniport drivers explicitly, although it is recommended.

- Determine the total length of the packet from the length of the first NET_BUFFER structure in the NET_BUFFER_LIST structure. This is different from the method drivers use for LSOv1.

- Support TCP options, IP options, and IP extension headers.

- When a send operation is complete, the miniport driver must set the **LsoV2TransmitComplete.Reserved** member of the NDIS_TCP_LARGE_SEND_OFFLOAD_NET_BUFFER_LIST_INFO structure to zero and the **LsoV2TransmitComplete.Type** member to NDIS_TCP_LARGE_SEND_OFFLOAD_V2_TYPE.

UDP Segmentation Offload (USO)

Article • 12/15/2021

UDP Segmentation Offload (USO), supported in Windows 10, version 2004 and later, is a feature that enables network interface cards (NICs) to offload the segmentation of UDP datagrams that are larger than the maximum transmission unit (MTU) of the network medium. By doing so, Windows reduces CPU utilization associated with per-packet TCP/IP processing. Requirements for USO are similar to LSOv2, which is for the TCP transport protocol.

Requirements for USO

This section refers primarily to NDIS protocol and miniport drivers. NDIS lightweight filter drivers (LWFs) must follow protocol driver requirements when modifying or sending packets, and can also assume that any packets provided to its *FilterSendNetBufferLists* handler meet the protocol driver requirements.

Miniport drivers can offload the segmentation of large UDP packets that are larger than the MTU of the network medium. A NIC that supports the segmentation of large UDP packets must also be able to do the following:

- Calculate IP checksums for sent packets that contain IPv4 options
- Calculate UDP checksums for sent packets

A miniport driver that supports USO must determine the offload type from the **NET_BUFFER_LIST** structure's out of band (OOB) information. If the value of the **NDIS_UDP_SEGMENTATION_OFFLOAD_NET_BUFFER_LIST_INFO** structure is non-zero, then the miniport driver must perform USO. Any **NET_BUFFER_LIST** that contains USO OOB data also contains a single **NET_BUFFER** structure. However, in the case where the miniport driver has received OID_TCP_OFFLOAD_PARAMETERS to turn off USO, after the miniport driver has completed the OID successfully it should reject and return any **NET_BUFFER_LIST** that has the USO OOB field set.

The TCP/IP transport offloads only those UDP packets that meet the following criteria:

- The packet is a UDP packet.
- The packet length must be greater than maximum segment size **(MSS)** * **(MinSegmentCount - 1)**.
- If the miniport driver does not set the **SubMssFinalSegmentSupported** capability, then each large UDP packet offloaded by the transport must have **Length % MSS == 0**. That is, the large packet is divisible into **N** packets with each packet segment

containing exactly **MSS** user bytes. If the miniport driver sets the **SubMssFinalSegmentSupported** capability, then this packet length divisibility condition on the transport does not apply. In other words, the final segment can be less than **MSS**.
- The packet is not a loopback packet.
- The **MF** bit in the IP header of the large UDP packet that the TCP/IP transport offloaded will not be set, and the **Fragment Offset** in the IP header will be zero.
- The application has specified UDP_SEND_MSG_SIZE/WSASetUdpSendMessageSize.

Before offloading a large UDP packet for segmentation, the TCP/IP transport does the following:

- Updates the large packet segmentation information that is associated with the **NET_BUFFER_LIST** structure. This information is an **NDIS_UDP_SEGMENTATION_OFFLOAD_NET_BUFFER_LIST_INFO** structure that is part of the **NET_BUFFER_LIST** structure's OOB information. The TCP/IP transport sets the MSS value to the desired MSS.
- Calculates a one's complement sum for the UDP pseudoheader and writes this sum to the **Checksum** field of the UDP header. The TCP/IP transport calculates the one's complements sum over the following fields in the pseudoheader: Source IP Address, Destination IP Address, and Protocol.

The one's complement sum for the pseudoheader provided by the TCP/IP transport gives the NIC an early start in calculating the real UDP checksum for each packet that the NIC derives from the large UDP packet, without having to examine the IP header.

Note that RFC 768 and RFC 2460 stipulate that the pseudoheader is calculated over the Source IP Address, the Destination IP Address, Protocol, and UDP Length (the length of the UDP header plus the length of the UDP payload, not including the length of the pseudoheader). However, because the underlying miniport driver and NIC generate UDP datagrams from the large packet that is passed down by the TCP/IP transport, the transport does not know the size of the UDP payload for each UDP datagram and thus cannot include the UDP Length in the pseudoheader calculation. Instead, as described in the following section, the NIC extends the pseudoheader checksum that was supplied by the TCP/IP transport to cover the UDP Length of each generated UDP datagram.

ⓘ **Important**

If the UDP header checksum field provided by the TCP/IP transport is zero, the NIC should not perform UDP checksum calculation.

Sending packets with USO

After the miniport driver obtains the **NET_BUFFER_LIST** in its *MiniportSendNetBufferLists* callback function, it can call the **NET_BUFFER_LIST_INFO** macro with an **_Id** of **UdpSegmentationOffloadInfo** to obtain the MSS value and IP protocol.

The miniport driver obtains the total length of the large packet from the length of the first **NET_BUFFER** structure and uses the **MSS** value to divide the large UDP packet into smaller UDP packets. Each of the smaller packets contains **MSS** or fewer user data bytes. Note that only the last packet that was created from the segmented large packet should contain less than **MSS** user data bytes. All other packets that were created from the segmented packet must contain **MSS** user data bytes. If a miniport driver does not adhere to this rule, the UDP datagrams will be incorrectly delivered. If the miniport driver does not set the **SubMssFinalSegmentSupported** capability, then the packet length divides by **MSS** and each of the segmented packets contains **MSS** user bytes.

The miniport driver affixes MAC, IP, and UDP headers to each segment that is derived from the large packet. The miniport driver must calculate the IP and UDP checksums for these derived packets. To calculate the UDP checksum for each packet that was derived from the large UDP packet, the NIC calculates the variable part of the UDP checksum (for the UDP header and UDP payload), adds this checksum to the one's complement sum for the pseudoheader that was calculated by the TCP/IP transport, then calculates the 16-bit one's complement for the checksum. For more information about calculating such checksums, see RFC 768 and RFC 2460.

The length of the UDP user data in the large UDP packet must be less than or equal to the value that the miniport driver assigns to the **MaxOffLoadSize** value.

After a driver issues a status indication to indicate a change to the **MaxOffLoadSize** value, the driver must not cause a bug check if it receives an LSO send request that uses the previous **MaxOffLoadSize** value. Instead, the driver must fail the send request. Drivers **must** fail any send request they can't perform, for any reason (including size, minimum segment count, IP options, etc.). Drivers must send a status indication as soon as possible if their capabilities change.

An intermediate driver that independently issues status indications that report a change in the **MaxOffLoadSize** value must ensure that the underlying miniport adapter that has not issued a status indication does not get any packets that are larger than the **MaxOffLoadSize** value that the miniport adapter reported.

A miniport-intermediate driver that responds to OID_TCP_OFFLOAD_PARAMETERS to turn off USO services must be prepared for a small window of time where USO requests could still reach the miniport driver.

The number of segmentation packets that were dervied from the large UDP packet must be equal to or greater than the **MinSegmentCount** value that is specified by the miniport driver.

When processing a large UDP packet, the miniport driver is responsible only for segmenting the packet and affixing MAC, IP, and UDP headers to the packets that are derived from the large UDP packet. If the miniport fails to send at least one segmented packet, the NBL must eventually be completed with a failure status. The miniport can continue sending subsequent packets but is not required to do so. The NBL cannot be completed back to NDIS until all segmented packets have transmitted or failed.

USO-capable miniport drivers must also do the following:

- Support both IPv4 and IPv6.
- Support replication of IPv4 options from the large packet in each segmented packet that the NIC generates.
- Use the IP and UDP header in the NET_BUFFER_LIST structure as a template to generate UDP and IP headers for each segmented packet.
- Use IP identification (IP ID) values in the range from **0x0000** to **0xFFFF**. For example, if the template IP header starts with an Identification field value of **0xFFFE**, the first UDP datagram packet must have a value of **0xFFFE**, followed by **0xFFFF**, **0x0000**, **0x0001**, and so on.
- If the large UDP packet contains IP options, the miniport driver copies these options, unaltered, to each packet that is derived from the large UDP packet.
- Use the byte offset in the **UdpHeaderOffset** member of NDIS_UDP_SEGMENTATION_OFFLOAD_NET_BUFFER_LIST_INFO to determine the location of the UDP header, starting from the first byte of the packet.
- Increment transmit statistics based on the segmented packets. For example, include the count of Ethernet, IP, and UDP header bytes for each packet segment, and the packet count is the number of **MSS**-sized segments, not **1**.
- Set the UDP total length and IP length fields based on each segmented datagram size.

NDIS interface changes

This section describes the changes in NDIS 6.83 that enable the host TCP/IP driver stack to harness the USO capabilities exposed by miniport drivers.

NDIS and the miniport driver perform the following:

- Advertise that the NIC supports USO capability
- Enable or disable USO

- Get the current USO functionality state

Advertising USO capability

Miniport drivers advertise USO capability by filling in the **UdpSegmentation** field of the NDIS_OFFLOAD structure, which is passed in the parameters of NdisMSetMiniportAttributes. The **Header.Revision** field in the **NDIS_OFFLOAD** structure must be set to **NDIS_OFFLOAD_REVISION_6** and the **Header.Size** field must be set to **NDIS_SIZEOF_NDIS_OFFLOAD_REVISION_6**.

Querying USO state

The current USO state can be queried with OID_TCP_OFFLOAD_CURRENT_CONFIG. NDIS handles this OID and does not pass it down to the miniport driver.

Changing USO state

USO can be enabled or disabled using OID_TCP_OFFLOAD_PARAMETERS. After the miniport driver processes the OID, it must send an NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG status indication with the updated offload state.

USO keywords

The USO enumeration keywords are as follows:

- ***UsoIPv4**
- ***UsoIPv6**

These values describe whether USO is enabled or disabled for that particular IP protocol. The USO settings are not dependent on the NDIS_TCP_IP_CHECKSUM_OFFLOAD configuration. For example, disabling ***UDPChecksumOffloadIPv4** does not implicitly disable ***UsoIPv4**.

Subkey name	Parameter description	Value	Enum description
***UsoIPv4**	UDP Segmentation Offload (IPv4)	0	Disabled
		1	Enabled
***UsoIPv6**	UDP Segmentation Offload (IPV6)	0	Disabled
		1	Enabled

Connection Offload Overview

Article • 12/15/2021

To increase its performance, the Microsoft TCP/IP transport can offload connections to a NIC that has the appropriate TCP/IP-connection offload capabilities.

The NDIS connection offload interface provides hooks to enable configuration of connection offload services such as TCP chimney offload. For more information about connection offload services in NDIS, see Offloading TCP/IP Connections.

TCP chimney offload services are supported in NDIS 6.0 and later.

This section includes:

- Determining Connection Offload Capabilities
- Reporting a NIC's Connection Offload Capabilities
- Enabling and Disabling Connection Offload Services
- Determining the Current Connection Offload Settings
- Using Registry Values to Enable and Disable Connection Offloading
- Offloading TCP/IP Connections

Determining Connection Offload Capabilities

Article • 12/15/2021

NDIS supports two categories of offload services: TCP/IP offload services that are enhanced forms of the NDIS 5.1 and earlier task offload services and connection offload services.

NDIS provides the offload hardware capabilities and the current configuration of the underlying miniport adapter to protocol drivers in the **NDIS_BIND_PARAMETERS** structure. NDIS provides the task offload hardware capabilities and current configuration of the underlying miniport adapter to filter drivers in the **NDIS_FILTER_ATTACH_PARAMETERS** structure.

Administrative applications use object identifier (OID) queries to obtain TCP/IP offload capabilities of a miniport adapter. However, overlying drivers should avoid using OID queries. Protocol drivers must handle changes in the TCP/IP offload capabilities that underlying drivers report. Miniport drivers can report changes in task offload capabilities in status indications. For a list of status indications, see NDIS TCP/IP Offload Status Indications.

Administrative applications (or overlying drivers) can determine the current connection offload configuration of a NIC by querying the OID_TCP_CONNECTION_OFFLOAD_CURRENT_CONFIG OID. The **NDIS_TCP_CONNECTION_OFFLOAD** structure that is associated with OID_TCP_CONNECTION_OFFLOAD_CURRENT_CONFIG specifies the miniport adapter's current connection-offload configuration.

Reporting a NIC's Connection Offload Capabilities

Article • 12/15/2021

An NDIS miniport driver specifies the current connection offload configuration of a NIC in an **NDIS_TCP_CONNECTION_OFFLOAD** structure. Miniport drivers must include the current connection offload configuration in the **NDIS_MINIPORT_ADAPTER_OFFLOAD_ATTRIBUTES** structure. Miniport drivers call the **NdisMSetMiniportAttributes** function from the *MiniportInitializeEx* function and pass in the information in NDIS_MINIPORT_TCP_CONNECTION_OFFLOAD_ATTRIBUTES.

Miniport drivers must report changes in the connection offload capabilities. The drivers request the stack to pause and upload all of the connections by issuing an status indication. (For information on NDIS_STATUS_OFFLOAD_PAUSE, see Full TCP Offload.) After any configuration changes are complete, the drivers request the stack to restart and re-query the miniport adapter's offload capabilities by issuing an status indication. (For information on NDIS_STATUS_OFFLOAD_RESUME, see Full TCP Offload.)

In response to a query of OID_TCP_CONNECTION_OFFLOAD_CURRENT_CONFIG, NDIS returns the **NDIS_TCP_CONNECTION_OFFLOAD** structure in the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure. NDIS uses the information that the miniport driver provided.

For more information about specifying connection offload capabilities, see Initializing an Offload Target in the NDIS 6.0 TCP chimney offload documentation.

Enabling and Disabling Connection Offload Services

Article • 12/15/2021

Protocol drivers enable connection offload services with an object identifier (OID) request.

Note Enabling or disabling task offload services is different than enabling or disabling connection offload services. Miniport drivers activate all of the available task offload services after a protocol driver specifies an encapsulation type.

The TCP/IP transport enables or disables the connection offload capabilities of a network interface card (NIC) by setting the OID_TCP_CONNECTION_OFFLOAD_PARAMETERS OID. In this set operation, the TCP/IP transport passes the NDIS_TCP_CONNECTION_OFFLOAD_PARAMETERS structure in the **InformationBuffer** member of the **NDIS_OID_REQUEST** structure. (For information on NDIS_TCP_CONNECTION_OFFLOAD_PARAMETERS, see NDIS 6.0 TCP chimney offload documentation.)

For more information about configuring connection offload services, see Initializing an Offload Target in the NDIS 6.0 TCP chimney offload documentation.

Determining the Current Connection Offload Settings

Article • 12/15/2021

Protocol drivers can obtain the connection offload services with an object identifier (OID) request.

To obtain the current connection offload settings of a network interface card (NIC), protocol drivers can query the OID_TCP_CONNECTION_OFFLOAD_PARAMETERS OID.

Using Registry Values to Enable and Disable Connection Offloading

Article • 12/15/2021

When you debug a driver's connection offload functionality, you might find it useful to enable or disable connection offload services with a registry key setting. There are standardized keywords that you can define in INF files and in the registry. For more information about standardized keywords, see Standardized INF Keywords for Network Devices.

The connection offload keywords are defined as follows:

***TCPConnectionOffloadIPv4**
Describes whether the device enabled or disabled the offload of TCP connections over IPv4.

***TCPConnectionOffloadIPv6**
Describes whether the device enabled or disabled the offload of TCP connections over IPv6.

The following table describes the grouped keywords that you can use to configure offload services.

SubkeyName	ParamDesc	Value	EnumDesc
TCPConnectionOffloadIPv4	TCP Connection Offload (IPv4)	0	Disabled
		1 (Default)	Enabled
TCPConnectionOffloadIPv6	TCP Connection Offload (IPv6)	0	Disabled
		1 (Default)	Enabled

Offloading TCP/IP Connections

Article • 12/15/2021

Offloading TCP/IP connections is supported in NDIS 6.0 and later.

The NDIS TCP/IP connection offload interface enables services such as TCP chimney offload.

For more information about offloading TCP/IP connections, see Overview of TCP Chimney Offload in the Full TCP Offload.

Task offload OIDs

Article • 12/15/2021

The following table summarizes the OIDs that support TCP/IP task offload operations. For more info about such operations, see TCP/IP Task Offload.-ndis-status-dot11-wfd-group-operating-channel.md

In this table, M indicates an OID is mandatory, while O indicates it is optional.

Length	Query	Set	Name
Arr		M	OID_TCP_TASK_IPSEC_ADD_SA
Arr		M	OID_TCP_TASK_IPSEC_ADD_UDPESP_SA
4		M	OID_TCP_TASK_IPSEC_DELETE_SA
4		M	OID_TCP_TASK_IPSEC_DELETE_UDPESP_SA
Arr	M	M	OID_TCP_TASK_OFFLOAD

NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG

Article • 03/14/2023

Miniport drivers use the **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** status indication to notify NDIS and overlying drivers that there has been a change in the task offload configuration of a NIC.

Remarks

Miniport drivers must report the current capabilities with the **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** status indication when current capabilities change. This status indication ensures that all of the overlying protocol drivers are updated with the new capabilities information. Miniport drivers are required to issue this status indication in the following cases:

1. When a miniport driver receives an OID_TCP_OFFLOAD_PARAMETERS set request, it must use the contents of the **NDIS_OFFLOAD_PARAMETERS** structure to update the currently-enabled task offload capabilities.
2. When a miniport driver receives an OID_OFFLOAD_ENCAPSULATION set request, it must use the contents of the **NDIS_OFFLOAD_ENCAPSULATION** structure to update the currently-enabled task offload capabilities.

The **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure contains an **NDIS_OFFLOAD** structure. When issuing the **NDIS_STATUS_TASK_OFFLOAD_CURRENT_CONFIG** status indication, a miniport driver must use the **NDIS_OFFLOAD** structure to report the current task offload configuration of the NIC.

Note The contents of the **NDIS_OFFLOAD** structure reflect only the NIC's current task offload configuration, not its actual hardware capabilities.

For more information about the current task offload configuration, see OID_TCP_OFFLOAD_CURRENT_CONFIG.

Requirements

Version	Supported in NDIS 6.0 and later.

Article • 03/14/2023

NDIS miniport drivers and MUX intermediate drivers use the **NDIS_STATUS_TASK_OFFLOAD_HARDWARE_CAPABILITIES** status indication to notify NDIS and overlying drivers that there has been change in the task offload hardware capabilities of the underlying NIC.

Remarks

If an underlying NIC is added or deleted, the overall set of hardware capabilities that is associated with a miniport driver or MUX intermediate driver can change. For example, if a miniport driver issues the **NDIS_STATUS_TASK_OFFLOAD_HARDWARE_CAPABILITIES** status indication, specifying that it cannot support Large Send Offload (LSO), the NIC can no longer be configured to support LSO.

The **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure contains an **NDIS_OFFLOAD** structure. This structure specifies the task offload hardware capabilities.

For more information about task offload hardware capabilities, see OID_TCP_OFFLOAD_HARDWARE_CAPABILITIES.

Requirements

Version	Supported in NDIS 6.0 and later.

Article • 03/14/2023

Miniport drivers use the NDIS_STATUS_OFFLOAD_ENCASPULATION_CHANGE status indication to notify NDIS and overlying drivers that there has been change in the encapsulation settings.

Remarks

The **StatusBuffer** member of the NDIS_STATUS_INDICATION structure contains an NDIS_OFFLOAD_ENCAPSULATION structure. NDIS_OFFLOAD_ENCAPSULATION specifies the encapsulation settings.

For more information about encapsulation settings, see OID_OFFLOAD_ENCAPSULATION.

Requirements

Version	Supported in NDIS 6.0 and later.

Article • 03/14/2023

MUX intermediate drivers use the NDIS_STATUS_TCP_CONNECTION_OFFLOAD_HARDWARE_CAPABILITIES CAPABILITIES status indication to notify NDIS and overlying drivers that there has been change in the connection offload characteristics of the underlying hardware.

Remarks

If an underlying NIC is added or deleted, the overall set of hardware capabilities that is associated with a MUX intermediate driver can change.

The **StatusBuffer** member of the **NDIS_STATUS_INDICATION** structure contains an **NDIS_TCP_CONNECTION_OFFLOAD** structure. NDIS_TCP_CONNECTION_OFFLOAD specifies the task offload hardware capabilities.

For more information about task offload hardware capabilities, see OID_TCP_CONNECTION_OFFLOAD_HARDWARE_CAPABILITIES.

NDIS_STATUS_PD_CURRENT_CONFIG

Article • 03/14/2023

This status indication is a notification that the **NDIS_PD_CONFIG** structure has changed.

A PacketDirect-capable miniport driver must make an NDIS_STATUS_PD_CURRENT_CONFIG status indication after an OID_PD_CLOSE_PROVIDER or OID_PD_OPEN_PROVIDER request.

The miniport driver calls **NdisMIndicateStatusEx** to make the status indication, and must pass a pointer to an **NDIS_STATUS_INDICATION** structure through the *StatusIndication* parameter. When making this indication, the miniport driver must set the following members of the **NDIS_STATUS_INDICATION** structure:

- **SourceHandle** must be set to the handle that the miniport received in the *MiniportAdapterHandle* parameter of the *MiniportInitializeEx* function.
- **StatusCode** must be set to NDIS_STATUS_PD_CURRENT_CONFIG.
- **StatusBuffer** must be set to the address of a ULONG variable, which stores the appropriate NDIS_STATUS_xxxx code for the result of the scan operation.
- **StatusBufferSize** must be set to **sizeof**(ULONG).

Requirements

Minimum supported client	Windows 10
Minimum supported server	Windows Server 2016
Header	Ndis.h (include Ndis.h)

Virtualized Networking Topics

Article • 07/07/2022

Virtualized networking refers to the NDIS technologies for packet transfer and management within a Hyper-V virtual environment.

This section describes the following components of virtualized networking:

Virtualized Networking Concepts and Terms

Overview of Virtualized Networking

Single Root I/O Virtualization (SR-IOV)

Virtual Machine Queue (VMQ)

Hyper-V Extensible Switch

Virtualized Networking Concepts and Terms

Article • 07/07/2022

The following list gives definitions of key concepts and terms that are used in the Virtualized Networking section. We recommend that you become familiar with these terms before you read the other topics in this section:

Child Partition
In Hyper-V, the child partition is a software-based virtual machine (VM) that has unprivileged access to the physical resources of the host computer.

Each child partition is created through the parent partition. There can be one or more child partitions that run under Hyper-V on the host computer. Each child partition hosts a guest operating system.

In general, child partitions do not have direct access to the physical hardware resources and are presented a virtual view of the resources as virtual devices. Requests to the virtual devices are redirected, either through the VM bus (VMBus) or the hypervisor, to the parent partition where these requests are handled. In addition, child partitions cannot create other partitions.

Note Starting with Windows Server 2012, child partitions do have direct access to the resources of a physical network adapter that supports single root I/O virtualization (SR-IOV).

Emulated Network Adapter
A Hyper-V extensible switch Ethernet adapter that is exposed in the guest operating system that runs in a Hyper-V child partition. An emulated network adapter is a type of VM network adapter. The emulated network adapter mimics an Intel network adapter and uses hardware emulation to forward packets to and from the extensible switch port.

This adapter is exposed in a guest operating system that is Windows XP, Windows Vista, or later versions of Windows. This adapter is also exposed in a guest operating system that is a non-Windows operating system.

External Extensible Switch

A virtual Ethernet switch over which packets are routed between the Hyper-V parent partition, one or more Hyper-V child partitions, and the physical networking interface of the host. This type of switch allows packets to be sent or received between all Hyper-V partitions and the physical network interface on the host.

Also, applications and drivers that run in the management operating system can send or receive packets through this type of switch.

External Network Adapter
A Hyper-V extensible switch Ethernet adapter that is exposed in the management operating system that runs in the Hyper-V parent partition. The external network adapter is bound to one or more physical network adapters on the host.

The external network adapter routes packets between the Hyper-V partitions and the physical network interface on the host.

Note Each instance of an extensible switch supports no more than one external network adapter.

Extensible Switch Team
This is a configuration in which the extensible switch external network adapter is bound to the virtual miniport edge of an NDIS multiplexer (MUX) intermediate driver. The MUX intermediate driver is bound to a team of one or more physical networks on the host.

In this configuration, the extensible switch extensions are exposed to every network adapter in the team. This allows the forwarding extension in the extensible switch driver stack to manage the configuration and use of individual network adapters in the team. For example, the extension can provide support for a load balancing failover (LBFO) solution over the team by forwarding outgoing packets to individual adapters. Such an extension is known as a *teaming provider*.

For more information, see NDIS MUX Intermediate Drivers.

Guest Operating System
The operating system that runs in a Hyper-V child partition. Each child partition can host only one operating system. However, many different operating systems can be hosted in child partitions. This includes different versions of Windows and Linux.

Hypervisor
In Hyper-V, the hypervisor is a layer of software that runs between the physical hardware and one or more operating systems that run in Hyper-V partitions.

The hypervisor's main purpose is to provide isolated execution environments called *partitions*. The hypervisor provides each partition with a set of hardware resources, such memory, devices, and CPU cycles. The hypervisor controls and arbitrates access from each partition to the underlying hardware.

Hyper-V Extensible Switch
A virtual Ethernet switch that runs in the management operating system. Each instance

of the extensible switch routes packets between ports that are connected to the Hyper-V extensible switch network adapters.

For more information, see Hyper-V Extensible Switch.

Note The Hyper-V extensible switch is supported in NDIS 6.30 and later versions of NDIS.

Hyper-V Extensible Switch Extension
A Hyper-V extensible switch extension is an NDIS filter driver that attaches to the extensible switch driver stack. Once attached, the extension can capture, filter, or forward network packets and NDIS OIDs. Packets and OIDs can be forwarded to network adapters that are connected to extensible switch ports.

Hyper-V extensible switch extensions are supported in NDIS 6.30 and later versions of NDIS.

Note The Windows Filtering Platform (WFP) provides an in-box extensible switch filtering extension (Wfplwfs.sys). This extension allows WFP filters or callout drivers to intercept packets along the Hyper-V extensible switch data path. This allows the filters or callout drivers to perform packet inspection or modification by using the WFP management and system functions. For an overview of WFP, see Windows Filtering Platform.

Hyper-V Extensible Switch Network Adapter
A network adapter that is managed by the Hyper-V extensible switch. These network adapters connect to ports on the extensible switch, and consist of the following adapter types:

- The external and internal network adapters that are exposed in the management operating system that runs in the Hyper-V parent partition.
- The synthetic or emulated VM network adapters that are exposed in the guest operating system that runs in a Hyper-V child partition.

Internal Extensible Switch
A virtual Ethernet switch over which packets are routed between the Hyper-V parent partition and one or more Hyper-V child partitions. This type of switch excludes packet traffic from the physical network interface on the host.

Also, applications and drivers that run in the management operating system can send or receive packets through this type of switch.

Internal Network Adapter
A Hyper-V extensible switch Ethernet adapter that is exposed in the management

operating system that runs in the Hyper-V parent partition. The internal network adapter sends or receives packets between all Hyper-V partitions. However, the internal network adapter is not bound to a physical networking interface of the host.

I/O Memory Management Unit (IOMMU)
An IOMMU is used to remap physical memory addresses to the addresses that are used by the child partitions. The IOMMU operates independently of the memory management hardware that is used by the processor.

Load Balancing Failover (LBFO) Team
This is a configuration in which the extensible switch external network adapter is bound to the virtual miniport edge of an LBFO provider. The LBFO provider itself can bind to a team of one or more physical network adapters.

In this configuration, the extensible switch extensions are exposed to only the underlying virtual miniport edge as a network adapter. This allows the provider to support an LBFO solution by binding to multiple physical network adapters. These adapters are not managed by a forwarding extension that runs in the extensible switch driver stack.

Management Operating System
The operating system that runs in the Hyper-V parent partition. The parent partition runs the operating system that is running on the host computer. For Hyper-V, the host computer must run x64 versions of Windows Server 2008 or later versions of Windows Server.

Network Virtual Service Client (NetVSC) Driver
An NDIS driver that runs in the guest operating system of a Hyper-V child partition. The NetVSC exposes a virtualized network adapter that is known as a *VM network adapter*.

The NetVSC accesses the Hyper-V extensible switch to forward packets over the network interface managed by the switch. The NetVSC does this by passing messages over the VMBus to the associated NetVSP driver. This driver runs in the management operating system of the Hyper-V parent partition.

In most cases, the NetVSC sends and receives packets by connecting to a port on the Hyper-V extensible switch. However, the NetVSC could be configured to connect to a Virtual Function (VF) of a physical network adapter that supports the SR-IOV interface. In this case, the NetVSC sends and receives packets directly over the underlying physical adapter.

Network Virtual Service Producer (NetVSP) Driver
An NDIS driver that runs in the management operating system of the Hyper-V parent

partition. This driver provides services to support networking access by the Hyper-V child partitions.

NIC Switch
The NIC switch is a hardware component of a network adapter that supports single root I/O virtualization (SR-IOV). This switch bridges network traffic between the adapter's physical network interface and the Physical Function (PF) and one or more VFs on the adapter.

Partition
A partition is managed by the hypervisor. Each partition represents a logical unit of isolated processor and memory resources. This allows multiple isolated operating systems to share a single hardware platform.

The hypervisor also manages policies for memory and device access on the host computer. These policies are different for parent and child partitions.

Parent Partition
In Hyper-V, the parent partition is the first partition on the host computer. This partition has privileged access to the physical resources of the host computer, such as access to memory and devices. In addition, the parent partition is responsible for starting the hypervisor and creating child partitions.

There is only one parent partition that runs under Hyper-V on the host computer. The parent partition hosts the management operating system.

Note The parent partition is also known as the *root* partition.

Physical Function (PF)
A PCI Express (PCIe) function that supports the single root I/O virtualization (SR-IOV) interface. SR-IOV extends the PCIe interface to enable multiple VMs to share the same PCIe physical hardware resources. The PF contains the PCIe SR-IOV Extended Capability structure in its PCI configuration space.

PF/VF Backchannel
A private software-based communication interface between the miniport drivers of a PCIe Virtual Function (VF) and the PCIe Physical Function (PF). Each VF miniport driver can issue requests over the backchannel to the PF miniport driver. The PF miniport driver can issue status notifications over the backchannel to individual VF miniport drivers.

Data exchanged between the PF and VF miniport drivers over the backchannel interface involves the use of a *VF configuration block*. Each VF configuration block is similar in concept to an interprocess communication (IPC) message, in which each block has a proprietary format, length, and block identifier. The independent hardware vendor (IHV) can define one or more VF configuration blocks for the PF and VF miniport drivers.

Private Extensible Switch
A virtual Ethernet switch over which packets are routed between one or more Hyper-V child partitions. This type of switch excludes packet traffic from the Hyper-V parent partition and the physical network interface on the host.

Note Applications and drivers that run in the management operating system cannot send or receive packets through this type of switch.

Single Root I/O Virtualization (SR-IOV)
SR-IOV is a method by which a PCIe network adapter can be partitioned into one Physical Function (PF) and one or more virtual functions (VF). Each function on the adapter is assigned a unique PCIe requester ID. This enables the adapter to apply memory and interrupt translations so that different network traffic streams can be delivered directly to the appropriate PF or VF. By avoiding the routing of network traffic through the Hyper-V extensible switch component, SR-IOV reduces the I/O overhead in the virtualized networking environment.

For more information, see Single Root I/O Virtualization (SR-IOV).

Note SR-IOV is supported in NDIS 6.30 and later versions of NDIS.

Synthetic Data Path
The networking data path between a VM network adapter exposed in a guest operating system and the Hyper-V extensible switch component in the management operating system.

Synthetic Network Adapter
A Hyper-V extensible switch Ethernet adapter that is exposed in the guest operating system that runs in a Hyper-V child partition. A synthetic network adapter is a type of VM network adapter. The network virtual service client (NetVSC) that runs in the VM exposes this synthetic network adapter. NetVSC forwards packets to and from the extensible switch port over the VM bus (VMBus) to the associated NetVSP driver.

This network adapter is exposed in a guest operating system that is Windows Vista or a later version of Windows.

Virtual Function (VF)
A PCIe function that is associated with a PF on a network adapter that supports SR-IOV. A VF shares one or more physical resources on the adapter, such as the physical Ethernet port, with the PF and other VFs that are associated with the same PF.

VF Data Path
The networking data path between a VM network adapter exposed in a guest operating system and the VF on an SR-IOV network adapter. In this data path, the VM network adapter is teamed with the VF network adapter in the guest operating system. The VF miniport driver forwards packets to or from the VM network adapter to the VF. The NIC switch on the SR-IOV network adapter then forwards packets to or from the VF to the physical network interface on the adapter.

VF Network Adapter
The virtual network adapter that is exposed in the guest operating system for the VF. When resources are allocated for the VF and it becomes attached to a child partition, the VPCI bus driver in the guest operating system of that partition exposes the VF network adapter. The VPCI bus driver also loads the VF miniport driver for this adapter.

Virtual Machine (VM)
A virtual guest computer that is implemented in software and is hosted within a physical host computer. A virtual machine emulates a complete hardware system, from processor to network adapter, in a self-contained, isolated software environment. This enables concurrent operation of otherwise incompatible operating systems.

Each guest operating system runs in its own isolated software virtual machine.

Note In Hyper-V, a child partition is also known as a VM.

Virtual Machine Bus (VMBus)
A virtual communications bus that passes control and data messages between the Hyper-V parent and child partitions. Access to the physical resources on the host computer by child partitions is made through messages that are passed over the VMBus between Virtual Service Client (VSC) and Virtual Service Provider (VSP) components.

Virtual Machine (VM) Network Adapter
A Hyper-V extensible switch virtual network adapter that is exposed in the guest operating system of a Hyper-V child partition.

The VM network adapter supports the following virtualization types:

- The VM network adapter could be a synthetic virtualization of a network adapter (*synthetic network adapter*). In this case, the network virtual service client (NetVSC) that runs in the VM exposes this virtual network adapter. NetVSC forwards packets to and from the extensible switch port over the VM bus (VMBus).

- The VM network adapter could be an emulated virtualization of a physical network adapter (*emulated network adapter*). In this case, the VM network adapter mimics an Intel network adapter and uses hardware emulation to forward packets to and from the extensible switch port.

A VM network adapter can be configured to access either the Hyper-V external, internal, or private network interfaces.

Virtual Machine Queue (VMQ)
A VMQ-capable network adapter uses DMA to transfer all incoming frames directly to VM memory. VMQ also improves network throughput by distributing the processing of network traffic for multiple VMs among multiple processors.

For more information, see Virtual Machine Queue (VMQ).

Note VMQ is supported in NDIS 6.20 and later versions of NDIS.

Virtual PCI (VPCI) Driver
The PCI bus driver that runs in the guest operating system of a Hyper-V child partition. This driver exposes the VF as a virtual network adapter in the guest operating system.

The VPCI driver is a Hyper-V VSC and communicates with the VPCI VSP that runs in the management operating system in the Hyper-V parent partition. Communication between the VPCI VSP and VSC components occurs over VMBUS.

For more information about the VPCI interface, see GUID_PCI_VIRTUALIZATION_INTERFACE.

Virtualization Stack
A collection of software components that manages the creation and execution of child partitions under Hyper-V. The virtualization stack manages the access by child partitions to the hardware resources on the host computer. The virtualization stack runs in the Hyper-V parent partition.

Overview of Hyper-V

Article • 12/15/2021

Hyper-V is a hypervisor-based virtualization technology for x64 versions of Windows Server 2008 and later versions of Windows Server. The hypervisor is the processor-specific virtualization platform that allows multiple isolated operating systems to share a single hardware platform.

Hyper-V supports isolation through separate *partitions*. A partition is a logical unit of isolation, supported by the hypervisor, in which operating systems execute. The virtualization stack runs in the management operating system of the Hyper-V parent partition, and has direct access to the hardware devices. The management operating system then creates the Hyper-V child partitions and starts the guest operating systems within them.

Partitions do not have access to the physical processor, nor do they handle the processor interrupts. Instead, they have a virtual view of the processor and run in a virtual memory address region that is private to each guest partition. The hypervisor handles the interrupts to the processor, and redirects them to the respective partition. Hyper-V can also hardware accelerate the address translation between various guest virtual address spaces by using an I/O memory management unit (IOMMU) which operates independently of the memory management hardware used by the processor. An IOMMU is used to remap physical memory addresses to the addresses that are used by the child partitions.

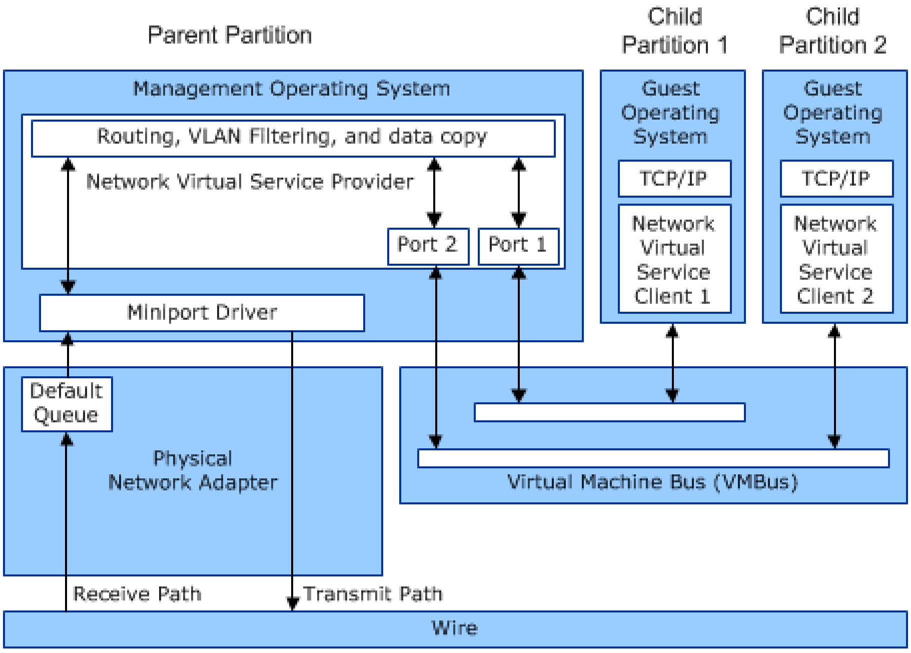
Child partitions also do not have direct access to other hardware resources. Instead, child partitions are presented a virtual view of the resources, known as *virtual devices*. Requests to the virtual devices are redirected either through the virtual machine bus (VMBus) or the hypervisor to the management operating system in the parent partition, which handles the device requests. The VMBus is a logical inter-partition communication channel, with separate channels allocated for communication between the parent partition and a child partition.

The management operating system hosts virtual service providers (VSPs) that communicate over the VMBus to handle device access requests from child partitions. The guest operating system on a child partition hosts virtual service clients (VSCs) that redirect device requests to VSPs in the management operating system by using the VMBus.

For network access to child partitions, a Network VSC (NetVSC) runs in a guest operating system. Networking requests and packets are sent between each NetVSC and the Network VSP that runs in the management operating system. The NetVSC also exposes a virtualized view of the physical network adapter on the host computer. This virtualized network adapter is known as a *synthetic network adapter*.

Note Hyper-V also supports another less-efficient virtualized network adapter that is known as an *emulated network adapter*. An emulated network adapter mimics an Intel network adapter and uses hardware emulation to forward packets to and from the NetVSP.

The following figure shows the networking data paths in Hyper-V over synthetic network adapters.



These data paths are extended by using NDIS virtualized networking interfaces, such as the virtual machine queue (VMQ), single root I/O virtualization (SR-IOV), or Hyper-V extensible switch interfaces. For example, the NetVSC could be configured to connect to a Virtual Function (VF) of a physical network adapter that supports the SR-IOV interface. In this case, the NetVSC sends and receives packets directly over the underlying physical adapter and not over the VMBus.

For more information about Hyper-V, see Hyper-V.

Single Root I/O Virtualization (SR-IOV) Interface

Article • 12/15/2021

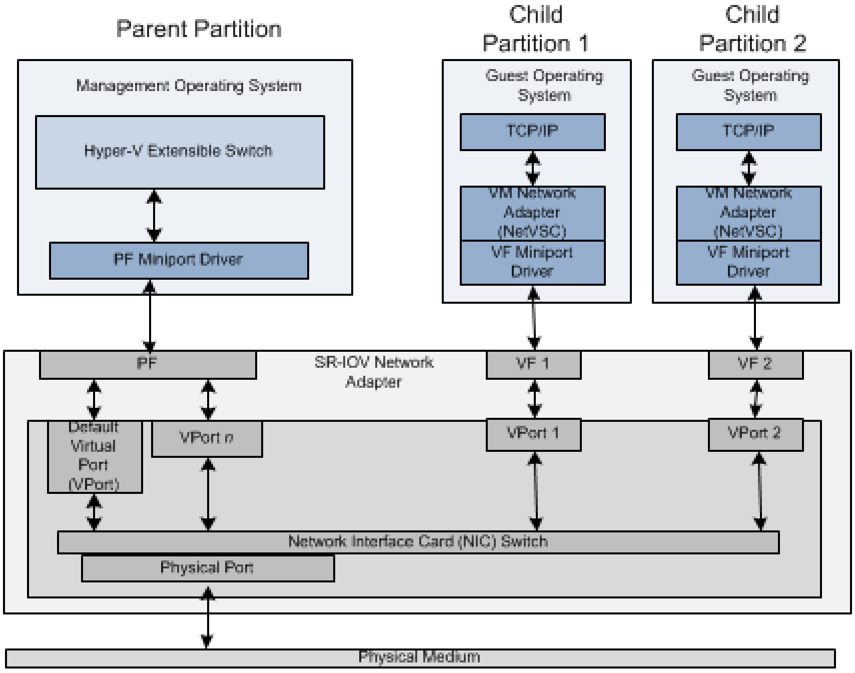
The SR-IOV interface allows for the partitioning of the hardware resources on a PCI Express (PCIe) network adapter into one or more virtual interfaces, known as *virtual functions (VFs)*. This allows the adapter resources to be shared in a virtual environment. SR-IOV enables network traffic to bypass the virtual software switch layer by assigning a VF to the Hyper-V child partition directly. By doing this, the I/O overhead in the software emulation layer is diminished and network throughput achieves nearly the same performance as in nonvirtualized environments.

Each PCIe VF is assigned a unique Requester ID, which allows an I/O memory management unit (IOMMU) to do the following:

- Distinguish between different traffic streams on each PCIe function of the network adapter. This allows the IOMMU to apply memory and interrupt translations so that these traffic streams can be delivered directly to the appropriate child or parent partition.

- Isolate traffic flows between partitions. This guarantees that traffic flow from a partition does not affect other partitions on the device.

The following figure shows the VF data path within the SR-IOV interface.



The use of the VF data path provides the following benefits:

- All data packets flow directly between the protocol stacks in the guest operating system and the VF. This eliminates the overhead of the synthetic data path in which data packets flow between the Hyper-V child and parent partitions. Once forwarded to the parent partition, the Hyper-V extensible switch module forwards these packets to other child partitions or to the physical network interface on the underlying SR-IOV physical adapter.

- The VF data path bypasses any involvement by the management operating system in packet traffic from a Hyper-V child partition. The VF provides independent memory space, interrupts and DMA streams for the child partition to which it is attached. This achieves networking performance that is almost compatible with nonvirtualized environments.

- The routing of packets over the VF data path is performed by the NIC switch on the SR-IOV network adapter. Packets are sent or received over the external network through the physical port of the adapter. Packets are also forwarded to or from other child partitions to which a VF is attached.

  Note Packets to or from child partitions to which no VF is attached are forwarded by the NIC switch to the extensible switch module. This module runs in the Hyper-V parent partition and delivers these packets to the child partition by using the synthetic data path.

For more information about the SR-IOV interface, see Single Root I/O Virtualization (SR-IOV).

Virtual Machine Queue (VMQ) Interface

Article • 09/27/2024

A network adapter that supports the VMQ interface includes hardware that routes packets to receive queues. This requires parsing of the packet header and configuration of the queues on the network adapter.

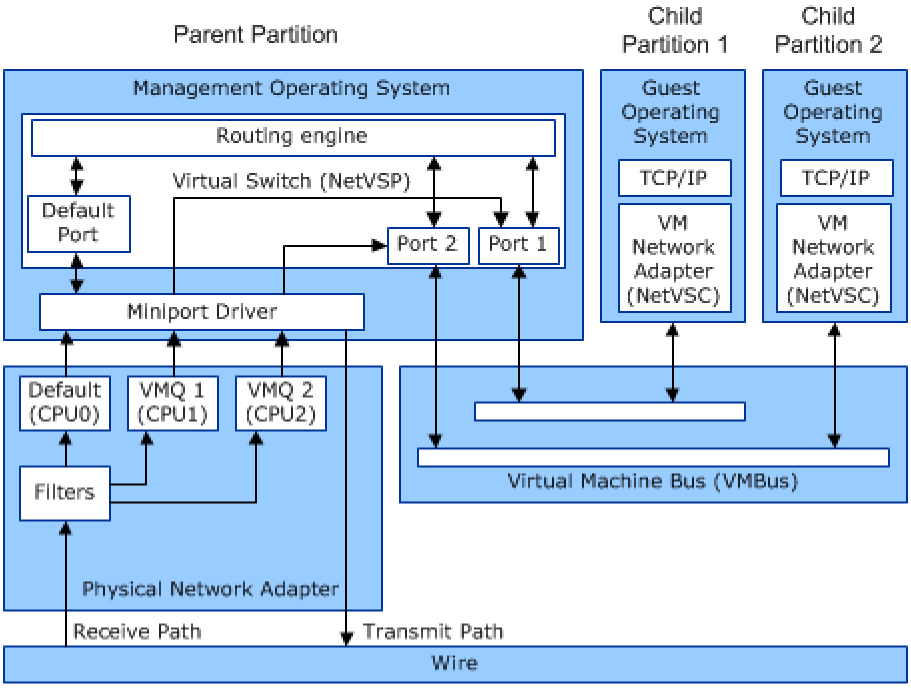
When a miniport driver makes a receive indication, all of the packets are for the same VM queue.

As an option, the network adapter can provide VLAN filtering in hardware for a specified media access control (MAC) address.

Routing the packets to queues and indicating all the packets on a queue to a VM allows concurrent receive processing for multiple VMs. Every queue is serviced by a different processor.

Routing to queues in the network adapter prevents a copy step to copy data from the network adapter receive buffers to the VM address space.

The following figure shows the synthetic data paths within the VMQ interface.



In the figure, the miniport driver for the physical network adapter indicates received data up to the Hyper-V extensible switch component. This component acts as a network virtual service provider (NetVSP) and provides services to support networking access by the Hyper-V child partitions.

The services that the extensible switch provides includes routing packets to and from the virtual machine (VM) network adapters in the guest operating systems. The VM network adapter is exposed by the network virtual service client (NetVSC) that runs in the guest operating system.

Under VMQ, the physical network adapter transfers the data that matches a receive filter test for a VMQ directly to that queue. This prevents software processing in the extensible switch. Data that does not pass any filter tests goes to the default queue where the extensible switch must process the data. In addition to preventing the routing and copying in the extensible switch, the receive interrupts for VM queues are assigned to different processors.

For more information about the VMQ interface, see Virtual Machine Queue (VMQ).

Hyper-V Extensible Switch Interface

Article • 12/15/2021

Note This page assumes that you are familiar with the information and diagrams in Overview of the Hyper-V Extensible Switch and Hybrid Forwarding.

A Hyper-V extensible switch is a virtual Ethernet switch that runs in the management operating system of the Hyper-V parent partition. Each instance of the extensible switch routes packets between the physical network interface in the host and the virtual network interfaces that are configured for the Hyper-V child partitions. These virtual network interfaces include Hyper-V external, internal, and private network interfaces.

Starting with NDIS 6.30 in Windows Server 2012, the extensible switch module supports an interface that allows NDIS filter drivers (known as *extensible switch extensions*) to bind within the extensible switch driver stack. This allows extensions to monitor, modify, and forward packets to extensible switch ports. This also allows extensions to inspect and inject packets in the virtual network interfaces that are used by the various Hyper-V partitions.

Extensions can be configured with switch and port policies to apply to packets that are routed through the extensible switch data path. This allows the driver to allow or deny a packet from being sent or received over a port.

In the extensible switch interface, the filter drivers are known as *extensible switch extensions* and the driver stack is known as the *extensible switch driver stack*.

The extensible switch interface supports the following types of extensions:

Capturing Extension
An extension that captures and monitors packet traffic. This type of extension cannot modify packets or packet destinations through the extensible switch. However, capturing extensions can originate packet traffic, such as packets that contain traffic statistics that the extension sends to a host application.

For more information, see Capturing Extensions.

Filtering Extension
An extension that captures and monitors packet traffic. This type of extension can also inspect and reject packet delivery based on custom port or switch policy settings.

For more information, see Filtering Extensions.

Forwarding Extension
An extension that has the same capabilities as a filtering extension. This type of extension can determine the extensible switch destination ports that a packet is delivered to, as well as inject packet traffic to any extensible switch port. This type of extension also inspects and rejects packet delivery based on standard port policy settings.

For more information, see Forwarding Extensions.

Note In NDIS 6.40 (Windows Server 2012 R2) and later, forwarding extensions must support Hybrid Forwarding.

Note If a forwarding extension is not installed and enabled in the extensible switch, the switch determines a packet's destination ports as well as filters packets based on standard port settings.

For more information about the extensible switch interface, see Hyper-V Extensible Switch.

Potential Performance Bottlenecks in an NDIS Virtualized Networking Environment

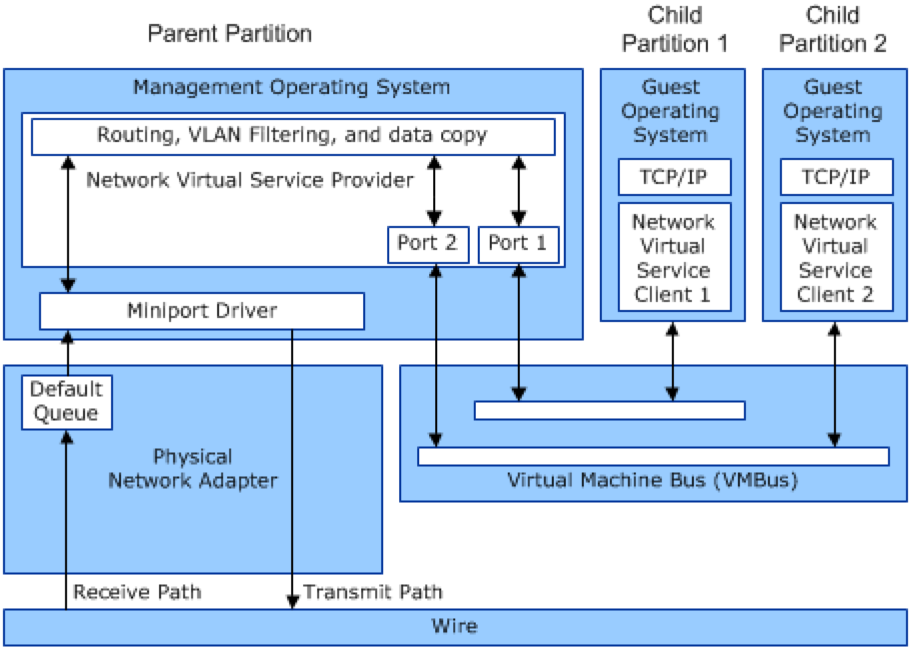
Article • 07/07/2022

In a networking environment that supports device sharing, a virtual interface with its own media access control (MAC) address is exposed in each Hyper-V child partition. These virtual interfaces use the underlying virtual machine bus (VMBus) to connect to a port on the Hyper-V extensible switch module that runs in the management operating system of the Hyper-V parent partition. The extensible switch transmits all the outgoing frames from the different partitions by issuing send requests to the underlying shared network adapter.

The physical network adapter indicates all incoming frames that it receives up to the extensible switch in the management operating system. The extensible switch uses the destination MAC address to assign the indicated incoming frames to virtual network adapters. For each child partition, the incoming frames must be copied from network adapter buffers in the management operating system to secondary buffers that were preallocated from the associated child partition. A notification is sent to each virtual interface that has pending frames. The virtual interface in each child partition indicates the incoming frames to overlying transport drivers. After identifying the application, transport drivers copy the data payload from the secondary buffer to an application buffer.

Therefore, in the virtualization environment, incoming received frames are copied twice, first from the network adapter buffer to a temporary buffer that is allocated from the target memory address space of a child partition, and then again from this temporary buffer to an application buffer. The extensible switch in the management operating system must use CPU cycles to parse incoming frames and place them in separate queues based on their destination MAC address.

The following figure shows the performance bottlenecks for receive processing in a virtualized environment.



The performance issues in the previous figure include the following:

- Each incoming packet must be examined to identify the target virtual network adapter.
- Received data must be copied from the parent partition's memory address space to the child partition's memory address space.
- Lack of concurrency for interrupts and DPCs.

Overcoming Performance Bottlenecks with VMQ

To address performance issues, the virtual machine queue (VMQ) interface allows:

- A network adapter to determine the target child partition by implementing MAC address filtering in hardware.
- A network adapter to use DMA to transfer received packets directly to a child partition's memory address space.
- A miniport driver to provide interrupt and DPC concurrency by indicating received packets for different child partitions on different CPUs.

Note Packets that are received from the external network still have to be forwarded by the management operating system to the guest operating system over the VMBus.

For more information about the VMQ interface, see Virtual Machine Queue (VMQ).

Overcoming Performance Bottlenecks with SR-IOV

The single root I/O virtualization (SR-IOV) interface provides a standards-based foundation for efficiently sharing a PCI Express (PCIe) device among multiple child partitions. Physical I/O resources are virtualized within the PCIe device, so each device presents multiple virtual I/O interfaces called *virtual functions* (VFs). The management operating system can configure each VF on the device and assign them to particular child partitions.

A VF is exposed as a hardware device to the child partition. All data packets flow directly between the guest operating system and the VF. This eliminates the software path between the management operating system and the child partition for data traffic. It bypasses the involvement by the management operating system in data movement by providing independent memory space, interrupts, and DMA streams for each child partition. Frames are sent to the external network by using the physical port of the device or to another child partition by using the internal port connected to the VF.

In all cases, the SR-IOV interface eliminates the need for any involvement of the management operating system in the data path. As a result, the SR-IOV interface provides the following:

- Improved I/O throughput and reduced CPU utilization.
- Lower latency.
- Improved scalability.

For more information about the SR-IOV interface, see Single Root I/O Virtualization (SR-IOV).

Introduction to Single Root I/O Virtualization (SR-IOV)

Article • 12/15/2021

This section describes the NDIS single root I/O virtualization (SR-IOV) interface. Starting with NDIS 6.30, the SR-IOV interface supports Microsoft Hyper-V performance improvements for virtualized networks on Windows Server 2012 and later versions of Windows Server.

The SR-IOV specification from PCI-SIG defines the extensions to the PCI Express (PCIe) specification suite that enable multiple virtual machines (VMs) to share the same PCIe physical hardware resources. This section describes the NDIS SR-IOV interface and describes the techniques for writing an NDIS miniport driver for an SR-IOV capable network adapter that implements the PCIe SR-IOV specification.

This section includes the following topics:

Overview of Single Root I/O Virtualization (SR-IOV)

Writing SR-IOV PF Miniport Drivers

Writing SR-IOV VF Miniport Drivers

SR-IOV PF/VF Backchannel Communication

SR-IOV OIDs

For more information on SR-IOV, refer to the PCI-SIG Single Root I/O Virtualization and Sharing 1.1 specification.

Overview of Single Root I/O Virtualization (SR-IOV)

Article • 09/27/2024

The single root I/O virtualization (SR-IOV) interface is an extension to the PCI Express (PCIe) specification. SR-IOV allows a device, such as a network adapter, to separate access to its resources among various PCIe hardware functions. These functions consist of the following types:

- A PCIe Physical Function (PF). This function is the primary function of the device and advertises the device's SR-IOV capabilities. The PF is associated with the Hyper-V parent partition in a virtualized environment.

- One or more PCIe Virtual Functions (VFs). Each VF is associated with the device's PF. A VF shares one or more physical resources of the device, such as a memory and a network port, with the PF and other VFs on the device. Each VF is associated with a Hyper-V child partition in a virtualized environment.

Each PF and VF is assigned a unique PCI Express Requester ID (RID) that allows an I/O memory management unit (IOMMU) to differentiate between different traffic streams and apply memory and interrupt translations between the PF and VFs. This allows traffic streams to be delivered directly to the appropriate Hyper-V parent or child partition. As a result, nonprivileged data traffic flows from the PF to VF without affecting other VFs.

SR-IOV enables network traffic to bypass the software switch layer of the Hyper-V virtualization stack. Because the VF is assigned to a child partition, the network traffic flows directly between the VF and child partition. As a result, the I/O overhead in the software emulation layer is diminished and achieves network performance that is nearly the same performance as in nonvirtualized environments.

For more information, see the following topics:

SR-IOV Architecture

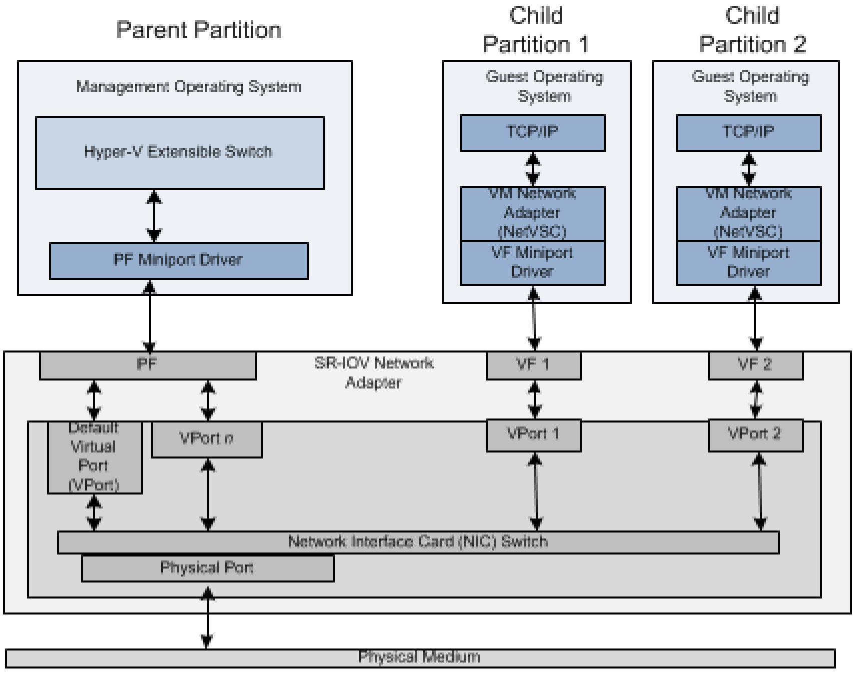
Article • 06/28/2024

This section provides a brief overview of the single root I/O virtualization (SR-IOV) interface and its components.

The following figure shows the components of the SR-IOV starting with NDIS 6.30 in Windows Server 2012.



The SR-IOV interface consists of the following components:

Hyper-V Extensible Switch Module
The extensible switch module that configures the NIC switch on the SR-IOV network adapter to provide network connectivity to the Hyper-V child partitions.

Note Hyper-V child partitions are known as *virtual machines (VMs)*.

If the child partitions are connected to a PCI Express (PCIe) Virtual Function (VF), the extensible switch module does not participate in data traffic between the VM and the network adapter. Instead, data traffic is passed directly between the VM and the VF to which it is attached.

For more information about the extensible switch, see Hyper-V Extensible Switch.

Physical Function (PF)
The PF is a PCI Express (PCIe) function of a network adapter that supports the SR-IOV interface. The PF includes the SR-IOV Extended Capability in the PCIe Configuration

space. The capability is used to configure and manage the SR-IOV functionality of the network adapter, such as enabling virtualization and exposing VFs.

For more information, see SR-IOV Physical Function (PF).

PF Miniport Driver
The PF miniport driver is responsible for managing resources on the network adapter that are used by one or more VFs. Because of this, the PF miniport driver is loaded in the management operating system before any resources are allocated for a VF. The PF miniport driver is halted after all resources that were allocated for VFs are freed.

For more information, see Writing SR-IOV PF Miniport Drivers.

Virtual Function (VF)
A VF is a lightweight PCIe function on a network adapter that supports the SR-IOV interface. The VF is associated with the VF on the network adapter, and represents a virtualized instance of the network adapter. Each VF has its own PCI Configuration space. Each VF also shares one or more physical resources on the network adapter, such as an external network port, with the PF and other VFs.

For more information, see SR-IOV Virtual Functions (VFs).

VF Miniport Driver
The VF miniport driver is installed in the VM to manage the VF. Any operation that is performed by the VF miniport driver must not affect any other VF or the PF on the same network adapter.

For more information, see Writing SR-IOV VF Miniport Drivers.

Network Interface Card (NIC) Switch
The NIC switch is a hardware component of the network adapter that supports the SR-IOV interface. The NIC switch forwards network traffic between the physical port on the adapter and internal virtual ports (VPorts). Each VPort is attached to either the PF or a VF.

For more information, see NIC Switches.

Virtual Ports (VPorts)
A VPort is a data object that represents an internal port on the NIC switch of a network adapter that supports the SR-IOV interface. Similar to a port on a physical switch, a VPort on the NIC switch delivers packets to and from a PF or VF to which the port is attached.

For more information, see NIC Switches.

Physical Port
The physical port is a hardware component of the network adapter that supports the SR-IOV interface. The physical port provides the interface on the adapter to the external networking medium.

SR-IOV Physical Function (PF)

Article • 09/27/2024

The Physical Function (PF) is a PCI Express (PCIe) function of a network adapter that supports the single root I/O virtualization (SR-IOV) interface. The PF includes the SR-IOV Extended Capability in the PCIe Configuration space. The capability is used to configure and manage the SR-IOV functionality of the network adapter, such as enabling virtualization and exposing PCIe Virtual Functions (VFs).

The PF is exposed as a virtual network adapter in the management operating system of the Hyper-V parent partition. The PF miniport driver is an NDIS miniport driver that manages the PF in the management operating system. The configuration and provisioning of the VFs, together with other hardware and software resources for the support of VFs, is performed through the PF miniport driver. The PF miniport driver uses the traditional NDIS miniport driver functionality to provide the access to the networking I/O resources to the management operating system. The PF driver is also used as a way to manage the resources allocated on the adapter for the VFs.

The PF supports the SR-IOV Extended Capability structure in its PCIe configuration space. This structure is defined in the PCI-SIG Single Root I/O Virtualization and Sharing 1.1 specification. This structure includes the following members:

TotalVFs
A read-only field that specifies the maximum number of VFs that can be associated with the PF.

NumVFs
A read-write field that specifies the current number of VFs that are available on the SR-IOV network adapter.

SR-IOV Control
A read-write field that specifies various control bits that enable or disable SR-IOV functionality on the network adapter. For example, if the **VF Enable** bit is set to one, VFs can be associated with the PF on the adapter. If this bit is set to zero, VFs are disabled and not visible on the adapter.

The PF also provides the mechanism for the management operating system to communicate with the external physical network. The PF provides network connectivity to the all virtual network adapters that are connected to the Hyper-V extensible switch module. This includes the following:

- Virtual network adapters that provide network connectivity to the Hyper-V parent partition.

- Virtual network adapters that provide network connectivity to the Hyper-V child partitions that do not have VFs allocated to them.

The PF miniport driver is responsible for managing resources on the network adapter that are used by one or more VFs. Because of this, the PF miniport driver is loaded in the management operating system before any resources are allocated for a VF. The PF miniport driver is halted after all resources that were allocated for VFs are freed.

SR-IOV Virtual Functions (VFs)

Article • 09/27/2024

A PCI Express (PCIe) Virtual Function (VF) is a lightweight PCIe function on a network adapter that supports single root I/O virtualization (SR-IOV).

The VF is associated with the PCIe Physical Function (PF) on the network adapter, and represents a virtualized instance of the network adapter. Each VF has its own PCI Configuration space. Each VF also shares one or more physical resources on the network adapter, such as an external network port, with the PF and other VFs.

A VF is not a full-fledged PCIe device. However, it provides a basic mechanism for directly transferring data between a Hyper-V child partition and the underlying SR-IOV network adapter. Software resources associated for data transfer are directly available to the VF and are isolated from use by the other VFs or the PF. However, the configuration of most of these resources is performed by the PF miniport driver that runs in the management operating system of the Hyper-V parent partition.

A VF is exposed as a virtual network adapter (*VF network adapter*) in the guest operating system that runs in a Hyper-V child partition. After the VF is associated with a virtual port (VPort) on the NIC switch of the SR-IOV network adapter, the virtual PCI (VPCI) driver that runs in the VM exposes the VF network adapter. Once exposed, the PnP manager in the guest operating system loads the VF miniport driver.

> ⓘ **Note**
>
> A Hyper-V child partition is also known as a *virtual machine (VM)*.

The VF miniport driver is an NDIS miniport driver that is installed in the VM to manage the VF. Any operation that is performed by the VF miniport driver must not affect any other VF or the PF on the same network adapter.

The VF miniport driver can function like any PCI device driver. It can read and write to the VF's PCI configuration space. However, access to the virtual PCI device is a privileged operation and is managed by the PF miniport driver in the following way:

- When the VF miniport driver calls NdisMGetBusData to read data from the PCI configuration space of the VF network adapter, the virtualization stack is notified. This stack runs in the management operating system of the Hyper-V parent partition. When the stack is notified of the read request, it issues an object identifier (OID) method request of OID_SRIOV_READ_VF_CONFIG_SPACE to the PF miniport driver. The data to be read is specified in an **NDIS_SRIOV_READ_VF_CONFIG_SPACE_PARAMETERS** structure that is contained in the OID request.

The driver reads the requested data from the VF PCI configuration space and returns the data by completing the OID request. This data is then returned to the VF miniport driver when the call to **NdisMGetBusData** completes.

- When the VF miniport driver calls **NdisMSetBusData** to write data to the PCI configuration space of the VF network adapter, the virtualization stack is notified of the write request. It issues an OID method request of OID_SRIOV_WRITE_VF_CONFIG_SPACE to the PF miniport driver. The data to be written is specified in an **NDIS_SRIOV_WRITE_VF_CONFIG_SPACE_PARAMETERS** structure that is contained in the OID request.
